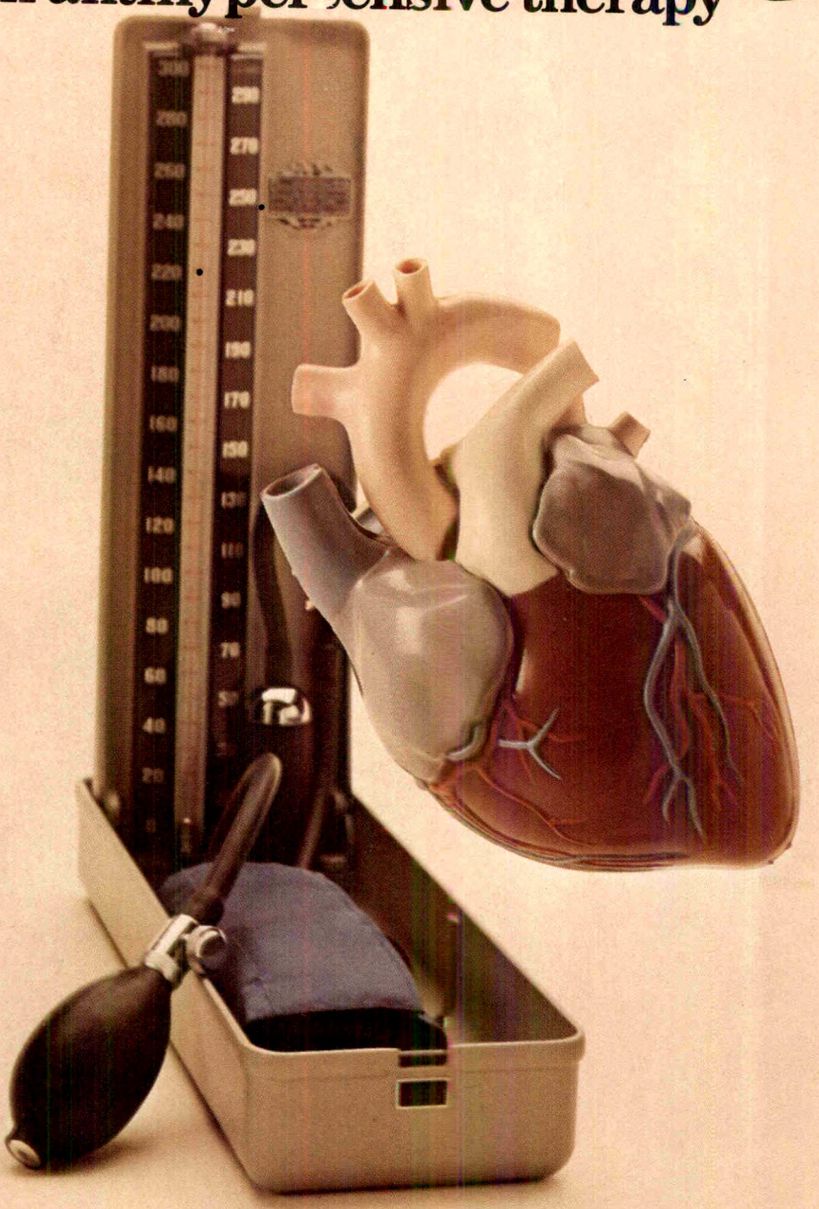
A Dual Challenge

in antihypertensive therapy



to lower blood pressure effectively...

without compromising existing cardiac output

addendum

MSD
MERCK SHARP DOHME

in hypertension

TABLETS: 250 mg, 500 mg, and 125 mg

ALDOMET®

(METHYLDOPA | MSD)

helps lower blood pressure effectively... usually with no direct effect on cardiac function— cardiac output is usually maintained

Some other characteristics of **ALDOMET** (Methyldopa, MSD) for your consideration

ALDOMET usually lowers blood pressure and:

- Usually does not compromise existing renal function
- Infrequently causes symptomatic postural hypotension
- Normal or elevated plasma renin activity may decrease during the course of therapy
- Usually is well tolerated. Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased. Headache, asthenia, or weakness may be noted as early and transient symptoms. However, significant adverse effects due to ALDOMET have been infrequent. (See brief summary for a complete listing of adverse reactions.)

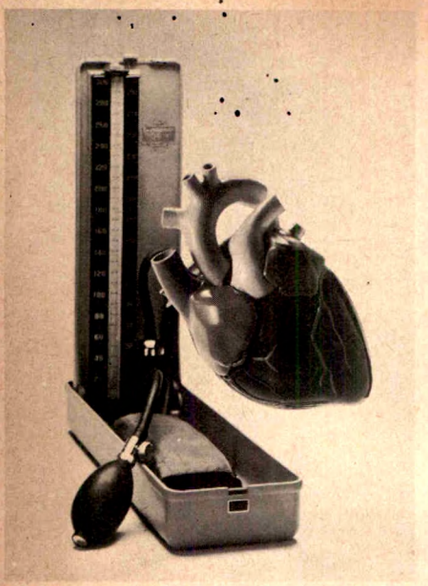
ALDOMET is useful in all degrees of hypertension and offers dosage flexibility with three tablet strengths—the standard 250 mg, the convenient 500 mg, and the 125 mg.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, and if previous methyldopa therapy has been associated with liver disorders.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details see the brief summary of prescribing information.

MSD
MERCK SHARP DOHME

For a brief summary of prescribing information, please see following page.



in hypertension

ALDOMET®

(METHYLDOPA | MSD)

helps lower blood pressure effectively... usually with no direct effect on cardiac function– cardiac output is usually maintained

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

Young Enough to be Innovators Old Enough to be Pioneers

American Pacemaker — is not a "Me Too" company but a successor company to American Optical's Pacemaker Division.

Most manufacturers today, and there are many, are new to pacing . . . not to be confused with industry pioneers. American Pacemaker is proud to be a pioneer in the field of cardiac pacing and is dedicated to improving pacemaker technology now and for decades to come. Each product manufactured that bears the name American Pacemaker reflects the excellence derived from over ten years of Pacemaker experience.

Of prime importance is American Pacemaker's worldwide contribution to cardiac pacing, the BIFOCAL®, A-V Sequential demand pacemaker. Our ten USA and many international patents along with an eight year history of A-V Sequential pacing experience gives American Pacemaker credibility in design, manufacturing and most important, quality & reliability.

APC product line consists of: *Implantable Pacemakers* • 8100 Series LITHIUM BIFOCAL®, A-V Sequential demand • 1600 Series LITHIUM R-wave Inhibited • 1400 Series PREDICTA® 4 R-wave Inhibited. *Temporary Pacemakers* • 2020 BIFOCAL for atrial, ventricular or A-V Sequential pacing, demand or continuous • 2101 MINI-Pacer. *Pacer Follow-up Instruments* • 1680 Pocket Transmitter • 1681 Transmitter • 1682 Receiver • 1685 Receivergraph *Accessories* • Implantable Pacing Leads • Temporary Pacing Leads • Lead Adapter Kit • Pacemaker Inhibitor.

ADD DYRENIUM® Capsules, 50 or 100 mg.

brand of

triamterene

TO FUROSEMIDE

IN CONGESTIVE HEART FAILURE WHEN CONSERVATION OF POTASSIUM BALANCE IS DESIRED.

'DYRENIUM' HELPS THE PATIENT RETAIN ESSENTIAL POTASSIUM STORES.

Initial dosage of both agents should usually be reduced when 'Dyrenium' is used with a diuretic, because of their additive effect. Careful supervision and dosage adjustment are required. Do not give potassium supplements unless hypokalemia develops or dietary K^+ intake is markedly impaired. Hyperkalemia can occur with any K^+ sparing agent, but it is rare in patients with normal renal function. Serum K^+ and BUN should be checked periodically, particularly in the elderly, diabetics, or those with suspected or confirmed renal insufficiency. Routine use of diuretics in healthy pregnant women is inappropriate.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: Edema associated with congestive heart failure, cirrhosis and nephrotic syndrome; steroid induced edema, idiopathic edema, and edema due to secondary hyperaldosteronism; to increase diuresis in patients resistant to other diuretics. Routine use of diuretics in healthy pregnant women is inappropriate; they are indicated in pregnancy when edema is due to pathological causes (see Warnings).

Contraindications: Anuria. Severe or progressive kidney disease or dysfunction. Severe hepatic disease. Pre-existing elevated serum potassium. Hypersensitivity. Continued use in developing hyperkalemia. Do not give potassium supplements, either by drug or by diet.

Warnings: Observe regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Check BUN and serum potassium periodically, especially in the elderly, diabetics, and those with suspected or confirmed renal insufficiency. Use in pregnancy requires weighing anticipated benefits against possible hazards to the fetus, including adverse reactions which have occurred in the [illegible]. Triamterene may appear in breast milk. If its use is essential, the patient should stop nursing.

'Dyrenium' and spironolactone are not usually used concurrently; if they are, however, frequent serum potassium determinations are required.

Precautions: If hyperkalemia develops, withdraw the drug. The following may also occur: electrolyte imbalance; low-salt syndrome (with low salt intake), reversible mild nitrogen retention; decreasing alkali reserve with possible metabolic acidosis. Triamterene is a weak folic acid antagonist. Do periodic hematologic studies in cirrhotics with splenomegaly. Concomitant use with antihypertensive drugs may result in an additive hypotensive effect. When 'Dyrenium' is to be discontinued after intensive or prolonged therapy, withdraw gradually because of possible rebound kaliuresis.

Adverse Reactions: Diarrhea, nausea and vomiting (may indicate electrolyte imbalance); other gastrointestinal disturbances, weakness, headache, dry mouth, anaphylaxis, photosensitivity, elevated uric acid, rash.

Note: When combined with another diuretic, the initial dosage of each agent should be lower than recommended.

Supplied: 50 and 100 mg. capsules, in bottles of 100 and in Single Unit Packages of 100 (intended for institutional use only).

Better patient compliance because there are fewer doses to take

Quinaglute maintains normal sinus rhythm with a convenient 8 or 12 hour dosage schedule.

The convenient dosage schedule of 1 to 2 tablets every 8 or 12 hours can mean improved compliance in patients who tend to forget or skip medication requiring more frequent administration. In addition, QUINAGLUTE® Dura-Tabs® provide the following advantages:

- Special wax matrix permits gradual release of quinidine gluconate to maintain quinidine plasma levels for 8 to 12 hours
- Convenient 8 or 12 hour dosage schedule helps avoid middle-of-the-night dosage and early morning reversion
- Prolonged control without peaks and valleys in plasma levels
- Well-tolerated, with few gastrointestinal disturbances to interfere with patient cooperation and compliance

Cooper Compliance Tip

Since most pharmacies have established patient drug profiles as a service to the community, you might advise your cardiac patients to use one pharmacy for all their prescription needs. This will help assure that the total therapeutic regimen is being carried out. Should any questions, untoward reactions or other problems develop, each person in the "physician-pharmacist-patient" alliance will be aware of it. Please forward your compliance tip to Cooper Laboratories, 300 Fairfield Road, Wayne, New Jersey 07470, Att: Mr. W.F. Cronin.

Patients with cardiac arrhythmias remember

Quinaglute® Dura-Tabs®

(quinidine gluconate)

324 mg

Indications:
Premature atrial and ventricular contractions. Paroxysmal atrial tachycardia. Paroxysmal A-V junctional rhythm. Atrial flutter. Paroxysmal atrial fibrillation. Established atrial fibrillation when therapy is appropriate. Paroxysmal ventricular tachycardia when not associated with complete heart block. Maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.
NOTE: Depending upon the response desired, the dosage may need to be varied and the blood level and/or electrocardiographic response closely monitored during initial treatment.

Contraindications: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis. Idiosyncrasy or hypersensitivity to quinidine.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.

Quinidine in large doses may reduce the contractile force of the heart; therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication.

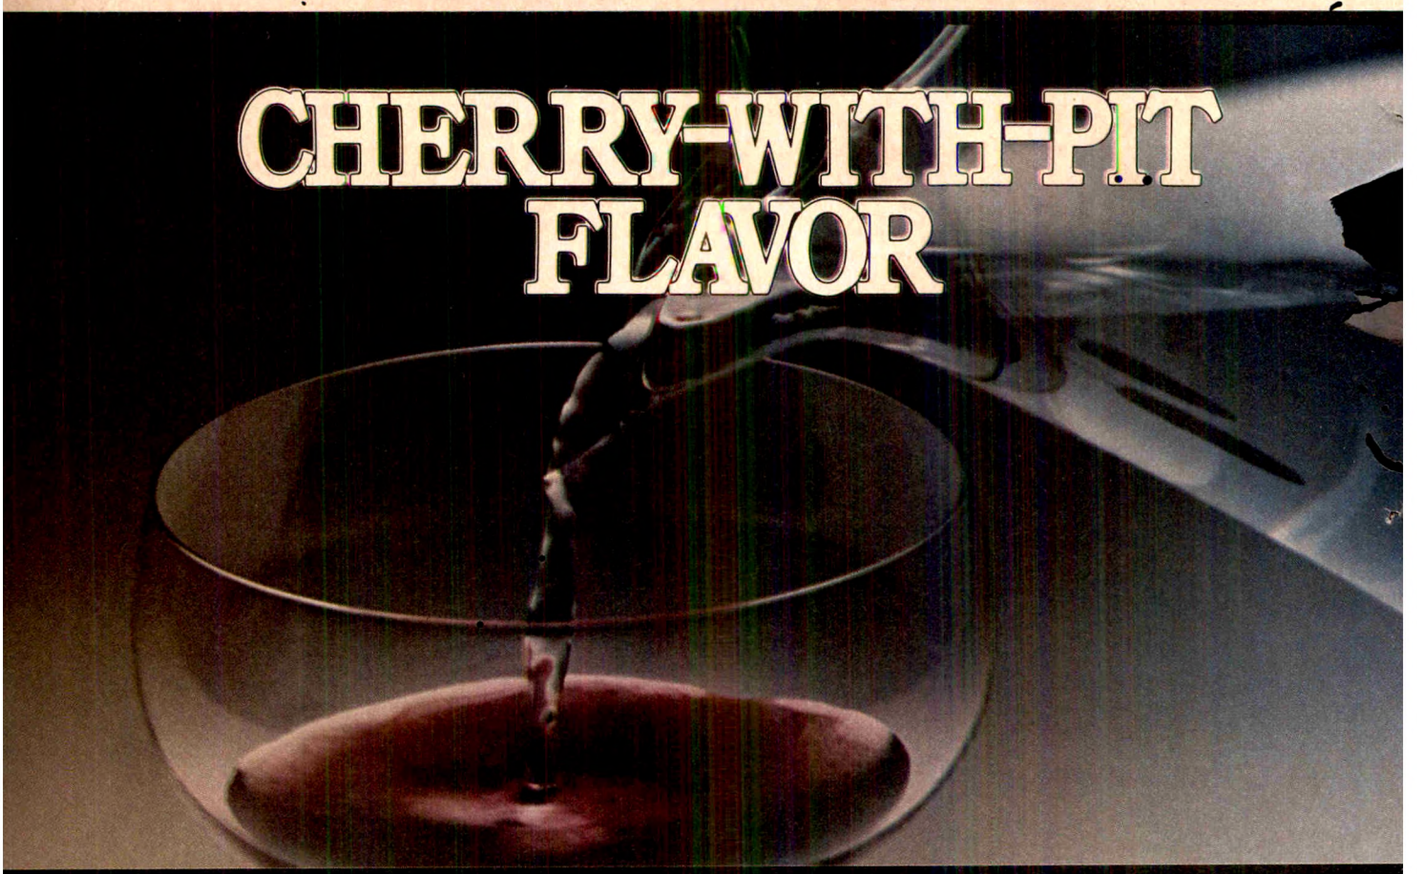
It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

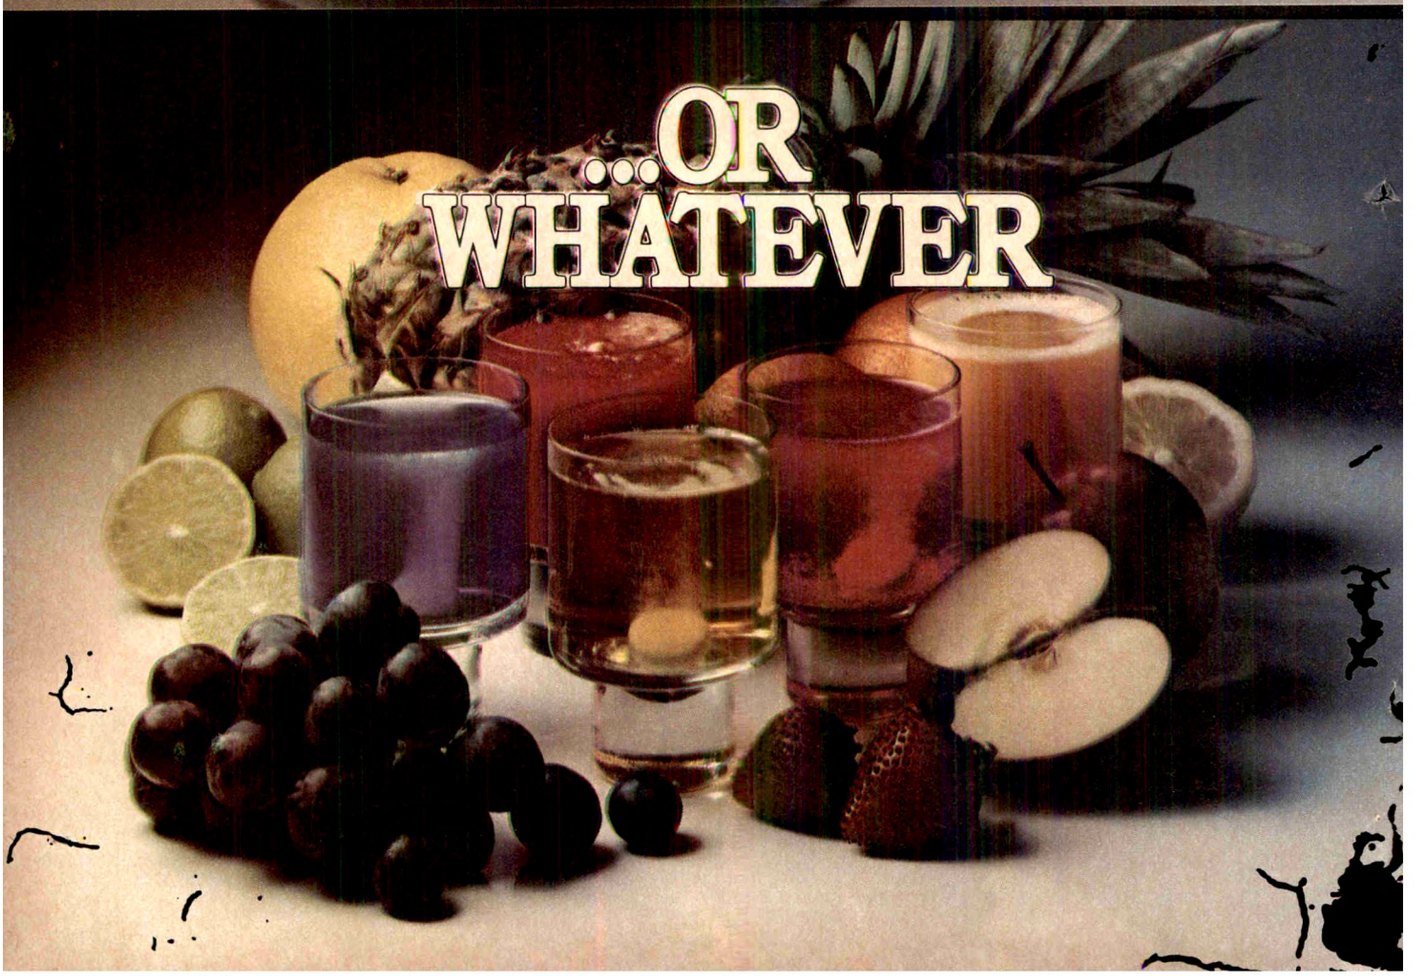
Adverse Reactions: Cinchonism, tinnitus, decreased auditory acuity, vertigo, headache, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis, hypotension, respiratory distress, and gastrointestinal disturbances.

101-48R

Cooper Laboratories, Inc., Wayne, N.J. 07470

FOR PATIENT COMPLIANCE IN





POTASSIUM SUPPLEMENTATION

DELICIOUS

KLORVESS® 10% LIQUID (potassium chloride)

Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable cherry-with-pit flavored vehicle, alcohol 1%.

Delicious cherry-with-pit flavor.
If you've tasted it, you know KLORVESS® (potassium chloride) 10% Liquid provides a delicious natural flavor. So good, in fact, that it should be mixed only with water.

THE SUBTLE MIXER

KLORVESS® EFFERVESCENT TABLETS

Each dry, sodium- and sugar-free effervescent tablet contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g.

Or whatever flavor your patients like . . . because the taste of KLORVESS® Effervescent Tablets is determined by what they're mixed with. The subtle mixer.

Convenience in therapeutic doses.
Both forms of KLORVESS offer 20 mEq of potassium and chloride in each dose. There is no need to prescribe several slow-release tablets per dose or space dosage administration beyond the patient's normal routine. Prescribe KLORVESS Liquid or KLORVESS Effervescent Tablets . . . for potassium supplement therapy that offers good taste and convenience at therapeutic dosages.

Description: Klorvess Effervescent Tablets: Each dry, sodium- and sugar-free effervescent tablet contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g. Dissolution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

Indications: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

Contraindications: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements.

Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis.

High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest.

To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve each Klorvess Effervescent Tablet in 3 to 4 ounces of water or fruit juice, or dilute each tablespoonful of Klorvess (potassium chloride) 10% Liquid in 3 to 4 ounces of water. Both of these solutions should be ingested slowly with or immediately after meals.

Adverse Reactions: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts.

The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest.

The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

Dosage and Administration: Klorvess Effervescent Tablets: Adults—One Klorvess Effervescent Tablet (20 mEq each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water or fruit juice 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) of Klorvess Liquid (20 mEq of potassium chloride) completely diluted in 3 to 4 ounces of water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating. Deviations from these recommended dosages may be indicated in certain cases of hypokalemia based upon the patient's status. The average total daily dosage must be governed by the patient's response as determined by frequent evaluation of serum electrolytes, EKG and clinical status.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

Treatment of Hyperkalemia: 1. Dextrose solution, 10 or 25% containing 10 units of crystalline insulin per 20 g dextrose, given IV in a dose of 300 to 500 ml in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resins, orally and as retention enema. (Caution: Ammonium compounds should not be used in patients with hepatic cirrhosis.) 3. Hemodialysis and peritoneal dialysis. 4. The use of potassium-containing foods or medicaments must be eliminated. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

How Supplied: Klorvess Effervescent Tablets (white)—60 tablets (2 Rx units of 30 effervescent tablets each). Each tablet is individually foil wrapped. Klorvess (potassium chloride) 10% Liquid (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Tablets and Liquid are also available in institutional packaging as follows: Klorvess Tablets—30 and 100 tablets; Klorvess Liquid—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

CLINICAL STUDIES

1 **Approach to the Estimation of Myocardial Infarct Size by Analysis of Precordial S-T Segment and R Wave Maps**

HARTMUT HENNING, THORDUR HARDARSON, GARY FRANCIS, ROBERT A. O'ROURKE, WILLIAM RYAN and JOHN ROSS, Jr.

Electrocardiographic mapping of the precordial S-T segment and R wave in 14 patients with uncomplicated acute anterior transmural myocardial infarction showed good correlation with infarct size as estimated from serial creatine kinase (CK) curves. Similar results were found prospectively in 10 additional patients. On the basis of these results, the investigators conclude that in selected patients CK-determined infarct size can be directly related to the initial height of S-T segment elevations and the early rate of R wave decline and inversely related to late ΣR values. However, the potential significance of these correlations for early prediction of infarct size from precordial electrocardiographic maps and for assessment of the effects of therapeutic interventions will require further exploration in a more diverse population.

9 **Computerized Orthogonal Electrocardiogram: Relation of QRS Forces to Left Ventricular Ejection Fraction**

MARTIN G. GOTTWIK, ALFRED F. PARISI, JOSEPH ASKENAZI and DONALD McCAUGHAN

This study in 52 consecutive patients being evaluated with cardiac catheterization for chest pain confirms that changes of the QRS complex may be used as an index of left ventricular function. The orthogonal ΣR value (Rx + Ry + Qz) in these patients proved to be a good indicator of left ventricular function, more accurate in the presence of anterior and lateral wall damage than in inferior infarction. A significant correlation was obtained between the voltages of the R waves in the X, Y and Z leads and of the Q waves in lead Z (Qz) as well as total amplitude Qx + Rx, Qy + Ry and ejection fraction ($P < 0.01$). ΣR contained important information of practical use in the precatheterization evaluation of patients with chest pain and follow-up evaluation of patients with myocardial infarction.

14 **Effects of Postextrasystolic Potentiation on Systolic Time Intervals**

NARASIMHAN RANGANATHAN, VAHE SIVACIYAN and ROBERT CHISHOLM

Measurement of changes in systolic time intervals associated with postextrasystolic potentiation in 48 patients is of value as a noninvasive method to assess resting left ventricular function. Postectopic potentiation caused a decrease in preejection period/left ventricular ejection time (PEP/LVET) ratio, the greatest occurring in beats where the differ-

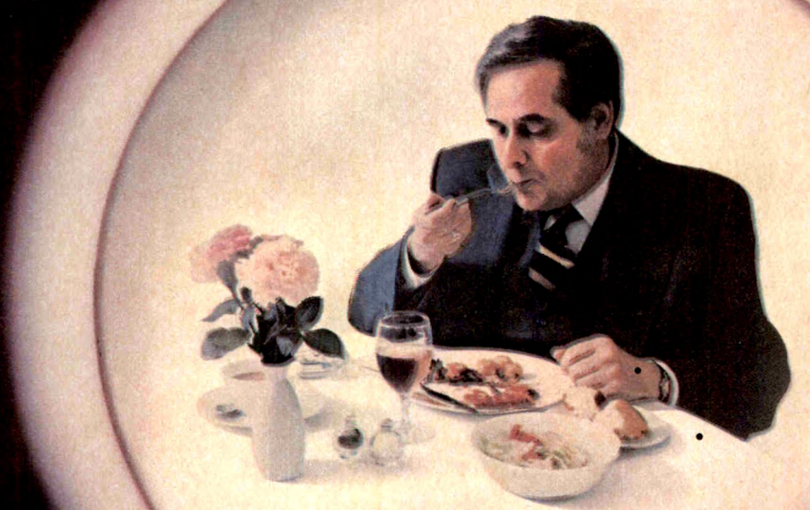
IN PREDICTABLE ANGINA*



...during the postprandial period

SUMMARY OF PRESCRIBING INFORMATION

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classifications of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: *Individual Dose:* To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.

Duration of Effect: One to two hours.

CHEWABLE SORBITRATE® 5 mg.

(ISOSORBIDE DINITRATE)

and a new 10 mg.

UP TO 2 HOURS OF ANGINA PROTECTION. AT MEALTIME...AND ANY OTHER TIME OF STRESS.

InterLith RP.

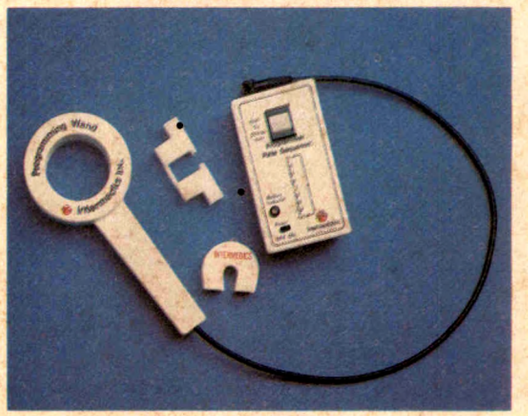
The pacemaker with a failsafe rate programming design.

It took Intermedics to combine the most straightforward, uncomplicated rate programming system in the industry with the proven reliability of c-mos circuitry. Utilizing the superior longevity of a lithium power cell, Intermedics now offers you one of the smallest, lightest, most comfortable programmable pacemakers available... the InterLith RP.

This pacemaker, unlike others on the market, utilizes circuitry that has been uniquely designed to avoid accidental reprogramming. This failsafe feature requires the occurrence of two simultaneous electrical events; first, the magnetic reed switch must be closed and secondly, the programmer must be activated in immediate proximity to the pacemaker. The nine programmable rates are 51, 55, 60, 65, 72, 80, 90, 103 and 120 BPM. The rate is incremented from one value to the next by simply depressing the programming button.

A triumph of design, the InterLith RP is hermetically sealed in tissue-compatible interference-resistant 316L stainless steel and measures only 6.0 cm × 4.6 cm × 1.5 cm (bipolar unit measures 6.3 cm in height), enabling a smaller incision resulting in a more cosmetic pocket. All edges are smoothly rounded for greatest patient comfort.

A lithium cell, plus low current drain under load, give the InterLith RP a potential longevity in excess of 12 years*; like all other Intermedics pacemakers, the InterLith RP is backed by a replacement credit agreement. Its universal connector readily accepts Intermedics' leads as well as most manufacturers' leads without adapters, making it an excellent choice when a replacement pulse generator is needed. InterLith RP. The better programmable pacemaker.



For the location of your nearest Intermedics representative, or for additional information about our products, call toll-free 1-800-231-2330. In Texas, call collect 1-713-233-8611.

*Based on 72 BPM, 500 OHM load and 100% pacing.

InterLith is a registered trademark of Intermedics, Inc.

ence in compensatory pause and coupling interval exceeded 40 percent. Marked shortening of ejection time with minimal shortening of preejection period occurred in patients with normal ventricular function. Marked shortening of preejection period and minimal shortening of ejection time were found in patients with severe left ventricular dysfunction. The probable mechanisms of postextrasystolic potentiation effects on systolic time intervals appear to be related to an increased mean systolic ejection rate accompanied by an increase in the rate of rise of intraventricular pressure (dP/dt).

23 The U Wave and Aberrant Intraventricular Conduction. Further Evidence for the Purkinje Repolarization Theory on Genesis of the U Wave

YOSHIO WATANABE and HITOSHI TODA

Correlating the incidence of aberrancy of atrial premature systoles with the timing of the U wave and other measurements in 126 electrocardiograms selected from 6,000 records, this study concludes that the U wave most likely represents phase 3 repolarization of the Purkinje system, and propagation of supraventricular impulses during this period is the cause of aberrant ventricular conduction. The Purkinje repolarization theory offers plausible explanations for at least several clinical electrocardiographic findings related to the U wave, although the validity of this concept still rests on more direct experimental studies to be carried out in the future.

32 Valve Origin of the Aortic Incisura

HANI N. SABBAH and PAUL D. STEIN

Observations in 66 patients and additional in vitro studies with high speed cinematography of a stented normal porcine valve indicate that the occurrence and magnitude of the incisura of the central aortic pressure depend upon the functional state of the aortic valve rather than upon the distension and rebound of the aortic walls. In the presence of a normal or diseased aortic valve the aortic incisura is produced primarily by valve distension or recoil. This mechanism explains satisfactorily the variations of the magnitude of the aortic incisura in various aortic valve diseases. A prominent aortic incisura implies that the aortic valve is normally distensible; a reduced amplitude implies malfunction of the aortic valve; and an absent or reduced aortic incisura implies aortic valve disease.

39 Myocardial Scintigraphy With Technetium-99m Pyrophosphate During the Early Phase of Acute Infarction

B. LEONARD HOLMAN, MICHAEL LESCH and JOSEPH S. ALPERT

Thirty-one patients admitted to a coronary care unit with prolonged ischemic pain underwent myocardial scintigraphy with technetium-99m pyrophosphate within 4 to 8 hours and again 24 hours after the onset of symptoms. Increased focal myocardial uptake was demonstrated on early myocardial scintigraphy in all 15 patients with documented acute myocardial infarction but in only 2 of 16 patients with unstable angina pectoris. Three of four patients with normal early scintigrams had massive transmural myocardial infarction. This study suggests that technetium-99m pyrophosphate scintigraphy can detect acute myocardial infarction as early as 4 hours after the onset of symptoms although the sensitivity rate (73 percent) is less than that at 24 hours. Infarct scintigraphy may estimate infarct size in most cases within 8 hours of symptoms, but technetium-99m pyrophosphate uptake may not reflect the degree of necrosis within the borders of the infarct.

Excessive sodium
elevates pressure[1]

Hygroton® 50 mg. one a day

(chlorthalidone USP)

Blocks sodium retention longer

As step-1 therapy

Diuretics reduce blood pressure by blocking sodium retention to lower "effective" volume. But, the body's renal compensatory mechanisms are mobilized to promote sodium conservation, expand "effective" volume and reelevate blood pressure. Sustained control of "effective" volume is therefore essential to treatment. Hygroton blocks sodium retention longer than any other diuretic available.

As baseline diuretic in step-2 therapy

Reduced blood pressure resulting from the use of step-2 agents (reserpine, methyldopa, propranolol) may cause compensatory sodium retention, secondary volume expansion and, eventually, reelevation of blood pressure. For this reason, the National Task Force[2] recommends the use of diuretics as baseline agents with step-2 therapy. Hygroton is an "ideal" choice because of its sustained blockade of sodium retention, dosage simplicity and enhanced patient compliance.

Hygroton® 50 mg.

(chlorthalidone USP)

Provides smooth, sustained control

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema.

Contraindications: Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs.

Warnings: Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing.

Precautions: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance.

Adverse Reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.

Usual Dose: One tablet daily.

How Supplied: Tablets—100 mg. (white, scored) and 50 mg. (aqua) in bottles of 100 and 1000; PAKs of 28 tablets, boxes of 6.

43 Thallium-201 Myocardial Perfusion Scintigraphy for the Clinical Clarification of Normal, Abnormal and Equivocal Electrocardiographic Stress Tests

ELIAS H. BOTVINICK, MICHAEL R. TARADASH, DAVID M. SHAMES and WILLIAM W. PARMLEY

This careful study of 65 patients shows thallium-201 relative myocardial perfusion scintigraphy was more sensitive, specific and accurate than stress electrocardiography to diagnose significant coronary arterial lesions in patients with isoelectric S-T segments at rest and even in the presence of a depressed S-T segment at rest. Scintigraphic defects corresponded well with the distribution of coronary arterial lesions as demonstrated on angiography. The stress-induced scintigraphic abnormalities largely reflect perfusion changes whereas stress-induced electrocardiographic changes reflect hypoxic, metabolic and electrophysiologic alterations arising from changes in perfusion. The presence of both an abnormal stress scintigram and an abnormal stress electrocardiogram guaranteed the presence of significant coronary disease in these subjects.

52 Hemodynamics at Rest and During Supine and Sitting Bicycle Exercise in Normal Subjects

UDHO THADANI and JOHN O. PARKER

These bicycle exercise studies in 10 normal untrained subjects show the hemodynamic profile differs in the supine and sitting postures at rest and during exercise. At rest the values for heart rate were higher and the values for cardiac index, stroke index, left ventricular stroke work index, mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure were lower in the sitting position. During both supine and sitting exercise left ventricular end-diastolic pressure, cardiac index, stroke index and left ventricular stroke work index increased significantly from the resting values. The good correlation found between left ventricular end-diastolic pressure and pulmonary capillary wedge pressure at rest and during exercise in the two postures suggests it should be possible to explore left ventricular hemodynamics in the upright posture using the flotation catheter technique, which is a safer procedure than obtaining direct left ventricular pressures.

60 Abnormal Platelet Survival Time in Men With Myocardial Infarction and Normal Coronary Arteriogram

PETER STEELE, JOSEPH RAINWATER and ROBERT VOGEL

Platelet survival time (using chromium-51 labeling) was shortened in eight men with an acute transmural myocardial infarction and a subsequent normal coronary arteriogram. Three patients had recurrent venous thromboembolism and one had had iliofemoral arterial thromboembolism. Platelet survival time was also shortened in 11 of 16 age-matched men with transmural infarction and arteriographic evidence of coronary obstructive disease. These data suggest that coronary arterial thrombosis may be responsible for the myocardial infarction in patients with this complication and a normal coronary arteriogram. Presumably the coronary thrombus completely recanalized by the time of coronary angiography.

EXPERIMENTAL STUDIES

63 Effects of Ionophore RO 2-2985 (X537A) on Conscious Dogs in Experimentally Induced Hemorrhagic Hypotension. Mortality, Systemic Pressure and Renal and Coronary Blood Flow

HENRY G. HANLEY, JULIE A. SWAIN, CRAIG J. HARTLEY, ROBERT M. LEWIS and ARNOLD SCHWARTZ

RO 2-2985, a potent inotropic agent, increases left ventricular pressure and coronary and renal blood flow in conscious dogs. In 18 conscious unsedated chronically instrumented dogs this drug decreased mortality and increased

blood flow in the coronary and renal beds during hemorrhage-induced hypotension. The mechanism by which RO 2-2985 produces these hemodynamic effects is not known although other studies indicate that this drug causes a translocation of large volumes of blood to the central circulation with a decrease in total body venous compliance. It is possible that the combined effects of inotropic stimulation and increased central blood volume are responsible for the results in this study. The striking decrease in mortality and the beneficial hemodynamic effects suggest that this type of chemical agent or a derivative of it may be clinically useful in combination with volume replacement in the therapy of acute hemorrhagic hypotension.

PEDIATRIC CARDIOLOGY

69 Bruce Treadmill Test in Children: Normal Values in a Clinic Population

GORDON R. CUMMING, DAYLE EVERATT and LAVERNE HASTMAN

In 327 children with innocent heart murmurs the Bruce treadmill exercise protocol proved to be highly suitable for the clinical exercise testing of children aged 4 years and older. Mean endurance time in boys increased from 10.4 minutes at age 4 to 5 years, to 14.1 minutes at age 13 to 15 years, and in girls, increased from 9.5 minutes at age 4 to 5 years to 12.3 minutes at age 10 to 12 years. Mean maximal heart rate ranged from 193 to 206 beats/min. For clinical purposes endurance time alone is a satisfactory indicator of exercise performance. The same protocol was used for all ages and permits the collection of longitudinal data on growing children. In contrast to the bicycle ergometer, this method avoids calibration problems and the need to have a large number of work loads based on body weight. No prior experience or practice by the patient is needed. Injury and fear of performing on the treadmill are minor issues because the belt speed is slow.

76 Surgical Significance of the Coronary Arterial Anatomy in Truncus Arteriosus Communis

KENNETH R. ANDERSON, DWIGHT C. McGOON and J. T. LIE

Surgical injury to a major coronary artery was identified in 2 of 30 hearts of patients with truncus arteriosus communis who died in the early postoperative period. In two other cases similar arteries of moderate size were obliterated by sutures attaching the conduit to the right ventriculotomy and in all cases some much smaller vessels were by necessity compromised. At special risk in surgical procedures utilizing a conduit anastomosed to a right ventriculotomy are large branches of the right coronary artery crossing the upper anterior surface of the right ventricle to supply the anterobasal surface of both ventricles and the upper part of the interventricular septum. Special care and preoperative documentation of the coronary arteries, particularly the right coronary artery, with selective coronary angiography may be indicated in these cases.

REPORTS ON THERAPY

82 Effects of Long-Term Oral Administration of Isosorbide Dinitrate on the Antianginal Response to Nitroglycerin. Absence of Nitrate Cross-Tolerance and Self-Tolerance Shown by Exercise Testing

GARRETT LEE, DEAN T. MASON and ANTHONY N. DeMARIA

This investigation indicates that long-term (1 month) oral administration of large doses of long-acting isosorbide dinitrate not only achieves therapeutic efficiency without evidence of self-tolerance but also does not cause cross-toler-

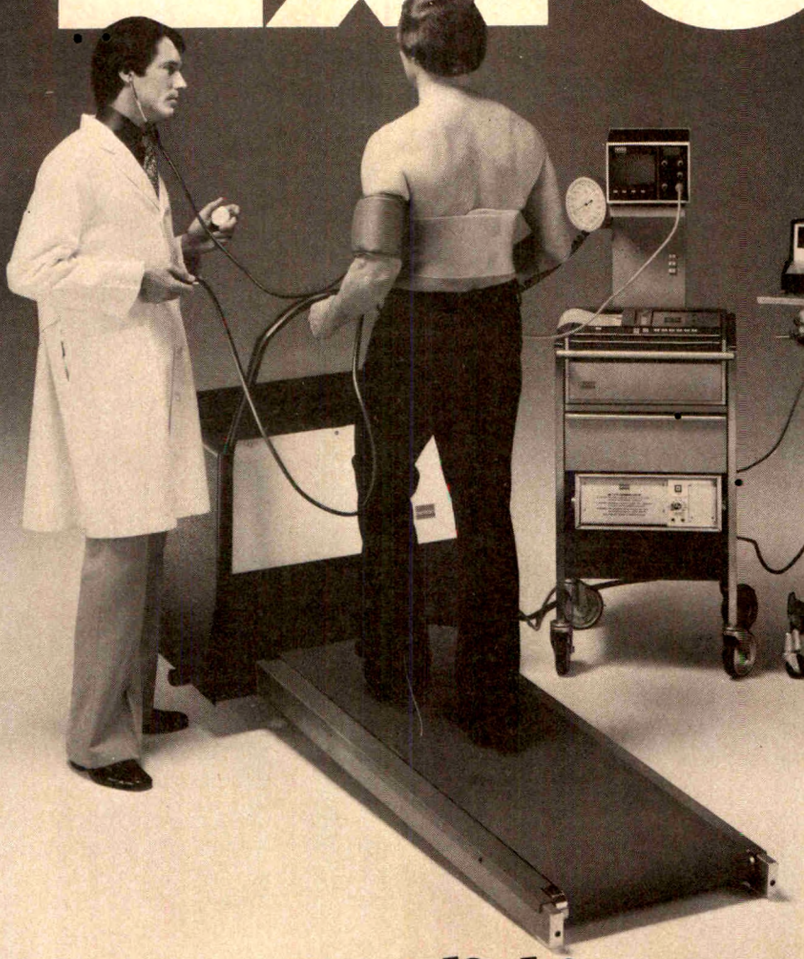
ExTOL™



Burdick's new Exercise Tolerance System helps track down coronary disorders.

Introducing Burdick's new ExTOL...the coordinated Exercise Tolerance System. Now from one source, the instrumentation components necessary to better detect clinically unsuspected or "silent" coronary disorders. All built, and backed, by Burdick, with the same quality that has made Burdick a leader in medical instrumentation for more than 60 years. The ExTOL System includes:

Burdick's new TMS-300 Treadmill. A treadmill that lets you start your patient testing sequence at zero miles per hour; an important contribution to patient safety, especially the older patient. Infinitely variable speed control 0-7 miles per hour. Elevation to a maximum of 25% grade. Wide walking belt area for an extra margin of safety. Durable, curl-resistant heavy polyester belt tracks well. Remote control unit with digital timer and ECG start/stop control for automatic-start ECG instruments. Speed-setting caution indicator for added safety.

EK-6 3-Channel Electrocardiograph. Complete 12-lead ECGs in 10 seconds. Automatic lead marking. Lead lengths, selection, standardizations, sensitivity settings, paper speed, and lead check can be automatically controlled. Heated styli and new BlueTrace paper produces clear, accurate, smudge-free ECG tracings.

New CS-625 Monitor/Heart Rate Meter. Viewing screen projects non-fade ECG display with freeze frame capability. Clear, easy-to-read, digital heart rate meter with range from 12-240 beats per minute. Heart-rate-limit alarm available.

DC-170 Defibrillator. Designed with the patient's and operator's safety in mind, simple operation. Energy levels from 5-400 joules in easy-to-select detented positions.

Install ExTOL, Burdick's Exercise Tolerance System. If you want accurate test results and control of the test sequence, you want Burdick. ExTOL components also available separately if you want to update your present system.

For a demonstration or more information, call toll-free 800-356-0701. Within Wisconsin: 608-868-7631. Or write **The Burdick Corporation, Milton, Wisconsin 53563.**

BURDICK®

The instrumentation described above for sale

ance to the antianginal action of sublingually administered nitroglycerin. Maximal duration of exercise, derived index of oxygen consumption, heart rate-blood pressure product and S-T segment depression after nitroglycerin were identical before and after such long administration of the long-acting nitrate preparation. The ability to achieve equivalent improvements in exercise performance before and 1 month after isosorbide dinitrate therapy supports these conclusions.

88 **Effects of Ouabain on Coronary and Systemic Vascular Resistance and Myocardial Oxygen Consumption in Patients Without Heart Failure**

HENRY DeMOTS, SHAHBUDIN H. RAHIMTOOLA, JOHN H. McANULTY and GEORGE A. PORTER

Rapid intravenous administration of ouabain in patients without heart failure produced systemic and coronary arteriolar constriction that may lead to clinical deterioration. Coronary vascular resistance increased 13.4 ± 5.2 percent after a 10 second infusion but did not change during or after a 15 minute infusion. Thirty minutes after ouabain administration mean arterial pressure had returned to control levels but myocardial oxygen consumption remained increased, indicating that ouabain produces a net increase in myocardial oxygen demand in patients without heart failure. These adverse effects can be avoided by slower delivery of the drug. It appears unwise to give digitalis rapidly to a patient with cardiogenic shock when vasoconstriction may be avoided by a slower infusion. The possible deleterious effects of glycosides in myocardial infarction may be more closely related to the vasoconstrictive properties of digitalis than to changes in myocardial oxygen consumption.

94 **Termination of Ventricular Tachycardia With Bursts of Rapid Ventricular Pacing**

JOHN D. FISHER, RAHUL MEHRA and SEYMOUR FURMAN

Bursts of rapid ventricular pacing proved an effective rapid pleasant alternative to repeated direct current cardioversion and a useful tool during electrophysiologic testing in patients with recurrent ventricular tachycardia. Used during 573 episodes of ventricular tachycardia in 23 patients, it terminated 512 episodes (89 percent) with burst rates averaging 56 beats/min above the ventricular tachycardia rate for 5 to 10 captures. A unipolar, low output implantable pacemaker delivering bursts of rapid ventricular pacing proved useful at home in two patients with episodic ventricular tachycardia. For many patients bursts of rapid ventricular pacing have the advantages of easy application, predictable effectiveness and apparent benignity.

CASE REPORTS

103 **Aortic Root Dissection Complicating Coronary Bypass Surgery**

W. JAY NICHOLSON, I. SYLVIA CRAWLEY, R. BRUCE LOGUE, EDWARD R. DORNEY, B. WOODFIN COBBS and CHARLES R. HATCHER, Jr.

Successful surgical correction of aortic root dissection after aortocoronary bypass surgery in two of four patients emphasizes the need to diagnose and treat this potentially fatal complication early. All four patients had long-standing severe hypertensive cardiovascular disease or severe generalized atherosclerotic disease, or both. Patients with dissecting aneurysm may present, as these subjects did, with evidence of aortic regurgitation, cardiac tamponade or severe chest pain, characteristically on the 6th to 8th postoperative day. Awareness of this complication can provide the opportunity for diagnostic aortography and prompt surgical correction. The finding of dilatation of the ascending aorta, congestive heart failure or aortic regurgitation of new onset, alone or in combination, should alert the physician to the occurrence of this complication.

BETHESDA CONFERENCE REPORT: OPTIMAL ELECTROCARDIOGRAPHY

Although electrocardiography has firmly established its value in helping to understand better the biologic processes of the heart and to sharpen the diagnosis of cardiac structure and function, the rather mundane but important problems of electrocardiography, such as standardization, record quality, cost effectiveness, and the more fascinating areas of computer analysis, clinical applications and future goals and objectives cannot be overlooked. This Bethesda report discusses these issues fully and the recommendations undoubtedly will become future guidelines for physicians, administrators and government officials. The report of Task Force IV on "Use of Electrocardiograms in Practice" contains useful suggestions on assessing competence and education in electrocardiography. Task Force VI predicts that future electrocardiography will be directed toward surface potentials, cardiac conduction and arrhythmias.

CORRECTION

A printer's error, made after release of final page proofs, resulted in inaccurate reproduction of the left panel of Figure 1 on page 2 of the July 1977 issue of the Journal (Mason JW, Myers RW, Alderman EL, et al: Technetium-99m pyrophosphate myocardial uptake in patients with stable angina pectoris. Am J Cardiol 40:1–5, 1977). The figure should have appeared as shown at right.

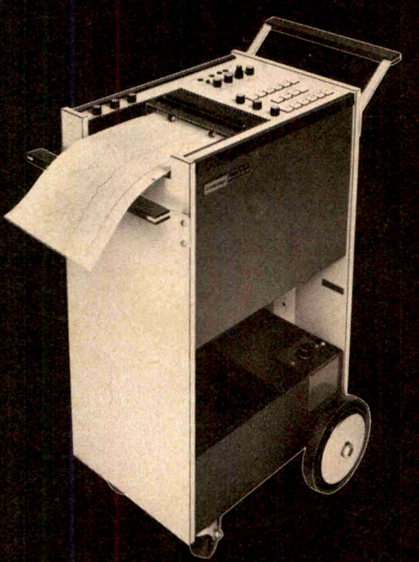
Why stop with the best ECG Tracing when you can get Phono and Pulse Recording, too!

Have it both ways with the Cambridge Model 3038 Three-Channel Electrocardiograph.

On one hand, you get the state-of-the-art writing accuracy no conventional edge- or ink-writing system can match. Combining high performance servo-motor with heated, curved-wire writing styli, the exclusive Cambridge system can write high frequency low amplitude signals other writers slur or miss entirely. Even the smallest P- and Q-wave deflections and R-wave notches are clear and crisp; vertical displacements in the ST segment are recorded with the extra accuracy only low pen-tip friction ensures.

What's more, the same writing system that gives you a superior 12-lead ECG tracing can record phonocardiograms and pulse-wave tracings as well! The optional Heart-Sound/Pulse-Wave unit has five frequency ranges for recording phono signals up to 1400 Hz — two lower-frequency ranges for direct recordings of heart sound, plus the envelope detection of three higher ranges to identify systolic murmurs. Pulse channel frequency response is 0.05 - 100 Hz between 3 dB points, with a pulse time constant of more than 3.2 seconds to ensure accurate recording of low-frequency pulse-wave components. Stethophone, phono transducer and pulse transducer are available to complete the package.



Best yet, this three-channel workhorse packs cost/efficiency benefits that can actually save its cost in just one year of use. Where conventional three-channel ECG's use up to 100% more paper for the blank run-out "gap" between recordings, Model 3038's no-waste design makes the electrocardiogram immediately visible without paper loss. What's more, pre-printed patient data and notation headings make it easy to write or type data at once for a single-sheet, file-folder size record requiring no time, labor or material expense for cutting or mounting.

First in total diagnostic flexibility, too!

Model 3038 offers three recording modes plus an observe mode, recording logic programmability, and optional computer compatibility. A drop-in paper-loading feature even eliminates winding and threading. Double insulated for safety, it is designed to meet or exceed all American Heart Association standards. But why stop there? To see how it suits *your* needs best, write or call: Cambridge Instrument Company, Inc., 73 Spring St., Ossining, N.Y., (914) 941-8100.

To build a Extracorporeal

BRIEF SUMMARY OF PRODUCT INFORMATION
BALLOON WEDGE PRESSURE CATHETERS

Indications: For sampling blood for oxygen levels and measuring pressures in the right heart, including central venous, right ventricular, pulmonary artery, and pulmonary artery wedge pressure. Also indicated in anatomical cardiac defect cases to sample blood and measure pressures in any chambers that can be entered from the right heart. **Warning:** Pulmonary artery perforation, thrombosis, segmental pulmonary infarction, transient obstruction of the pulmonary outflow by the inflated balloon, balloon rupture without serious sequelae, premature ventricular contractions, and knotting of the catheter have been reported as complications of the use of balloon catheters. Balloon rupture with possible latex embolus is a potential complication in the use of balloon catheters. **Precaution:** In pressure monitoring at bedside when catheter has been introduced in an antecubital vein, patient's arm should be immobilized to reduce the possibility of catheter advancement due to arm motion.

BERMAN ANGIOGRAPHIC CATHETER

Indications: For use in right-heart catheterization for cardiac angiography, pulmonary angiography, and measurement of right-heart and pulmonary artery pressures. It can be used to inject radiopaque media and measure pressures in any chambers and vessels that can be entered from the right heart. **Warnings:** Angiograms should be done with balloon inflated to minimize myocardial staining. When injecting radiopaque media, do not exceed stated maximum flow rate and pressure. Transient obstruction of the pulmonary outflow tract, balloon rupture without serious sequelae, premature ventricular contractions, and knotting of catheters are reported complications of the use of balloon catheters. Balloon rupture with possible latex embolus is a potential complication in the use of balloon catheters. **Precaution:** Manipulate catheter carefully and gently to avoid kinking or knotting.

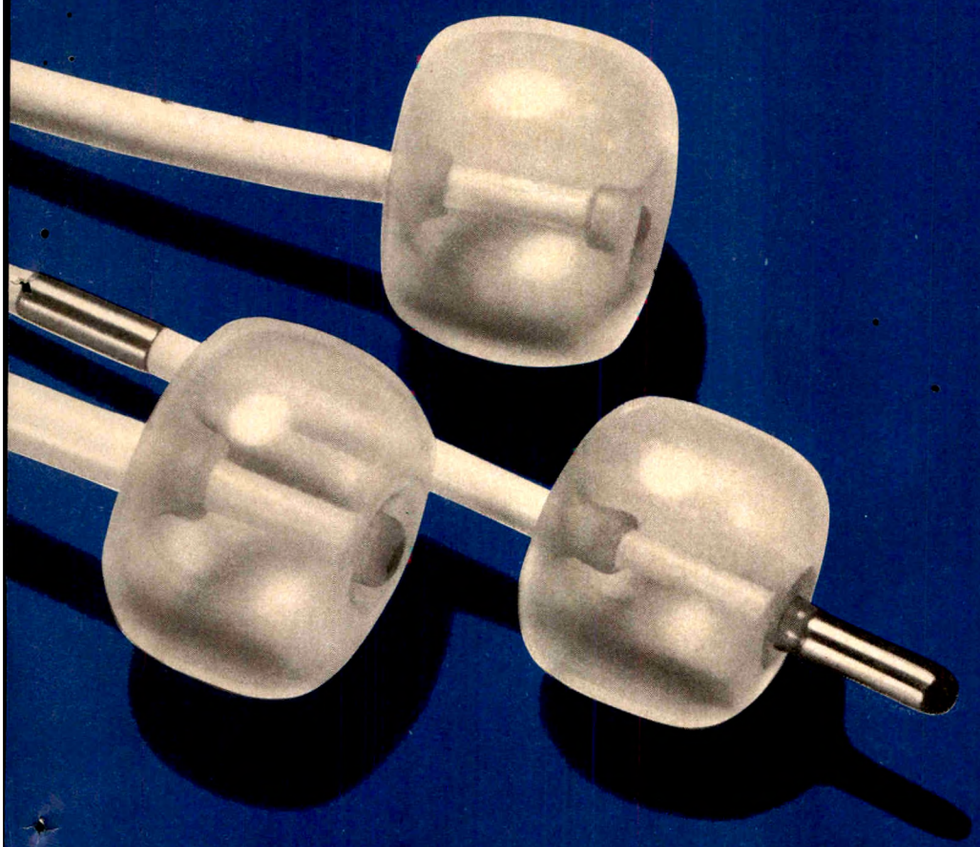
BIPOLAR TEMPORARY PACING W/STYLET AND BALLOON TEMPORARY PACING CATHETERS

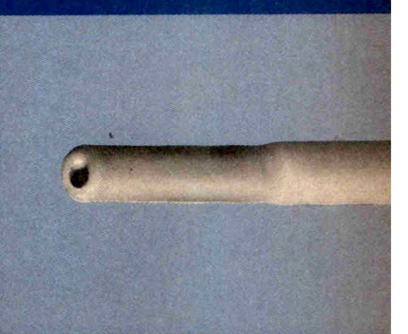
Indications: For temporary transvenous cardiac pacing when impulse formation or conduction is impaired. **Warnings:** Myocardial perforation, fibrillation and arrhythmia, pulmonary embolism, thrombus formation, and infection are general complications of transvenous pacing. Balloon rupture with possible latex embolus, vessel perforation, and intimal disruption are potential complications of use of balloon temporary pacing catheters. With the transbrachial approach, malpositioning and perforation occur more frequently due to arm movement. Pneumothorax, air embolism, and puncture of the subclavian artery have been reported with the subclavian approach. **Precautions:** Avoid kinking or bending catheter to prevent damage to internal wires or occlusion of inflation lumen (in balloon pacing catheter). Maintain insertion site with regular meticulous redressing performed with aseptic technique. Remove stylet from Bipolar Pacing Catheter after it is in position because leaving stylet *in situ* increases the potential for perforation.

FOR BALLOON CATHETER USE, IN GENERAL

General Warnings: Carbon dioxide must be used to inflate balloon if there is a possibility that balloon rupture would result in air embolism in the left heart or systemic circulation. Do not inflate balloon beyond stated maximum inflation capacity. Exercise care when passing catheters in patients with left bundle-branch block because right bundle-branch block induced by traumatic catheter passage could result in complete heart block and asystole. **General Precautions:** Do not use liquids as balloon-inflation media. Pass catheter with continuous cardiographic monitoring and fluoroscopic guidance, and confirm final tip position by X-ray. Deflate balloon prior to withdrawing catheter to avoid possible valve damage. Use aseptic technique throughout procedure. All catheters are for single use only. Do not resterilize or reuse. Federal law (U.S.A.) restricts these devices to sale by or on the order of a physician. **Contraindication:** Not for use except as indicated. For complete use information, see the package insert.

better cardiac catheter, starts with a built-in tip.





The Extracorporeal built-in tip, balloon deflated.

Other manufacturer's built-on tip, balloon deflated.

As you can see, the Extracorporeal tip is smooth, tapered, unruffled, suture free, no wider than the catheter itself. The benefits are built-in:

- **The introducer is the same size as the catheter.*** Not larger. This means a smaller insertion hole and less likelihood of trauma and intimal damage. And it simplifies introducer selection.
- **Less blood is lost.** Because the introducer is smaller and because the catheter fits it snugly the entire length of the catheter.
- **Our tapered tip has a larger lumen** which reduces the likelihood of clotting and makes it easier to introduce drugs and dyes.
- **A smaller diameter catheter may be used,** because a larger lumen also produces pressure measurements of a fidelity that can usually be matched only by a larger-diameter competitive catheter.
- **The tip is suture-free,** eliminating clotting caused by the sutures' irregular surface.

Beyond the tip, a host of other benefits.

- **Inflation is more convenient** because every Extracorporeal balloon catheter is packaged with an appropriately sized syringe.
- **Pure platinum electrodes for better electrical characteristics.** Blood may alter the conductivity properties of stainless steel and cause inferior readings. That's why our balloon pacing catheters employ only inert platinum for electrodes.
- **High pressure tubing** used in our Berman angiographic catheters permits higher pressures to be used to achieve better flow rates when drugs or dye must be inje
- **More sizes available.** Especially Berman angiographic and wed pressure models. And we can supply custom catheters, too.
- **Even our package works hard for you.** Each catheter comes in own sterile peel-pack that store easily and has a fold down tab for quick identification.
- **Our new brochure has all the facts.** Just let us know where yo are and we'll send you one. Ca your Extracorporeal represento tive, or write or call us toll free: 800-523-1740.

*With one small exception—the Extracorporeal size uses a 4-1/2 size introducer.

One of the Most Frequently Overdiagnosed Diseases!

■ *Here at last is an objective study of essential reactive hypoglycemia . . . definition, recognition, pathology, etiology, and treatment.*

Editors:

D. Andreani, MD, Prof. of Clinical Endocrinology, Univ. of Rome
P. Lefèbvre, MD, Dept. of Medicine, University of Liège
V. Marks, DM, Prof., Dept. of Biochemistry, Univ. of Surrey

This European (Rome) Symposium was the first free interchange of ideas among scientists in the various medical disciplines—physiology, internal medicine, endocrinology, clinical biochemistry, etc.—necessary to the understanding, diagnosis and treatment of hypoglycemia. The concentration was on the various aspects of insulin-producing tumors and the vexed question of essential reactive hypoglycemia. Special attention was given to the widespread misinterpretation of laboratory data relating to the prolonged oral glucose test which has resulted in the erroneous belief that "millions suffer from hypoglycemia."

PRONESTYL® TABLETS (Procainamide Hydrochloride Tablets)
PRONESTYL® CAPSULES (Procainamide Hydrochloride Capsules U.S.P.)

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate considerations of alternative anti-arrhythmic therapy.

DESCRIPTION: Pronestyl (Procainamide Hydrochloride) is the amide analogue of procaine hydrochloride and is available for oral administration as capsules and veneer-coated tablets providing 250 mg., 375 mg., and 500 mg. procainamide hydrochloride.

CONTRAINDICATIONS: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; bear in mind cross sensitivity to procaine and related drugs. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of second degree and third degree A-V block unless an electrical pacemaker is operative.

ADMINISTRATION: Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

PRECAUTIONS: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous if myocardial damage exists.

The dislodgment of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with severe organic heart disease and ventricular tachycardia that complete heart block, which may be difficult to diagnose, may be present. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related to continued procainamide therapy (see boxed Warning). Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

ADVERSE REACTIONS: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see Precautions). Reactions consisting of fever and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever or any symptoms of upper respiratory tract infection. If any of these symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions and for full prescribing information.

HOW SUPPLIED: Pronestyl Tablets (Procainamide Hydrochloride Tablets) and Pronestyl Capsules (Procainamide Hydrochloride Capsules U.S.P.) providing 250 mg., 375 mg., and 500 mg. are available in bottles of 100 and Unimatic® single-dose packaging in cartons of 100. The 250 mg. and 500 mg. tablets and capsules are also available in bottles of 1000.

©1978 E. R. Squibb & Sons, Inc. 448-502

tried and true

in the treatment of life-threatening arrhythmias

Documented effectiveness in ventricular arrhythmias; indicated for certain atrial arrhythmias as well.

Backed by 26 years of clinical experience; over 15,000,000 prescriptions written!

Extensively used and studied in post-MI patients.

Compatibility with other cardiovascular drugs researched.

Three oral strengths (250mg, 375mg, 500mg) for dosing flexibility; available in easy-to-swallow veneer coated tablets.

See preceding page for brief summary.

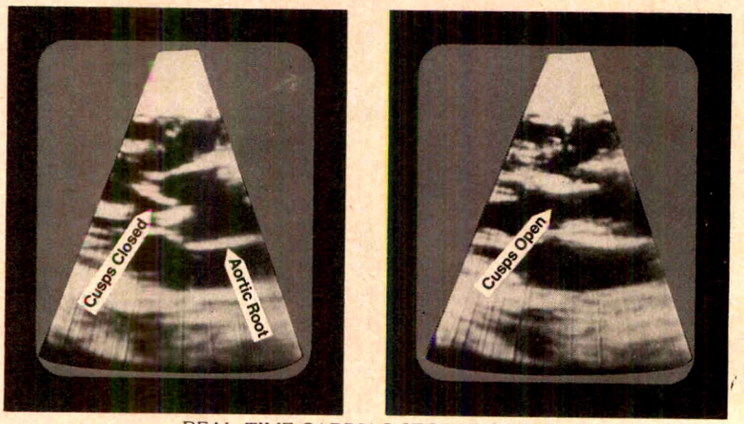
THE HOFFREL REAL-TIME TWO-DIMENSIONAL CARDIAC SECTOR SCANNER



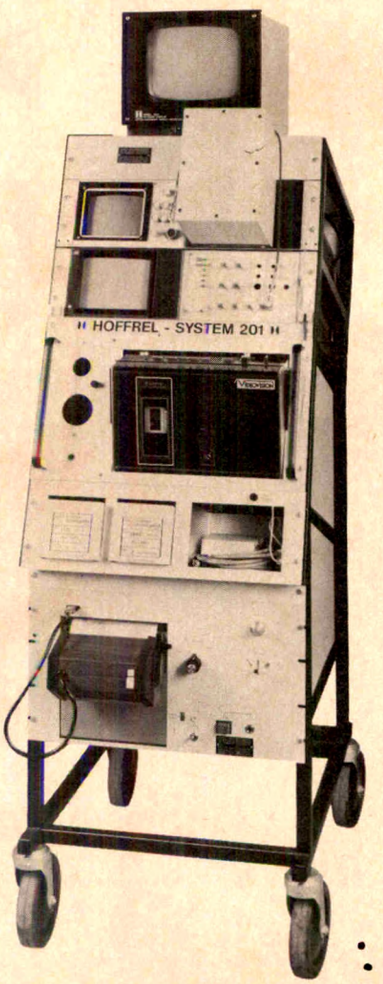
REAL-TIME CARDIAC SECTOR SCAN

Features of the **Hoffrel Mechanical Sector Scanner (MSS)** include:

- 35° sector, optimal angle commensurate with an acceptable line density.
- Ability to change scan rate to optimize line density according to heart rate or type of examination.
- Full quality M-Mode recordings may be derived from any angle within the central 30° of the sector, operator selectable with a movable cursor.
- Recordings are made in standard T.V. format for display on conventional television systems.
- Procedures may be recorded for play back in real-time, slow motion or stop-frame modes.
- Frames are numbered sequentially or EKG timed.
- Different frequency transducers are easily interchangeable by operator.

No sacrifice in exceptional M-Mode capabilities:

- High resolution tracings.
- Excellent phono and pulse recording.



Write or phone today for full clinical and technical details.

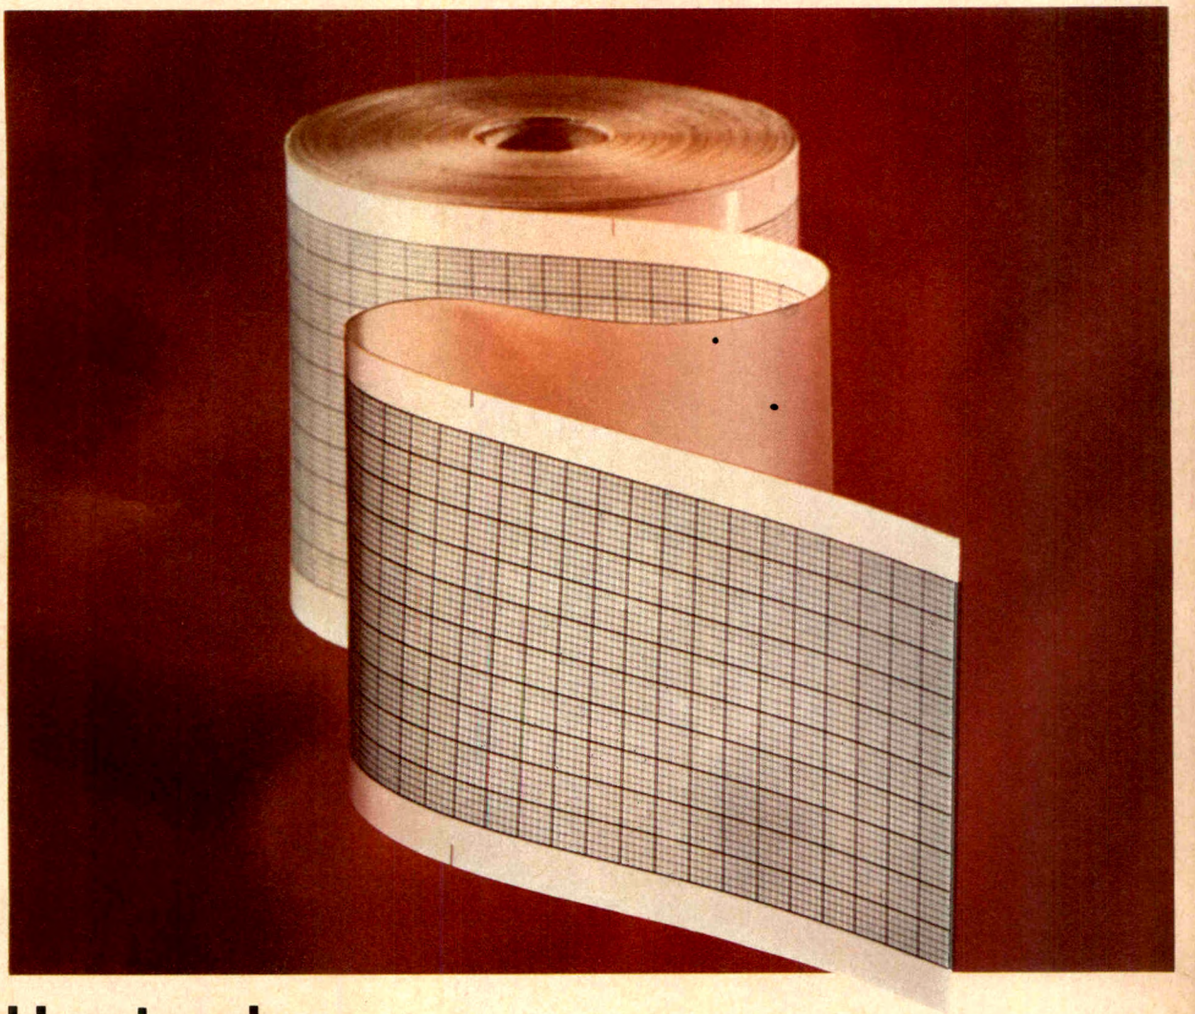
Hot stylus recorders work best with NASHUA HEATRACE® CHART PAPER.



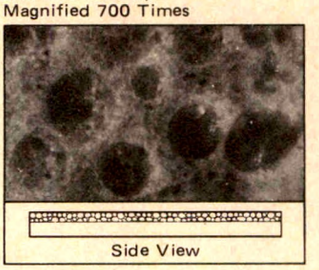
Here's why...

Nashua makes heat sensitive recording chart paper by an exclusive process that puts a bubble-type coating on its paper instead of a solid layer of plastic (the conventional blush-type coating). The result is a lighter weight coating (almost 30% lighter), that:

- requires minimum heat
- minimum torque to drive stylus
- eliminates stylus build-up
- reduces stylus wear

If you want highest performance for your hot stylus recorders, ask your vendor if the charts they supply are made by Nashua ...the prime source chartmaker.

HEATRACE Paper
Magnified 700 Times



Conventional Paper

A New Vision of Catapres® (clonidine HCl)

20/20

The first 20 days

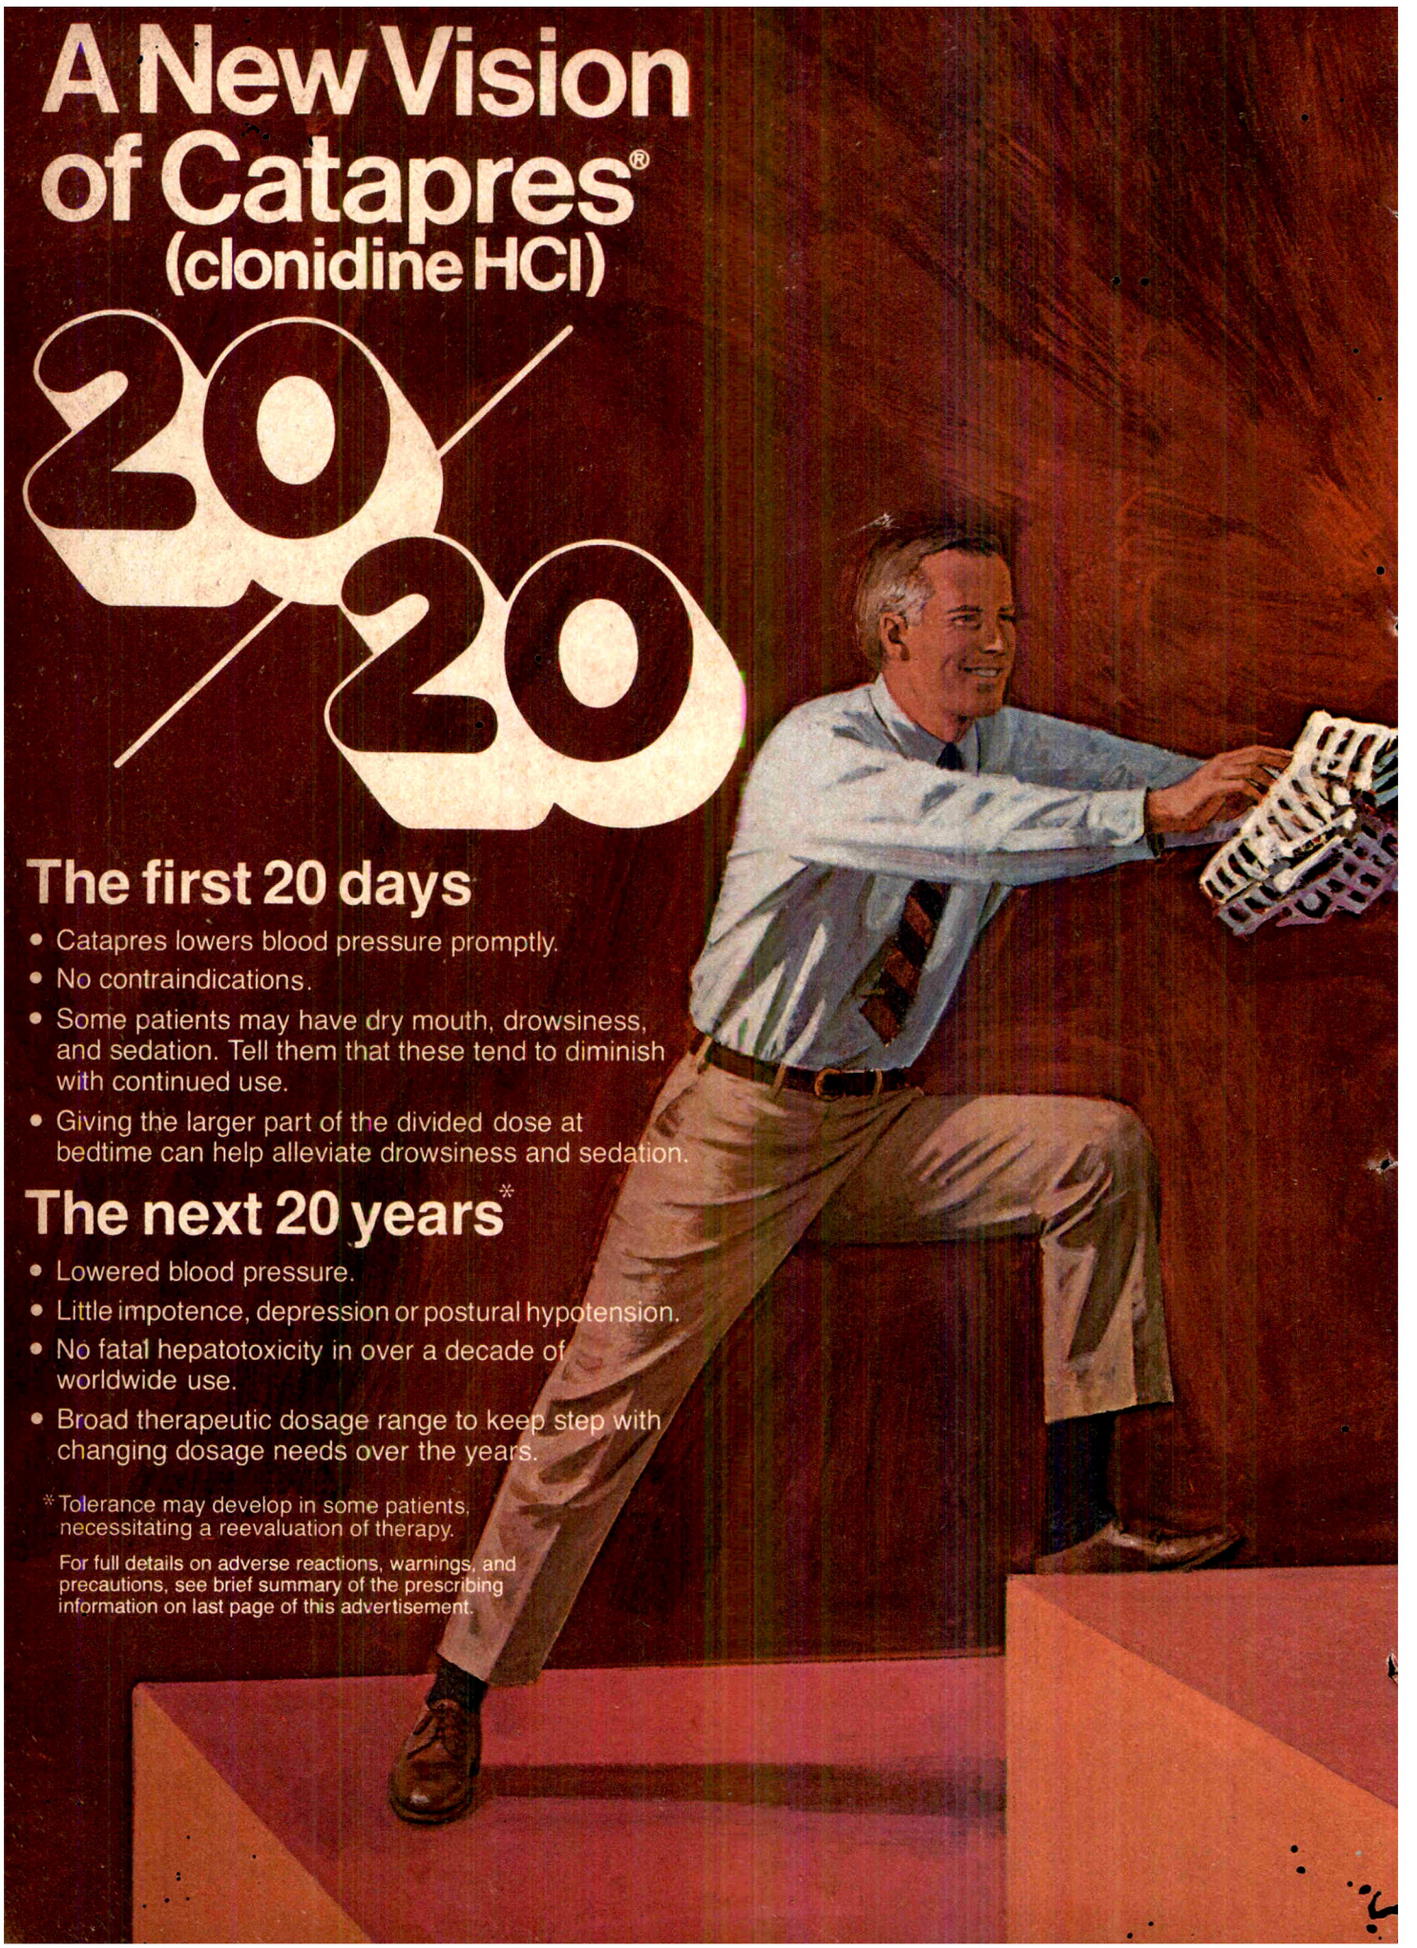
- Catapres lowers blood pressure promptly.
- No contraindications.
- Some patients may have dry mouth, drowsiness, and sedation. Tell them that these tend to diminish with continued use.
- Giving the larger part of the divided dose at bedtime can help alleviate drowsiness and sedation.

The next 20 years*

- Lowered blood pressure.
- Little impotence, depression or postural hypotension.
- No fatal hepatotoxicity in over a decade of worldwide use.
- Broad therapeutic dosage range to keep step with changing dosage needs over the years.

* Tolerance may develop in some patients, necessitating a reevaluation of therapy.

For full details on adverse reactions, warnings, and precautions, see brief summary of the prescribing information on last page of this advertisement.

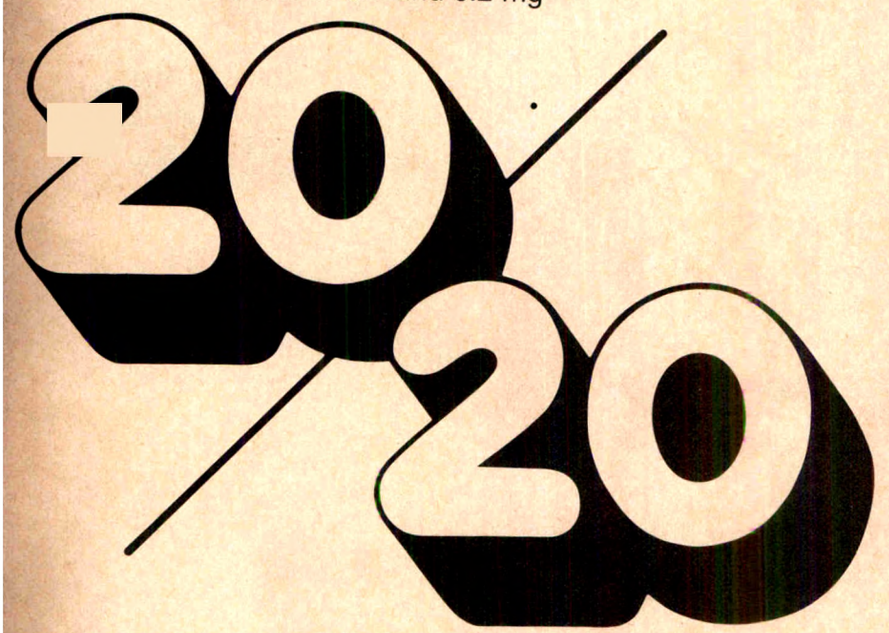


Catapres® (clonidine HCl
For Step 2 in
Hypertension

HYPERTENSION

A New Vision of Catapres® (clonidine HCl)

Tablets of 0.1 and 0.2 mg



What you do the first 20 days Can help him the next 20 years

Catapres®
(clonidine hydrochloride)
Tablets of 0.1 mg and 0.2 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone, and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000.

For complete details, please see full prescribing information.

LET'S FACE IT...

ECG storage and retrieval systems have come a long, long way. Digital storage, instant and automatic retrieval, epidemiological research, you name it ... today's technology now makes it all possible.

But the more we build into it, the more expensive it gets. Many hospitals just cannot truly justify the "ultimate" system, and health planning agencies are looking critically at large expenditures.

So we looked for ways to bring all of the tasks you really need to tackle into a system that can be shared with others. And we found it. It's called μMUSE*, a remote ECG management terminal.

micro-MUSE gives you access to your own section of a central storage base, with privacy and control over your own records. micro-MUSE even retrieves your patient's previous ECG and prints it out next to the current ECG, **automatically**.

So, before you buy another ECG machine, from us or anyone else, let's spend a moment together to make sure it's compatible with the big step forward in electrocardiography ... μMUSE.

Call us at 414/355-5000 to have a sales engineer evaluate your needs.

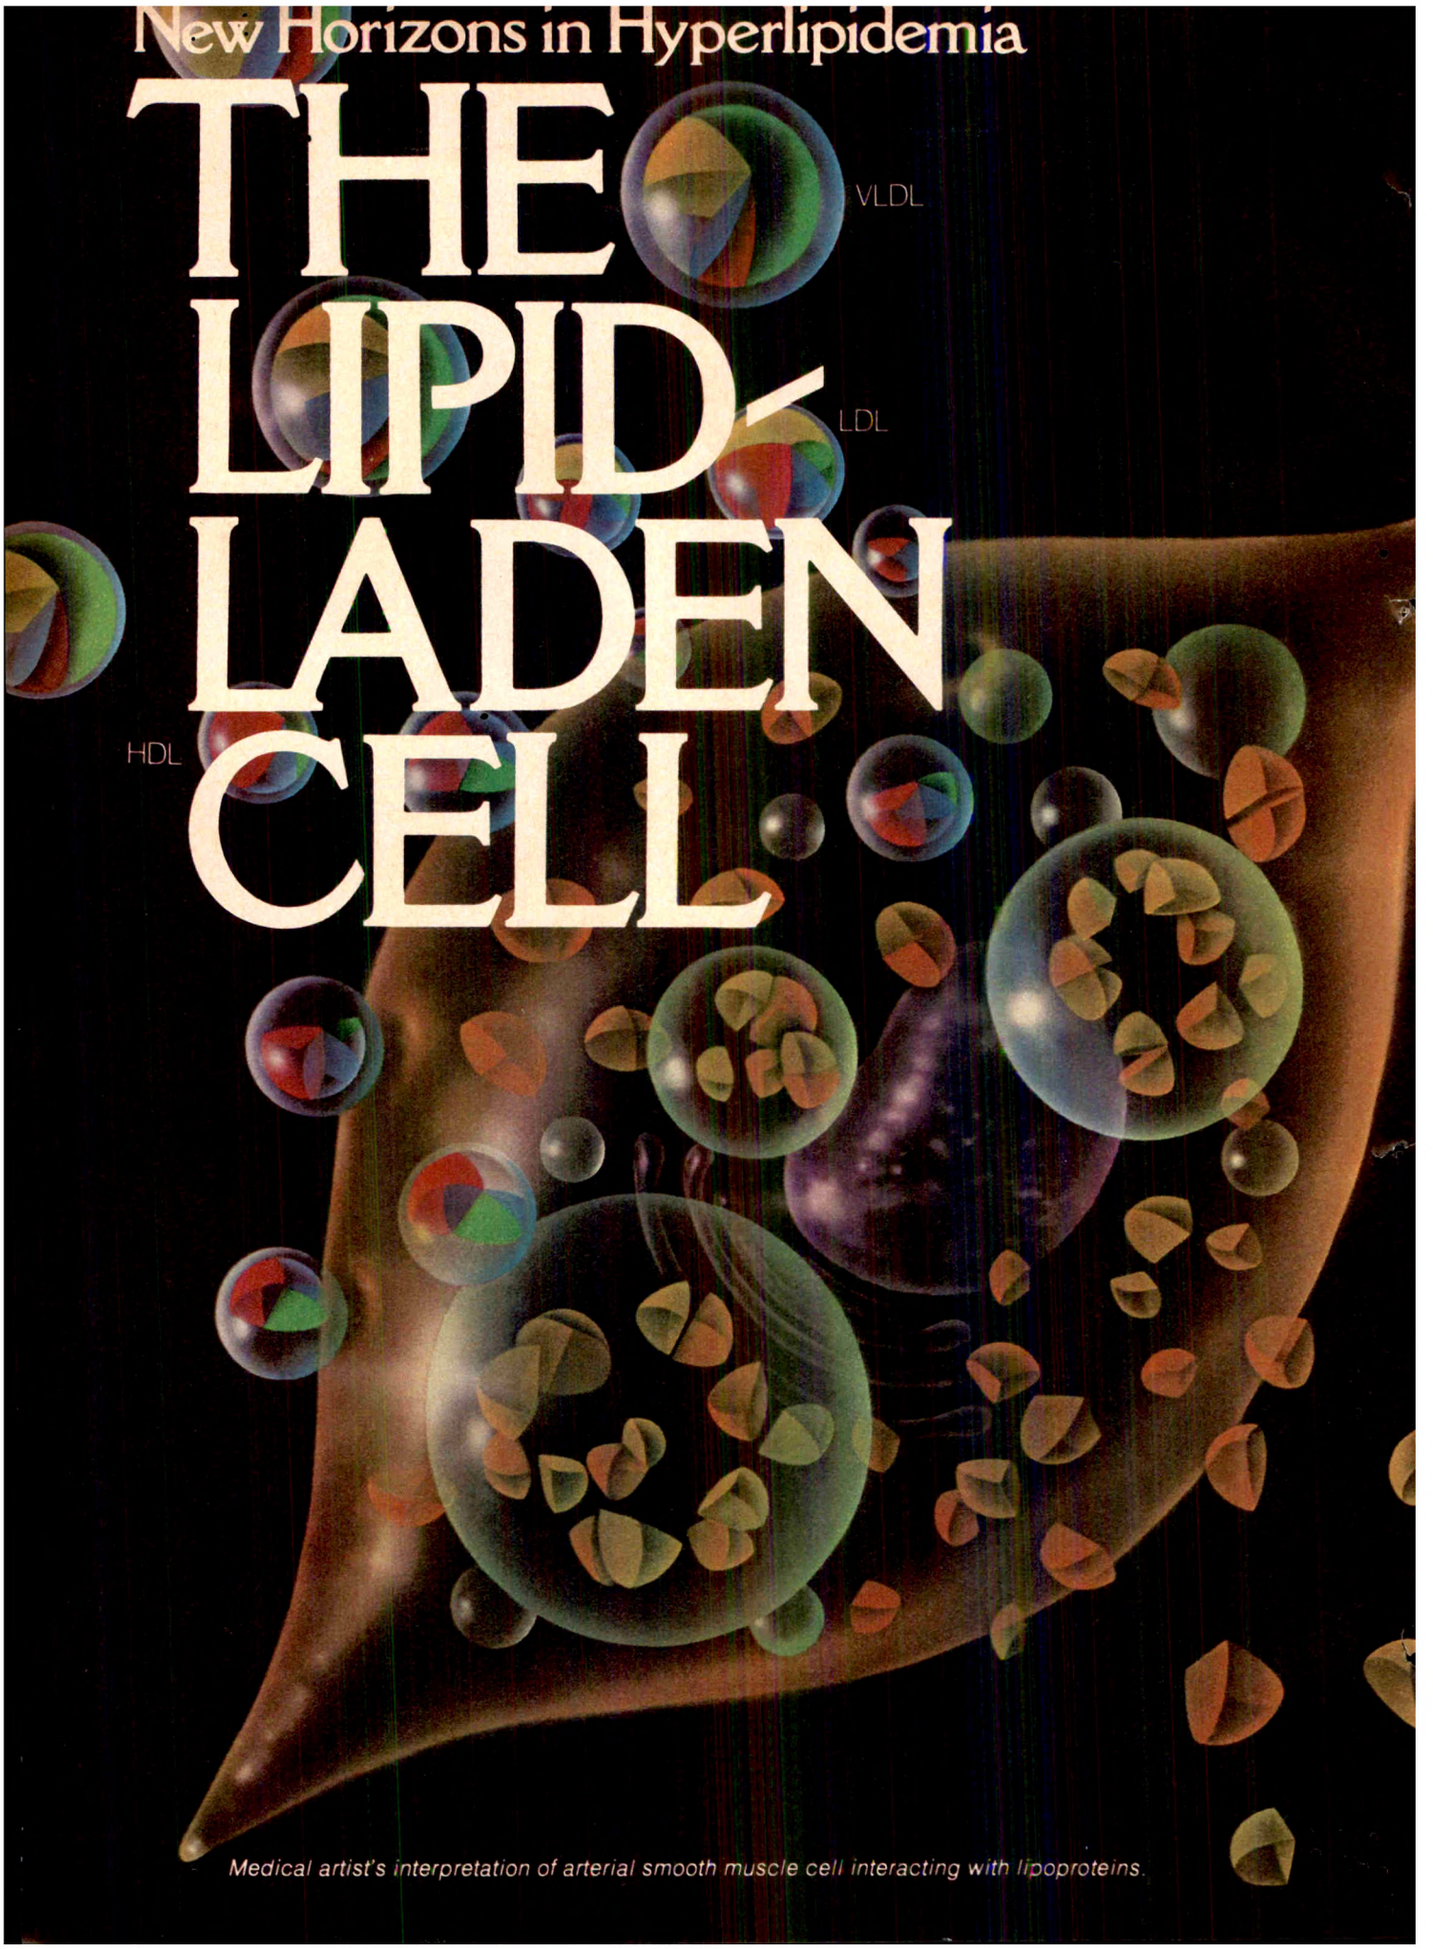
New Horizons in Hyperlipidemia

THE LIPID-LADEN CELL



Medical artist's interpretation of arterial smooth muscle cell interacting with lipoproteins.

Lipid overloading in the arterial smooth muscle cell: proposed biochemical mechanisms

The process by which a normal arterial smooth muscle cell is transformed into a lipid-laden "foam" cell is highly complex and, as yet, not completely understood. But from the findings of an ever-increasing number of animal and human studies,[1-28] investigators have begun to piece together a theoretical picture of what may occur—a picture that adds important new perspectives to an understanding of hyperlipidemia.

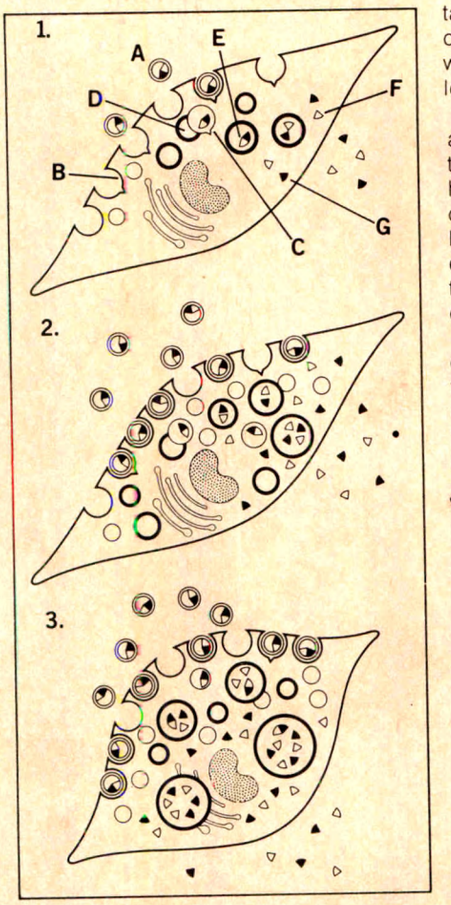
What emerges from this research is that induced and/or genetic abnormalities in the metabolism of arterial smooth muscle cells may be crucial to their evolution into a lipid-laden form.[6,9,11,19] Specifically, there appear to be alterations in the ability of these cells to bind, internalize and degrade triglyceride-rich very low density lipoproteins (VLDL) and cholesterol-rich low density lipoproteins (LDL).[1,2]

The endothelium, which normally acts as a selective barrier[20,25] to the entry of plasma constituents into the arterial wall, also appears to influence the behavior of arterial smooth muscle cells.[23,26] As a result of injury to the endothelium and/or increased concentrations of circulating lipoproteins, excessive quantities of lipids may breech the endothelial barrier, and accumulate in smooth muscle cells.[1,2,5,20,23] Eventually, the cells die and rupture, releasing their lipid content into the extracellular matrix of the arterial wall.

Human tissue cultures yield new insights into an insidious progression

Theories postulating the sequence of events that may produce lipid-laden cells were originally based on observations in a variety of animal species. Now, through the application of dramatic new biochemical techniques, many of these theories are finding support in studies of human cells. It is now possible to culture human arterial smooth muscle cells from explants of tissue obtained during vascular surgery,[1-3,10,18] human fibroblasts taken from the skin,[6,8,12,14] and human endothelial cells derived from umbilical veins.[15-17] Methods for studying the interaction of these cells with lipoproteins in culture have permitted the assessment of lipoprotein binding, uptake, and degradation.[1,2] (See diagrams at right). While this *in vitro* data requires *in vivo* confirmation, it can serve as a useful basis for investigation and discovery with regard to the relationship between plasma lipids and lipid accumulations in arterial walls.

The evolution of a lipid-laden cell: a working hypothesis[24] Disturbances in the normal metabolism of arterial smooth muscle cells can lead to marked changes in the lipid content of the arterial wall. The most notable change is an increase in cholesterol esters, but there are also increases in the concentration of other lipids, including triglycerides.[20] Following is a highly simplified outline of a working hypothesis to explain lipid overloading, as it relates primarily to LDL:[24]



1. *The arterial smooth muscle cell's natural defenses against lipid overload*[6-8,12] Given an artery with the endothelium intact, and a low level of circulating plasma lipoproteins, LDL uptake is predominantly of the high affinity, receptor-dependent type: LDL molecules (A) are bound to receptor sites (B) on the endothelial surface, internalized via pinocytotic vesicles (C), fused with lysosomes (D) which hydrolyze the cholesterol ester (E) component of the lipoprotein into its basic constituents, free cholesterol (F) and fatty acid (G). The free cholesterol triggers compensatory mechanisms which decrease cholesterol synthesis by the cell and also reduce the number of its LDL receptors, thereby helping to limit further entry of LDL. Under normal conditions, this acts to protect the arterial smooth muscle against lipid overload.

2. *The cell's response to an increased metabolic load.* Injury or disruption of the endothelium and/or a substantial increase in circulating plasma lipoproteins leads to entry of larger amounts of LDL and other lipid substances into the cells. At these higher plasma levels, lipids appear to be taken up predominantly via a low affinity, nonreceptor-mediated process.[7] Endocytosis is greatly stimulated and the number and size of the lysosomes increase in an effort to keep up with the increased load.[21]

3. *The cell's lipid-regulating mechanism overwhelmed.* If the state of increased metabolic activity needed to handle the extra lipid load persists, the "finely-tuned" regulatory mechanism may break down. With lipid passage into the cell virtually unchecked, massive intracellular accumulations of cholesterol and other lipids ensue. As a result, cellular function may be compromised, leading to cell death and deposition of lipids in the extracellular space.

High levels of circulating lipoproteins: a key factor in cellular overload

In human tissue cultures, arterial smooth muscle cells take up substantial quantities of VLDL and LDL and relatively small amounts of HDL.[1,2] This contrasts with the low uptake of VLDL and high uptake of HDL observed in smooth muscle cells of certain animal species (e.g., rats)[2] which have no propensity for lipid overloading in arterial cells.

Cellular concentrations of lipids also bear a relation to lipid concentrations in the serum. For example, both human and calf endothelial cells in tissue culture evidenced significantly higher levels of triglycerides and fatty acids after exposure to hypertriglyceridemic serum than did controls subjected to medium containing normal serum.[17]

These provocative studies have exciting implications for further investigation. *However, it must be remembered that there is to date no proof that lowering serum lipoprotein concentrations in humans will prevent or reverse the processes that produce lipid-laden cells.*

CARDIOGUARD® 4000 STRESS TEST SYSTEM

We ask questions before any of our instrumentation gets to the drawing board. Because knowing what you need is the most important part of designing what you can use.

Our Cardioguard 4000, for example. You wanted a system for stress testing and resting ECG your office could use and afford. So the 4000 is compact, mobile, and simple to operate. And with the Exerstress® Display Memory Scope, ST Segment Computer, and one of our low-cost treadmills, you get a complete, automatic 3-channel system for a lot less than you might expect to pay.

The 4000 automatically produces 12-lead ECGs on a letter-size, chart-ready format. With simple, push-button controls, you can pre-select—any standard lead group, an XYZ lead group, plus your choice of a monitor lead group. And you can change any lead group anytime during the procedure.

The Exerstress Display has a 5-second memory for immediate chart documentation of observed abnormalities. ECG Traces, Elapsed Time, Heart Rate, and the optional ST Level Display all appear on the bright, non-fade, memory scope.

Like all Del Mar Avionics Systems, the 4000 is backed by an extensive service and supply network throughout the country. For more information or a demonstration, write Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714. Or just call any sales office listed below.

Together, your ideas and our ideas built the 4000. An economical, reliable, yet state-of-the-art approach to office and private practice stress testing as well as resting electrocardiograms.

Which is the very reason we ask questions **before we build answers**

requires the BEST:

ELECATH®
Balloon Catheters

ELECATH® Flow-Directed Catheters

Elecath Balwedge® Flow-Directed Catheters For Arterial Wedge Pressures & C.V.P.
- ☐ Larger lumen offers better frequency response.
- ☐ The 7 Fr. Catheter will fit easily through a 7 Fr. Introducer.
- ☐ Single pressure (2 Lumen) available in sizes 4 Fr. - 7 Fr.
- ☐ Double pressure (3 Lumen) available in sizes 5 Fr. - 7 Fr.

Elecath Balwedge® Pulmonary Angiography Catheters
- ☐ A flow-directed Catheter for radiological studies in the pulmonary artery

Elecath Baltherm® Thermo-Dilution Flow-Directed Catheters
- ☐ Operates properly with all popular computers
- ☐ Pre-calibrated for ease of use and accuracy
- ☐ A wide range of sizes (4 Fr. - 7 Fr.)
- ☐ A 7 Fr. Catheter fits easily through a 7 Fr. introducer
- ☐ Rapid thermistor response time
- ☐ Room temperature injectate recommended

Elecath Arterial Embolectomy Catheters
- ☐ A device for the removal of arterial emboli and thrombi
- ☐ Available in sizes from 3 Fr. - 7 Fr.

Elecath Balectrode® Flow-Directed Pacing Catheters
- ☐ For temporary bedside pacing without flouroscopy
- ☐ Easy placement and rapid capture
- ☐ Easy to attach to external Pacemakers

Holter monitoring™ and ambulatory blood pressure

Pressurometer® II

It took Del Mar Avionics to combine these important diagnostic monitoring techniques—ambulatory non-invasive blood pressure, and ambulatory ECG. After all, who could have done it better. We have been the leader in automatic blood pressure instrumentation for more than a decade—not to mention Holter Monitoring, our trademark.

And we did it in such a way that you could pick right up where Holter Monitoring left off—by introducing Pressurometer® II. Our Model 1977 Pressurometer automatically takes blood pressure at 100 programmed intervals around-the-clock. The information is recorded on our new Model 446A Electrocardiocorder® during its recording of two-channel electrocardiograms, and is scanned and written out on our 660A Electrocardioscanner®, with a new module that gives digital readouts and a trend chart of systolic and diastolic blood pressure.

Your existing 660A and 445 Recorders can be updated to accept Pressurometer II.

Pressurometer II, coupled with your new or modified Electrocardiocorder and 660A Electrocardioscanner, completely updates any Dynamic Electrocardiography® system. Now you can have your 24-hour ECG and blood pressure, too.

HE SHOULD FEEL GOOD DURING THE THERAPY FOR HYPERTENSION*

DYAZIDE®

Trademark

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

TRIAMTERENE LIMITS POTASSIUM LOSS AS HYDROCHLOROTHIAZIDE LOWERS BLOOD PRESSURE

You can't expect to make the asymptomatic patient feel better, but it's easy to make him feel worse. And the active, younger patient won't put up with side effects or complex drug schedules that interfere with his busy life. With potassium-sparing 'Dyazide', hypokalemia and its attendant fatigue, muscle cramps and malaise are seldom a problem.

Convenient, economical for long-term control

One or two capsules, once or twice daily for maintenance, according to the response of the patient. Tedious, expensive K^+-rich diets or potassium salts should not be used unless hypokalemia develops or dietary K^+ intake is markedly impaired.

Serum K^+ and BUN should be checked periodically

particularly in the elderly, diabetics, and those with suspected or confirmed renal insufficiency (See Warnings in Brief Summary). Elevated serum potassium levels can occur because of the K^+-sparing effect of triamterene, but they are rare in patients with normal renal function. If hyperkalemia develops, substitute a thiazide alone. Routine use of diuretics in healthy pregnant women is inappropriate.

*Not for initial therapy (see box warning). See next page for brief summary of prescribing information, including indications, contraindications and adverse reactions.

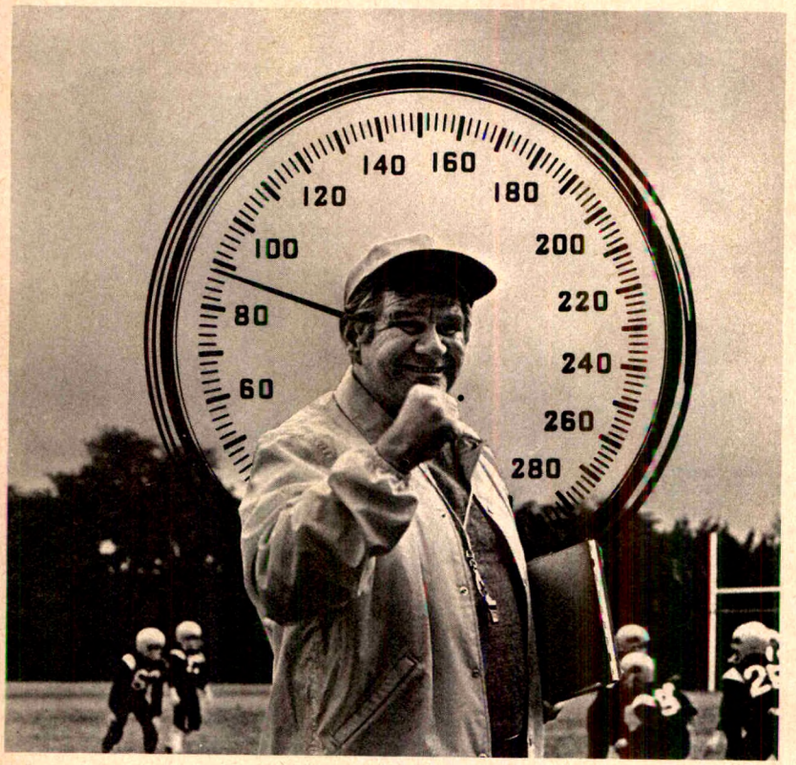
FOR LONG-TERM CONTROL OF HYPERTENSION*



Trademark

DYAZIDE® MAKES SENSE

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

TRIAMTERENE LIMITS POTASSIUM LOSS AS HYDROCHLOROTHIAZIDE LOWERS BLOOD PRESSURE

SK&F CO.
a SmithKline company

Before prescribing, see complete prescribing information in SK&F Co. literature or PDR. A brief summary follows:

*

WARNING
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

* **Indications:** When the combination represents the dosage determined by titration: Adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, the nephrotic syndrome. Corticosteroid and estrogen-induced edema, idiopathic edema; hypertension, when the potassium sparing action of triamterene is warranted. (See Box Warning.) Routine use of diuretics in healthy pregnant women is inappropriate; they are indicated in pregnancy only when edema is due to pathological causes.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone.

Supplied: Bottles of 100 and 1000 capsules; Single Unit Packages of 100 (intended for institutional use only).

CLINICAL STUDIES

Approach to the Estimation of Myocardial Infarct Size By Analysis of Precordial S-T Segment and R Wave Maps

HARTMUT HENNING, MD
THORDUR HARDARSON, MD
GARY FRANCIS, MD, FACC
ROBERT A. O'ROURKE, MD, FACC
WILLIAM RYAN, MBBS
JOHN ROSS, Jr., MD, FACC

San Diego, California

To assess the correlation of S-T segment elevations and the height of R waves of the precordial electrocardiogram with myocardial infarct size, we performed 35 lead precordial electrocardiograms (maps) in 24 patients with uncomplicated acute anterior transmural myocardial infarction. The initial analysis was carried out in 14 patients. Infarct size was estimated from the integration, from normal baseline to baseline, of serial serum creatine kinase (CK) values obtained at 2 to 4 hour intervals and expressed as IU/liter·hours. The first electrocardiographic maps were recorded 12 hours or less after the onset of symptoms. All S-T segment elevations and R waves were summed for each map (ΣS-T and ΣR). There were positive correlations between the ultimate CK infarct size and the initially recorded ΣS-T ($r = 0.69$), the initially recorded log ΣR ($r = -0.70$) and the initial early decline in log ΣR per hour [$(\Delta\log \Sigma R/\Delta hour)\cdot 10^3$, $r = 0.88$]. Therefore, these variables were combined in a multiple regression analysis: CK infarct size = $0.23\ \Sigma$S-T + $0.20\ [(\Delta\log \Sigma R/\Delta hour)\cdot 10^3] - 14.9 \log \Sigma R + 36.8$ ($r = 0.97$). In addition, on the basis of previous studies the initially recorded ΣS-T and log ΣR values were normalized with respect to time by calculating the expected ΣS-T value at 12 hours after the onset of symptoms ($\Sigma S\text{-}T_{12}$) and the 12 hour interpolated values for ΣR (ΣR_{12}). These values also showed a good correlation with infarct size: CK infarct size = $0.37\ \Sigma S\text{-}T_{12} + 0.16\ [(\Delta\log \Sigma R/\Delta hour)\cdot 10^3] - 18.2 \log \Sigma R_{12} + 40.4$ ($r = 0.97$).

To validate this approach, 10 additional patients were studied prospectively. Correlations between CK infarct size and the various measurements from the serial precordial maps were similar to those in the first study group, and CK infarct size correlated well with the electrocardiographic infarct estimates ($r = 0.90$ and $r = 0.95$, respectively). It is concluded that in selected patients CK infarct size can be directly related to the initial height of S-T segment elevations and the early rate of R wave decline and inversely related to later ΣR values, thereby providing a general approach for use in studies on the estimation of myocardial infarct size from precordial electrocardiographic maps.

From the Division of Cardiology, Department of Medicine, University of California Medical Center, San Diego, San Diego, California. This project was supported by NIH Research Grant HL 17682 from the Specialized Center of Research on Ischemic Heart Disease, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received June 17, 1976; revised manuscript received June 24, 1977, accepted June 29, 1977.

Address for reprints: John Ross, Jr., MD, Division of Cardiology, University of California, San Diego, Department of Medicine M-013, La Jolla, California 92093.

Recent studies suggest that the prognosis of patients with acute myocardial infarction is affected by the extent of myocardial damage when the latter is estimated quantitatively.[1,2] In the dog, the depletion of myocardial creatine kinase (CK) and its appearance in serum appear to have a relatively predictable relation,[3–5] and the total amount of CK released into the circulation, estimated with serial serum CK measurements, has been used in dogs and man as a measure of infarct size[1,2,4] although the reliability of this relation has been questioned in some experimental studies.[6] CK depletion has been shown to correlate relatively well with damage at the site of depletion as well as with the extent of local S-T segment change; thus, S-T segment elevations recorded from multiple epicardial leads after acute coronary occlusion were useful in predicting histologically and enzymatically determined extent of ischemic injury 24 hours after occlusion.[7,8] Studies on such correlations and the use of precordial electrocardiographic maps have been reviewed elsewhere.[9] Changes in the electrocardiographic QRS voltage have also been related to ischemic injury in dogs[10,11] and monkeys.[12] In man, however, few studies are available that attempt to correlate myocardial infarct size as estimated from serial serum enzyme levels with precordial electrocardiographic variables.[13,14]

Accordingly, we reviewed serial precordial electrocardiograms (maps) in a selected group of 24 patients with uncomplicated acute anterior myocardial infarction. The relations among S-T segment elevations, alterations in R wave voltage and infarct size estimated from serial CK values were examined retrospectively in 14 patients and validated in an additional group of 10 patients studied prospectively.

Patients and Methods

Retrospective Study

Criteria for patient selection: In the retrospective study in 14 patients, the following criteria were set for the review and acceptance of precordial electrocardiographic recordings: (1)

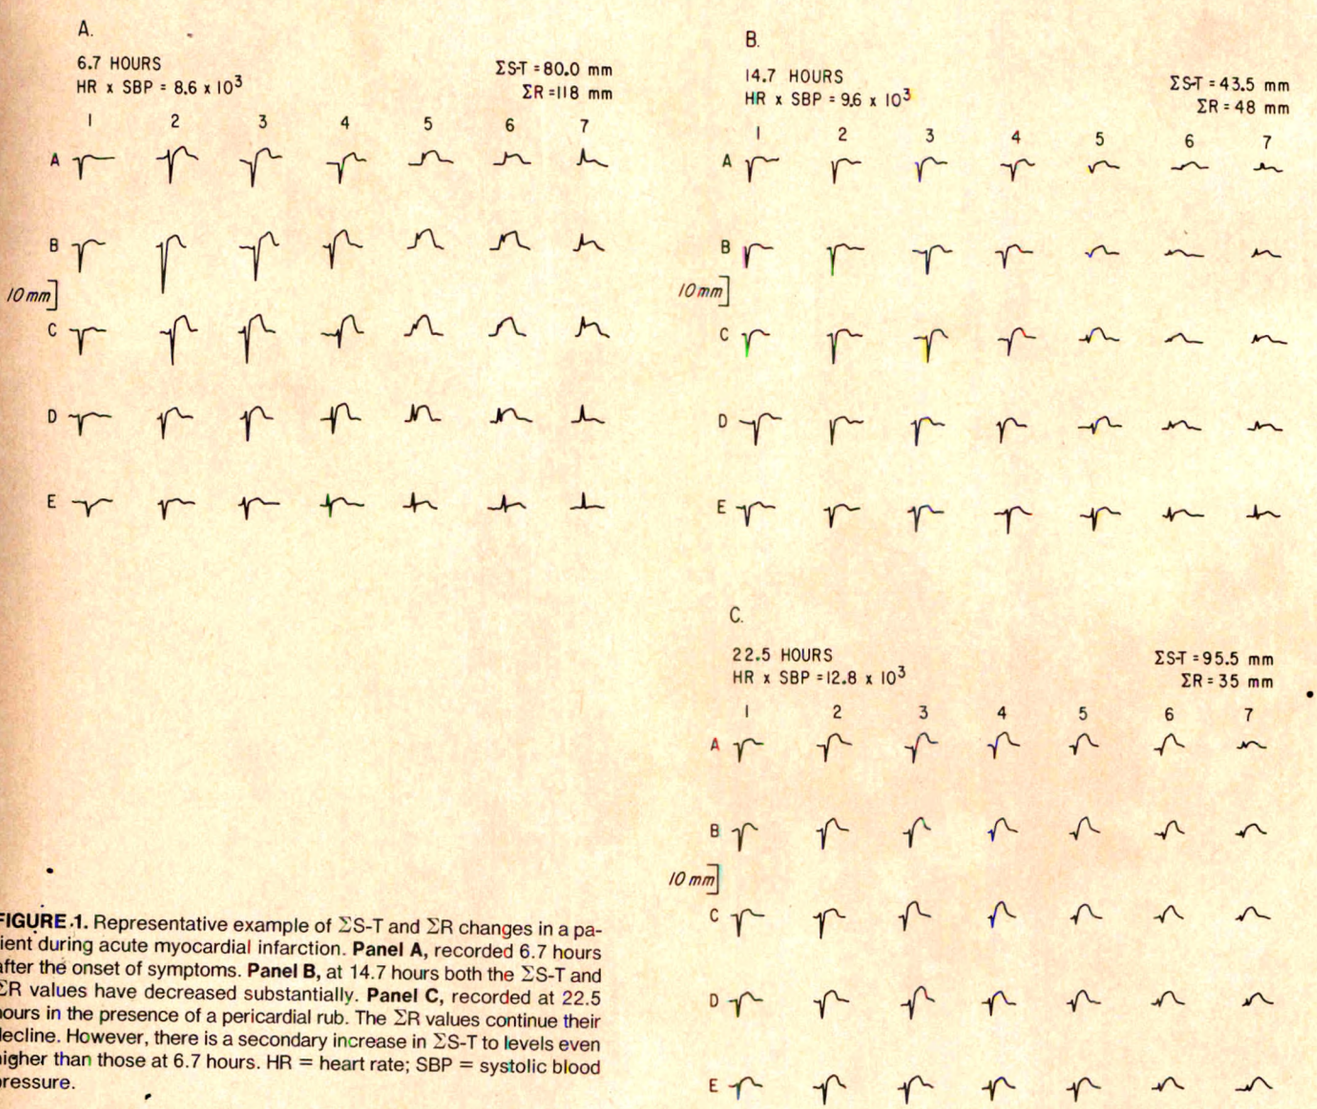

FIGURE 1. Representative example of ΣS-T and ΣR changes in a patient during acute myocardial infarction. **Panel A,** recorded 6.7 hours after the onset of symptoms. **Panel B,** at 14.7 hours both the ΣS-T and ΣR values have decreased substantially. **Panel C,** recorded at 22.5 hours in the presence of a pericardial rub. The ΣR values continue their decline. However, there is a secondary increase in ΣS-T to levels even higher than those at 6.7 hours. HR = heart rate; SBP = systolic blood pressure.

All patients included in the study had an acute transmural myocardial infarction involving the anteroseptal or anterolateral wall of the left ventricle as evidenced by a history of prolonged chest pain, characteristic elevations in serum enzymes (creatine kinase [CK], glutamic oxaloacetic transaminase [GOT] and lactic dehydrogenase [LDH]) and serial changes in 12 lead electrocardiograms. (2) No patient had a history of electrocardiographic evidence of previous infarction involving the anterior or lateral walls of the left ventricle. (3) All patients had sinus rhythm at the time of study. Precordial maps were excluded when the duration of the QRS complex exceeded 0.09 second or when a definite change in the QRS frontal plane axis occurred between two electrocardiograms. No patient had electrocardiographic evidence of left or right ventricular hypertrophy.[15] (4) In all patients the first map was recorded 12 hours or less after the onset of symptoms and at least two maps were recorded within 24 hours of the onset of symptoms. (5) All patients had an initial serum CK value within normal limits (less than 50 IU/liter) on admission. In addition, in all patients a complete CK curve obtained from serial serum CK determinations could be plotted against time from baseline to baseline. (6) No patient had clinical evidence of other systemic diseases.

Of 231 patients admitted and studied over a 3.5 year period in the Myocardial Infarction Research Unit, University of California, San Diego, 14 patients with acute anterior transmural myocardial infarction were found who fulfilled these strict criteria. (Of these, 109 patients had anterior infarction and underwent electrocardiographic mapping.) Ten were men and four women; their average age was 59.2 years. They were admitted to the coronary care unit 1 to 11 hours after the onset of symptoms (mean 4.5 hours). Four patients had a previous inferior wall infarct as judged from electrocardiographic criteria. Three patients were in clinical class I (Killip and Kimball[16] classification) on the first hospital day, 10 were in class II and 1 was in class III. No patient experienced cardiogenic shock and none had secondary increases in serum enzyme levels suggesting infarct extension. Patients with such complications were excluded from the study.

Precordial mapping and measurements: A blanket was used containing 35 unipolar electrocardiographic leads arranged in seven horizontal and five vertical rows and connected through a switch to the V lead of an electrocardiograph.[17] The upper right corner of the blanket was placed over the second right intercostal space close to the sternum and the skin was marked to assure the same location for serial studies in the same patient. The left border of the blanket was near the mid axillary line. All S-T segment elevations above baseline were measured to the nearest 0.5 mm, 20 msec after the J point, using the average of five complexes. The measured S-T elevations were summed and expressed as ΣS-T. All of the R waves in each map were likewise measured to the nearest 1.0 mm and summed and expressed as ΣR (Fig. 1).

The ΣR was plotted semilogarithmically against the time in hours after the onset of symptoms in all patients (Fig. 2). The initial hourly decline in ΣR was calculated by taking the difference between the first two log ΣR values (Δlog ΣR) and dividing by the number of hours separating the two recordings (Δlog ΣR/Δhour). For the second ΣR measurement the first consecutive map was selected that had a time difference of at least 2 hours between the two maps.

Normalization of ΣS-T and ΣR with respect to time: Because the initial precordial maps were not all recorded at the same time in relation to onset of symptoms, an attempt was made to normalize the ΣS-T and ΣR values with respect to time. Previous studies from our laboratory have shown that in patients pursuing clinically uncomplicated courses without therapeutic interventions, the mean ΣS-T values fall progressively during the first 12 hours after the onset of acute symptoms.[18] The mean ΣS-T values at 3 to 6 hours were arbitrarily set at 100 percent (actual value 72 mm), and the mean corresponding values at subsequent times are shown in Figure 3. The initially recorded S-T values were normalized with respect to time, the expected ΣS-T value at 12 hours ($\Sigma S\text{-}T_{12}$) being calculated by subtracting an appropriate percent from the initial ΣS-T value; for example, 60 percent was subtracted

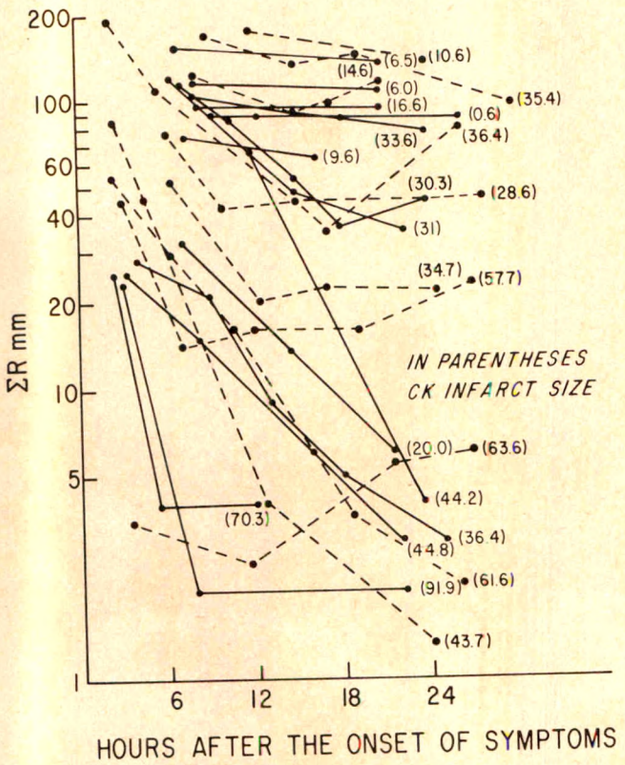

FIGURE 2. Individual changes in ΣR with time from the onset of symptoms. Numbers in parentheses indicate creatine kinase (CK)-determined infarct size. The **solid lines** represent the initial study group of 14 patients (retrospective), the **dashed lines** the validation group of 10 patients (prospective). Most ΣR values are between 70 and 200 mm.

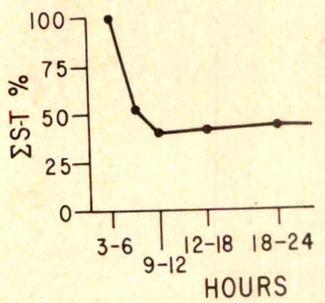

FIGURE 3. The mean percent decline in ΣS-T values 3 to 24 hours after the onset of symptoms, based on a previous study[18] of patients with uncomplicated myocardial infarction without therapeutic interventions.

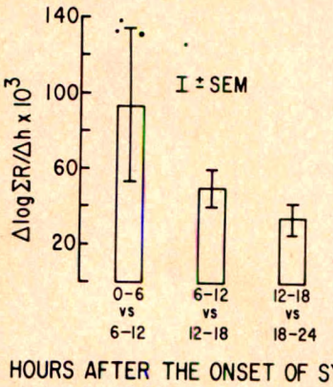

FIGURE 4. Individual ΣR slopes [(Δlog ΣR/Δhour)·10³] in relation to hours after the onset of symptoms. Each slope is obtained by comparing paired log ΣR values of adjacent time windows. The steepest declines in log ΣR values are seen between 0 to 6 and 6 to 12 hours. SEM = standard error of the mean.

for maps recorded at 3 hours, 45 percent for recordings at 6 hours, 20 percent at 8 hours, 5 percent at 10 hours and 0 percent for maps recorded at 12 hours after the onset of symptoms. The ΣR values were normalized by taking the interpolated value at 12 hours in each patient (Fig. 2). Corrected initial S-T segments rather than interpolated values were used for $\Sigma S\text{-}T_{12}$ because S-T segment elevations are susceptible to drug interventions.[7] Two patients received digoxin, 0.25 mg, during the first 24 hours after the onset of symptoms (at 8.5 and 11 hours), in four patients a trimethaphan infusion (20 to 80 mg/min) was started at 6, 9, 11 and 12 hours, respectively, and one patient received practolol (10 mg intravenously) at 11 hours, but none of these medications were administered before the recording of the first precordial map and the subsequent map used for the second ΣR measurement. A pericardial friction rub developed in three patients, but in each instance it occurred more than 12 hours after the onset of symptoms (22, 24 and 27 hours, respectively).

Creatine kinase determinations: Blood samples for CK determinations were obtained at 2 hour intervals during the first 24 hours and at 4 hour intervals after 24 hours. Blood samples (2.5 ml) were obtained in tubes containing 16λ1 millimolar ethyleneglycoltetraacetic acid (EGTA), immediately spun, and the serum was separated from the clot and quick-frozen at −70° C before storage in a −20° C freezer. Creatine kinase was assayed with Rosalki's method.[19] To obtain a measure of the extent of myocardial injury, the CK values were plotted against time in hours, the full curve between normal baseline values was integrated and the results were expressed as international units/liter × hours (IU/liter·hours). No patient received electric countershock or intramuscular injections.

Standard statistical procedures, including multiple linear regression and correlation and analysis of variance, were used to evaluate the data.

Validation: Prospective Study

To validate our approach a second group of 10 patients with acute anterior transmural myocardial infarction were studied prospectively with the same criteria used in the first study group. Seven were men and three women; their average age was 57.6 years. They were admitted an average of 4.7 hours after the onset of acute symptoms. Three patients were in clinical class I at the time of the first precordial S-T segment map, six were in class II and one was in class III. One patient had a prior inferior myocardial infarction. A pericardial friction rub occurred in two patients 24 and 42 hours, respectively, after the onset of symptoms; one patient received digoxin 19 hours after onset of symptoms, after recording of the second precordial map used for the analyses. In these prospectively studied patients, maps were recorded every 4 to 6 hours over the first 48 hours after the onset of symptoms. Complete CK curves were obtained in all.

Results

Evolution of ΣR values after the onset of symptoms: Figure 2 shows the log ΣR values plotted against time in hours in the initial 14 patients (solid lines). To obtain an estimate of the average ΣR changes over time during the first 24 hours after the onset of symptoms, this period was divided into four time windows, 0 to 6, 6 to 12, 12 to 18 and 18 to 24 hours. All individual changes in log ΣR that occurred between two adjacent time windows in the same patient were calculated to derive the individual log ΣR slopes [(Δlog ΣR/Δhour)·10³]. The mean log ΣR slopes between time windows are shown in Figure 4. The steepest declines in log ΣR occurred between 0 to 6 hours and 6 to 12 hours (mean slope 96 ± 45 mm/hour). Between 6 to 12 and 12 to 18 hours the mean slope was 49 ± 11 mm/hour and between 12 to 18 and 18 to 24 hours the mean slope was 33 ± 8 mm/hour. However, because of the wide variability in the early slopes (0 to 6 versus 6 to 12 hours), these differences in slopes did not reach statistical significance using analysis of variance for unpaired samples. Nevertheless, it is apparent from Figure 2 that in two patients with the largest infarct sizes, the ΣR values had diminished maximally by 9 hours, and no further changes were seen after the very steep early decline. Conversely, the patients with a CK infarct size of less than 10 IU/liter·hour showed small ΣR changes, although a slight decline in ΣR values was observed in all cases. Most of the other patients showed an uninterrupted decline in log ΣR values during the first 24 hours.

The decline in log ΣR was similar in the validation group of 10 patients (Fig. 2, dashed lines). These patients were studied at shorter time intervals (at least every 6 hours for 48 hours after the onset of symptoms). In 9 of 13 patients from both study groups who had precordial maps recorded beyond 24 hours, increases in ΣR after the early decline were observed. This increase in ΣR occurred between 12 and 32 hours (mean 22 hours) after the onset of symptoms.

Correlations of ΣS-T and ΣR values with CK infarct size: Table IA shows the initially recorded ΣS-T values, the first and second recorded ΣR values, the initial log ΣR slope, the normalized ΣS-T values, the log ΣR value taken at the individual intercepts with the 12 hour time line (ΣR_{12}) and the CK infarct size for the initial 14 patients.

A correlation was found between the first recorded ΣS-T value and infarct size ($r = 0.69$), and a fair correlation ($r = 0.47$) existed between $\Sigma S\text{-}T_{12}$ and CK infarct size. The initially recorded log ΣR showed a negative correlation with infarct size ($r = -0.70$) and using the

Measurements from precordial electrocardiograms and serum creatine kinase (CK) curve analysis. Initially recorded ΣS-T values, serially recorded ΣR values, initial log ΣR slope, ΣS-T and log ΣR values at 12 hours are shown for the initial 14 patients (**A**, 14 patients) and for the validation group (**B**, 10 patients).

12 hour interpolated values (log ΣR_{12}) improved the correlation substantially ($r = -0.84$). The initial log ΣR slope [(Δlog ΣR/Δhour)·10^3] also showed a good correlation with the eventual infarct size ($r = 0.88$). Thus, patients with a large myocardial infarct tended to show high initial ΣS-T values and steep descents of log ΣR during the first 12 hours after the onset of symptoms, as well as low log ΣR values at 12 hours.

The initially recorded variables were combined in a multiple regression analysis which showed an improved correlation ($r = 0.97$) with CK infarct size in comparison with the single variables:

$$\text{CK infarct size} = 0.23\ \Sigma\text{S-T} + 0.20[(\Delta\log \Sigma R/\Delta\text{hour}) \cdot 10^3] - 14.9 \log \Sigma R + 36.8 \quad (1)$$

Multiple regression analysis was also performed using the time-normalized values ΣS-T_{12} and ΣR_{12} and yielding an r value of 0.97:

$$\text{CK infarct size} = 0.37\ \Sigma\text{S-T}_{12} + 0.16[(\Delta\log \Sigma R/\Delta\text{hour}) \cdot 10^3] - 18.2 \log \Sigma R_{12} + 40.4 \quad (2)$$

Figure 5A illustrates the relation of infarct size to initially recorded ΣS-T and ΣR values using Equation 1, and Figure 5B shows the relation between the electrocardiographic variables and CK infarct size, using the time-corrected values (Equation 2). The mean absolute difference between the calculated infarct size using the electrocardiographic data in Equation 1 and the observed infarct size by CK criteria was 4.9 IU/liter·hour, or 15 percent of the mean infarct size (31.6 ± 6.9 IU/liter·hour). The mean absolute difference calculated using Equation 2 was identical.

Validation: Table IB shows the ΣS-T and ΣR values and the initial log ΣR slope and the CK infarct size for the 10 patients studied prospectively. Correlations between the CK estimate of infarct size and the ΣS-T and ΣR measurements were similar to those in the initial study group. CK infarct size correlated well with the first recorded ΣS-T ($r = 0.69$) but was only fair with ΣS-T_{12} ($r = 0.50$). The initially recorded log ΣR showed a negative correlation with CK infarct size ($r = -0.65$), and this improved with the 12 hour interpolated values (log ΣR_{12}, $r = -0.82$); the correlation was not good when the initial log ΣR slope was used ($r = 0.35$).

Figure 5A shows the relation of CK infarct size to the initially recorded ΣS-T and ΣR values (Equation 1) for the 10 patients ($r = 0.90$). There was also a good correlation between CK infarct size and the time-corrected electrocardiographic variables (Equation 2, $r = 0.95$) (Fig. 5B). The mean absolute difference between the calculated infarct size from the electrocardiographic variables (Equation 1) and the CK infarct estimate was 3.5 IU/liter·hour, or 9 percent of the mean CK infarct size (38.6 ± 18.0 IU/liter·hour); the mean absolute dif-

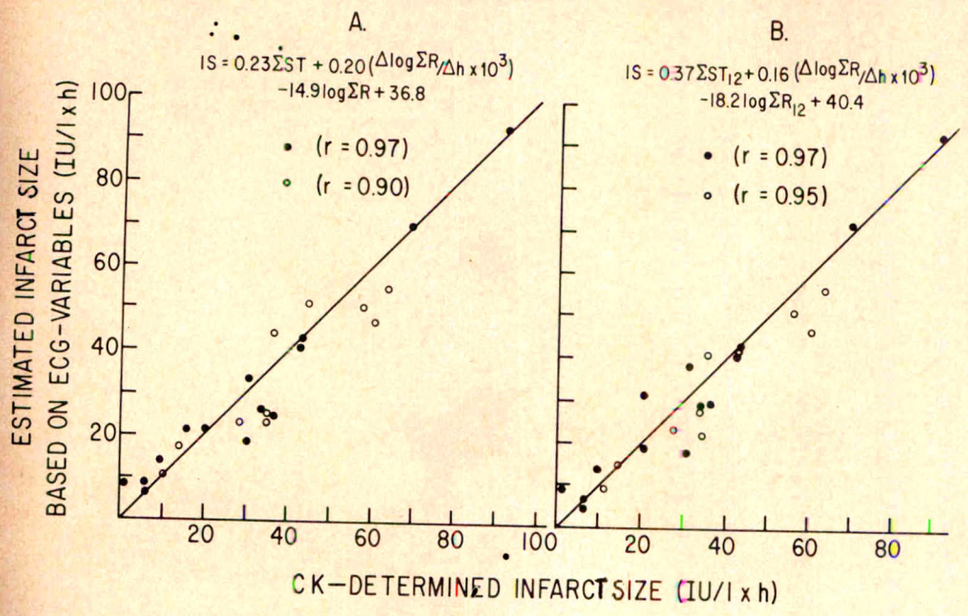

FIGURE 5. The correlation between electrocardiographic (ECG) variables [ΣS-T, log ΣR and (Δlog ΣR/Δhour)·10³] and creatine kinase (CK) infarct size, using the initially recorded data (**A**) and time-corrected values (**B**). The **solid dots** represent the initial study group (14 patients) and the **open circles** the validation group (10 patients). **Diagonal lines** represent the lines of identity. Similar correlations were found for the study group and the validation group. IU/l × h = international units/liter·hour.

ference using Equation 2 was 5.2 IU/liter·hour (13 percent of the mean CK infarct size).

The correlation between the eventual infarct size by CK curve analysis and the initially recorded log ΣR was fair for the total group of 24 patients ($r = -0.63$), improved when correlated with log ΣR at 24 hours ($r = -0.74$) and was best at 48 hours ($r = -0.82$). Thus, in the total group ΣR values recorded 24 hours or more after onset of symptoms correlated better with CK infarct size than earlier ΣR measurements (initial log ΣR, ΣR at 12 hours).

Discussion

Accurate and early prediction of the eventual size of an acute myocardial infarction would, or course, be of considerable value in evaluating and guiding therapy in patients with this condition. Several methods have been utilized to estimate completed infarct size in man[1,2,17,20–23] and in experimental animals[3,7,22,24] and have included S-T segment mapping,[1,7,17] radionuclide imaging[20,21,24,25] and analysis of serum creatine kinase (CK) values.[1–3,22,23] Prediction of the eventual infarct size from early serum CK values[4] or by curve fitting has not yet received general acceptance[26]; however, the method used in our study for estimating infarct size from CK data does not involve estimation or prediction of the fractional decay rate of CK. Bleifeld et al.[23] have recently reported a close correlation between total CK release and morphologic ischemic damage in patients at postmortem examination.

The correlation found in this study between infarct size estimated from completed CK curves and ΣS-T suggests that a relation similar to that observed experimentally[7,9,11,27] may exist in man using precordial S-T segment mapping. This finding contrasts with a recent report by Norris et al.[13] A recent analysis by Holland and Brooks[28] using a single centrally placed electrode indicates that precordial and epicardial S-T segment deflections are complex functions of the geometric size and shape of the ischemic zone, the extent of the latter being directly related to precordial S-T segment elevations but inversely related to epicardial S-T elevations. Their study is difficult to compare with investigations in closed chest dogs in which S-T segment changes in multiple epicardial and precordial leads were compared and found to correlate closely during several acute interventions.[29] The problem might be elucidated by solid angle analysis in the dog using multiple electrocardiographic leads. Furthermore, the influence of conduction disturbances needs further study.[9]

R wave amplitude and size of myocardial infarct: A decrease in the amplitude of epicardial R waves within 4 hours of coronary occlusion was first reported by Johnston et al.[30] Subsequently, Prinzmetal and coworkers[31,32] showed that epicardial sites associated with a decrease in R wave amplitude were characterized by a variable mixture of viable and necrotic myocardial tissue, and Myers et al.[33,34] in clinical studies demonstrated that the larger the infarct the more widespread were the presence of Q waves and the disappearance of R waves. Muller et al.[29] found a decrease of 31 percent in epicardial R wave height in ischemic areas 15 to 60 minutes after coronary occlusion in dogs. Additional studies in monkeys[12] and dogs[10] showed a progressive loss of QRS voltage and bipolar potential electromotive force after coronary occlusion with stabilization at 6 hours. The results of our study suggest that the R wave amplitude declines most rapidly in patients with large infarcts, and that at 12 hours after the onset of symptoms their ΣR values may be smaller than those of patients with small infarcts. The timing of the steep early decline in log ΣR values in two patients of the initial study group with the largest infarcts was similar to that of the R wave changes that Smith et al.[12] described in monkeys after coronary occlusion. In addition, Cox et al.[10] recorded intramyocardial bipolar potentials in dogs

after coronary occlusion and found that sites with the greatest loss of electromotive force also demonstrated the greatest degree of histologic injury. Both studies showed that reperfusion up to 6 hours after coronary occlusion resulted in a partial preservation of QRS voltage. Recently, Hillis et al.[11] reported on the interrelation of S-T segment elevation and subsequent changes in R and Q waves after coronary arterial occlusion. In their study early S-T elevation predicted changes in R and Q waves 24 hours after coronary occlusion, and the decrease in R wave height and the development of Q waves correlated with the histologic extent of necrosis and myocardial CK depletion. This finding is similar to our observation that the decline in ΣR and ΣR at 24 hours and later after the onset of acute symptoms correlate with myocardial CK release as assessed from completed serum CK curves.

Correlation of CK infarct size and ΣR and ΣS-T: The wide range of CK infarct size and the variable initial study time did not allow a good correlation between CK infarct size and the initial ΣR value, but good correlations with ΣR were obtained in our study when ΣR was measured at 24 and 48 hours. This may be related to the fact that late increases in ΣR after the initial decline were observed in some patients. These patients received no drug therapy, and no complications or conduction abnormalities occurred; the reason for such recovery of ΣR is not clear. Prinzmetal et al.[31] and Shaw et al.[32] found an early increase in the height of R waves after coronary occlusion in some experiments, which may be explained by localized conduction abnormalities.[29] Such early increases in R waves were not observed in our patients, but no maps were recorded during the first 2 hours after the onset of infarction.

Our study demonstrated a correlation between infarct size estimated from serial CK measurements and three electrocardiographic variables: ΣS-T, log ΣR and rate of decline of log ΣR. Furthermore, multiple regression analysis showed that a combination of these variables yielded a correlation with infarct size that was superior to that of any single variable, and this approach was validated in a prospective study of 10 patients. A similar approach might be of value for the prediction of infarct size early in a patient's course, permitting the evaluation of therapeutic interventions designed to limit myocardial infarct size. For this purpose, two precordial recordings at least 3 hours apart would be required to obtain control values of ΣS-T, log ΣR and Δlog ΣR/Δhour.

In our study, the mean absolute difference between the electrocardiographically estimated severity of ischemia and the CK infarct size was 4.9 ± 1.0 IU/liter·hour, using both Equations 1 and 2; a similar difference was found in the second, prospectively studied group. This finding suggests that a group of 10 to 15 patients with a control group of equal size would suffice to reveal a statistically significant mean reduction of infarct size of 5 IU/liter·hour at the 5 percent probability level in the patient group receiving a therapeutic intervention. Although time correction (Equation 2) did not result in an improved correlation with CK infarct size compared with that obtained with Equation 1, it is possible that better results could be obtained if actual rather than interpolated values were used.

Clinical implications: It is uncertain how applicable the present approach might be in a more heterogeneous group of patients comprising persons with left ventricular hypertrophy or previous myocardial infarction involving the anterior, lateral or posterior walls of the left ventricle, or acute anterior infarction extending inferiorly or posteriorly. Probably, however, Equations 1 and 2 would have to be modified to include such patients. The use of vectorcardiographic approaches should also be explored. The log ΣR slopes are unknown for patients studied very early (0 to 2 hours), as well as for patients with small infarcts (who tended to have milder symptoms and to be admitted later than patients with large infarcts). Also, it is apparent from Figure 2 that the decline in ΣR values was not completed in most patients at the time of the first map, which was obtained not later than 12 hours after the onset of symptoms. However, no further decline in ΣR was observed in two patients with a large CK infarct size sooner than 12 hours after the onset of symptoms. It is possible that in future studies a time limit for the initial ΣR in reference to the onset of symptoms and a lower limit for the absolute value of the initial ΣR should be defined in a larger group of patients before applying such electrocardiographic analysis in predictive studies.

Despite these limitations, this small retrospective study in 14 patients and the prospective study of 10 patients indicate that the ΣS-T value and the rate of R wave decline in the precordial electrocardiogram can be reliably related to infarct size estimated from complete CK curves. The potential significance of these correlations for early prediction of infarct size and for assessment of the effects of therapeutic interventions will require further evaluation in a larger number of patients in a more diverse population.

Computerized Orthogonal Electrocardiogram: Relation of QRS Forces to Left Ventricular Ejection Fraction

MARTIN G. GOTTWIK, MD

JOSEPH ASKENAZI, MD
DONALD McCAUGHAN, MD

West Roxbury and Boston, Massachusetts

Several studies have suggested a relation between Q wave or R wave amplitude in the standard 12 lead electrocardiogram and the left ventricular ejection fraction. Accordingly, we analyzed the relation between Q wave and R wave amplitudes obtained with computerized orthogonal (Frank) electrocardiography and the angiographically determined left ventricular ejection fraction. A computerized orthogonal electrocardiogram was obtained before cardiac catheterization in 52 consecutive patients being evaluated for chest pain. The electrocardiographic diagnosis indicated 14 normal tracings, 20 inferior, 12 anterior and 6 lateral myocardial infarctions. Linear correlations were made between X, Y and Z axis lead voltages and ejection fraction. A significant correlation was obtained between the voltages of the R waves in the X, Y and Z leads (Rx, Ry, Rz) and of the Q waves in lead Z (Qz) as well as total amplitude Qx + Rx, Qy + Ry and ejection fraction ($P < 0.01$). Arithmetic summation of Rx + Ry + Qz (ΣR) significantly augmented the correlation with ejection fraction ($r = 0.78$, $P < 0.001$); this was only slightly improved by multivariate analysis of Rx, Ry, Qz ($r = 0.80$, $P < 0.001$) or Rx, Ry, Rz, Qx, Qy, Qz ($r = 0.82$, $P < 0.001$). ΣR, utilized as a means of predicting whether an ejection fraction was more or less than 50 percent, had an accuracy rate of 92 percent. Thus, ΣR contains important information that can be used practically in the precatheterization evaluation of patients with chest pain and follow-up evaluation of patients with myocardial infarction.

In recent years a large volume of clinical and experimental information has shown an interrelation among electrocardiographic, biochemical and functional changes that occur in the acutely ischemic myocardium.[1–5] Earlier observations were concerned with S-T segment variations as measures of the extent of acute injury; more recent attention has been focused on QRS changes.[2,3] Several studies[4,5] have suggested that QRS forces in the standard 12 lead electrocardiogram or precordial maps also relate to ventricular function in chronic ischemic heart disease. These observations led us to explore the computerized orthogonal electrocardiogram as an index of left ventricular function. Because the orthogonal electrocardiogram gives equal representation to potentials in the frontal, sagittal and horizontal planes it is not limited to anterior forces as in recordings from precordial blankets nor is it encumbered by the problem of weighing six precordial against the remaining leads of a standard 12 lead electrocardiogram. Computer readout also eliminates observer bias and variation in assessing the presence and magnitude of normal and abnormal QRS forces.

We report herein the relation between orthogonal resting electrocardiographic forces and the left ventricular ejection fraction in a series of patients who underwent diagnostic cardiac catheterization.

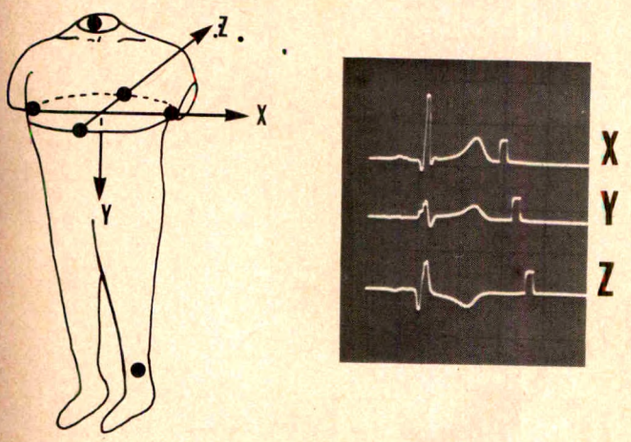

FIGURE 1. Left, schematic representation of the Frank lead system demonstrating the orientation of the three orthogonal leads: The X axis lead is oriented right to left in the horizontal plane, the Y axis lead is oriented vertically in the frontal plane and the Z axis lead is oriented anteroposteriorly along the line of the intersection of the horizontal and sagittal planes. **Right,** scalar orthogonal electrocardiogram of a normal person. By convention, the Z polarity is reversed when compared with the standard lead V_2, that is, anterior forces are inscribed as Q waves and posterior forces as R waves.

Methods

Patients: The study population consisted of 56 consecutive men, mean age 52, who presented for evaluation of chest pain. An orthogonal Frank electrocardiogram (Fig. 1) was obtained in each patient 24 to 48 hours before catheterization and stored on magnetic tape.

Angiography: All patients underwent biplane (30° right anterior oblique and 60° left anterior oblique) ventriculography and coronary angiography. The ejection fraction was calculated according to the length-area method of Dodge.[10] An electrocardiogram was projected simultaneously on the cine film to assure the selection of sinus beats for these measurements. Postextrasystolic beats were not used for determination of ejection fraction.

Orthogonal electrocardiography: The Z lead of the Frank orthogonal electrocardiogram is by convention[6] recorded with a polarity reversed in comparison with that of lead V_2 of the standard 12 lead scalar electrocardiogram. Thus, the Q wave in the orthogonal Z lead (Frank) represents anterior forces and corresponds to the R wave in lead V_2 of the standard electrocardiogram whereas the R wave of the Z lead of the Frank electrocardiogram is comparable with the S wave in lead V_2. As previously described,[7] a Control Data Corporation computer was used to evaluate the electrocardiographic tracings. To eliminate beat to beat variation an average of five to six instrumental measurements were used to establish the required diagnostic criteria. Computer electrocardiographic diagnoses were obtained using multivariate analysis based on a reference data pool of more than 28,000 tracings.[8] Diagnoses were reported in percent probability.[9] A myocardial infarction was diagnosed only when the probability was in excess of 50 percent.

Patients were excluded only if the computer diagnosis indicated a conduction defect or left ventricular hypertrophy, or both. On this basis one patient with left bundle branch block and three with left ventricular hypertrophy were eliminated, leaving a final study group of 52 patients.

In the following determinations and correlations the nomenclature of the Frank electrocardiogram has been used, thus labeling the forces in the Frank Z lead opposite to the standard 12 lead electrocardiogram.[6] To clarify this for the reader accustomed to the standard electrocardiogram a normal orthogonal (Frank) electrocardiogram is shown in Figure 1.

Statistical evaluation was performed with Student's t test, and linear multivariate regression analyses were made according to standard formulas.[11]

TABLE I

Relation of Q and R Forces to Left Ventricular Ejection Fraction (EF)

Linear Correlations (r)		
Q Amplitude With EF	R Amplitude With EF	Total Voltage With EF
Q_x 0.21	R_x 0.59*	QR_x 0.40*
Q_y 0.08	R_y 0.41*	QR_y 0.45*
Q_z 0.51*	R_z 0.46*	QR_z 0.01
$R_x + R_y + Q_z$ 0.78*; $QR_x + QR_y + QR_z$ 0.56*		

Multiple Correlations (r)
R_x, R_y, Q_z 0.80*
R_x, R_y, R_z
Q_x, Q_y, Q_z 0.82*

* ≐ $P < 0.01$.
r = correlation coefficient.

Results

Relation of R and Q amplitudes to ejection fraction: Regression analysis results showing the relation of R waves in leads X, Y, Z (Rx, Ry, Rz) and Q waves in leads X, Y and Z (Qx, Qy, Qz) to the ejection fraction are listed in Table I. A statistically significant correlation ($P < 0.01$) existed between the R waves in the X, Y and Z leads and Q wave in the Z lead. By comparison, the correlation of the Q wave amplitude with ejection fraction was not significant in the X and Y axis leads, whereas the Rz wave did correlate with ejection fraction ($r = 0.46$, $P < 0.01$). A simple arithmetic summation of the three forces Rx + Ry + Qz (ΣR) improved the correlation coefficient to 0.78. A significant correlation also existed between total voltage, that is, sum of the Q and R wave amplitudes in the X and Y leads and ejection fraction as well as the arithmetic sum of (Qx + Rx) + (Qy + Ry) + (Qz + Rz), but the latter was less impressive than ΣR.

Multivariate correlation was performed wherein the Q and R wave amplitudes of the X, Y and Z leads were considered independent variables and ejection fraction the dependent variable. The resulting correlation coefficient for Rx, Ry, Qz was 0.80, slightly above the value calculated for the arithmetic sum of these forces.

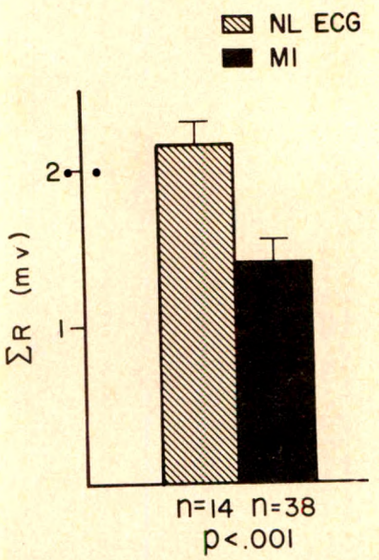

FIGURE 2. Comparison of the arithmetic sum ± standard error of Rx + Ry + Qz (ΣR) of 14 patients with a normal electrocardiogram (NL ECG) **(hatched bar)** and 38 patients with the electrocardiographic diagnosis of myocardial infarction (MI) **(solid bar).** p = probability.

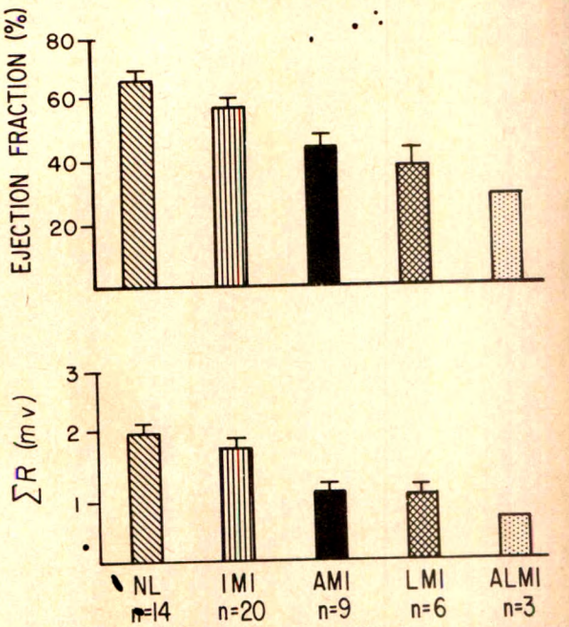

FIGURE 3. Top, ejection fraction in the 52 patients classified according to infarct location. There was a progressive decrease in mean ejection fraction from normal (NL) persons to patients with inferior (I), anterior (A), lateral (L) and anterolateral (AL) myocardial infarction (MI). **Bottom,** ΣR (Rx + Ry + Qz) shows a similar decrease within the same patient subgroups. n = number of patients.

The addition of Qx, Qy and Rz to a total of six independent variables in the multiple correlation minimally increased this correlation coefficient to 0.82.

Infarction versus normal group: The sum of the amplitudes Rx + Ry + Qz (ΣR) in millivolts (mv) was compared in a group of subjects with a normal electrocardiogram and a group with myocardial infarction (Fig. 2). The group with infarction had a significantly lower ΣR (1.46 ± 0.34 mv) than the normal group (2.13 ± 0.5 mv) (P <0.001).

Infarct location also showed an association with ejection fraction (Fig. 3, top). The patients with electrocardiographic changes of anterolateral infarction had a significantly lower ejection fraction than those with inferior myocardial infarction, who in turn had a mean ejection fraction significantly lower than that of the normal group. A similar association could be shown for ΣR and infarct location (Fig. 3, bottom). In comparison with the normal population there was a progressive decrease in ΣR as one proceeded to examine patients with inferior, anterior, lateral and combined infarcts. When ΣR within each infarct group was related to ejection fraction there was a statistically significant correlation with ΣR in all infarct groups (Table II).

Regression relation with ΣR as a predictor of ejection fraction: The 52 values for ΣR (Rx + Ry + Qz) were related to ejection fraction (Fig. 4). The resulting formula for the regression line was ejection fraction percent = 24.6 + 18.7 (Rx + Ry + Qz) (mv); r = 0.78. The use of this regression relation with ΣR as a screening test was evaluated for its capacity to predict an ejection fraction greater or less than 50 percent. Fourteen of 16 patients with an ejection fraction of less than 50 percent had an ΣR value of less than 1.2 mv, whereas 2 had an ΣR value of more than 1.2 mv. In contrast, two of 36 patients with an ejection fraction greater than 50 percent had an ΣR value of less than 1.2 mv. These values indicate a sensitivity rate of 88 percent, a specificity rate of 94 percent and an accuracy rate of 92 percent in predicting an ejection fraction above or below 50 percent.

Discussion

The ejection fraction as a measure of left ventricular pump function is generally considered an important prognostic index in coronary artery disease, whether the patients are treated medically or surgically. Whereas systolic time intervals,[12] echocardiography[13] and radionuclide left ventricular angiography have received considerable attention for their ability to predict ejection fraction,[14] little heed has been paid to the information derivable from the inexpensive readily available technique of electrocardiography.

Previous studies on correlation of electrocardiogram and ejection fraction: Both experimental work and clinical observations using epicardial and precordial

TABLE II

Relation of ΣR (Rx + Ry + Qz) With Ejection Fraction in Each Group of Patients With Infarction

Infarct Location	Cases (no.)	r	P
Inferior wall	20	0.48	<0.05
Anterior wall	9	0.82	<0.01
Lateral wall	6	0.93	<0.01

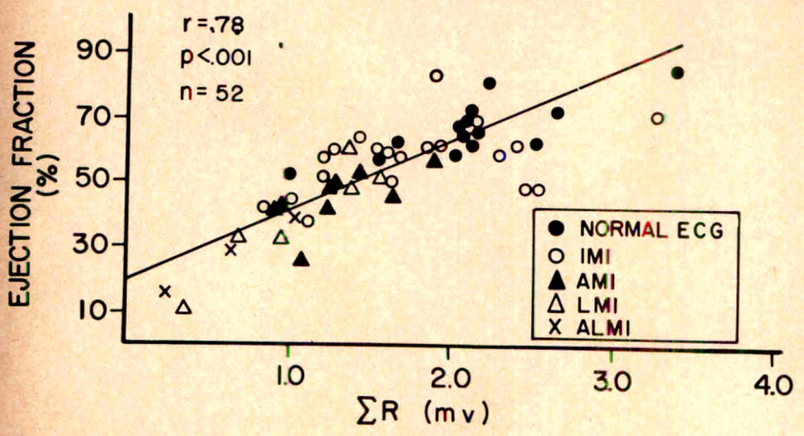

FIGURE 4. Correlation of ejection fraction with ΣR (Rx + Ry + Qz) for each patient studied. The **solid circles** represent a normal electrocardiogram (ECG); the myocardial infarcts are coded by location as indicated in the inset. p = probability; other abbreviations as in Figure 3. Formula for regression line: ejection fraction (percent) = 24.6 + 18.7 (ΣR) mv.

maps[3–5] have shown that Q waves and R waves correlate with the extent of myocardial necrosis[15,16] as assessed with histologic examination and creatine kinase enzyme studies.[17] Previously there was also documentation that the amount of muscle necrosis correlated well with the ejection fraction as a measure of left ventricular function.[18] Whereas most of the experimental studies have been performed in the acute stage of infarction, many clinical surveys[19–23] have been extended to the chronic stage, when the infarcted area has been transformed into a noncontractile segment of the left ventricular wall.

Several recent studies have indicated a relation between the standard 12 lead electrocardiogram and left ventricular function.[1–5] Usually the number of Q waves,[4] their amplitude[1,24] and duration[25] have been analyzed for a relation to left ventricular function. In a recent report, Askenazi et al.[5] showed significant correlation between the sum of unipolar R wave amplitudes in leads I, aVL and V_1 to V_6 of the 12 lead scalar electrocardiogram with ejection fraction; this relation improved when the augmented ejection fraction obtained from postextrasystolic beats was evaluated.

R wave in orthogonal leads as an index of left ventricular ejection fraction: Because much previous work has been limited to information derived from the anterior cardiac wall that is easily accessible to mapping in the open chest dog model or with use of a precordial set of 6 to 35 electrodes,[4,5] it appeared appropriate to use an orthogonal electrocardiographic system that provided an unbiased assessment of the QRS voltage in the frontal, horizontal and sagittal planes.[6–9] This approach allowed us to include patients with inferior infarction in this study. In the scalar 12 lead electrocardiogram inferior infarction cannot be evaluated in a way comparable with anterolateral infarction because leads II, III and aVF are the only three denominators for location of an inferior infarct whereas 8 leads are available to render measurements pertaining to anterolateral infarction, that is, leads I, aVL and V_1 to V_6. Our results, based on the Frank orthogonal system, indicate that the R wave is superior to the Q wave as an index of left ventricular ejection fraction in patients evaluated for chest pain. Statistical analysis indicated that the simple arithmetic summation of orthogonal amplitudes Rx + Ry + Qz was an adequate and practical index that had an important linear correlation with ejection fraction. It was improved only slightly by using much more complex and time-consuming multivariate correlations.

The determination of sensitivity, specificity and accuracy of QRS forces as a predictor of ejection fraction serves as a useful and accurate clinical tool for discriminating ejection fractions greater or less than 50 percent. With ΣR (Rx + Ry + Qz) of the orthogonal electrocardiogram alone, regardless of location of infarction or the presence of Q waves, this accuracy rate was 92 percent.

Our results were obtained in men nearly homogeneous in age. A similar study will have to be performed in women because the regression relation might be different because of inherent sexual differences in the electrocardiograms of men and women.[26]

R wave voltage in group with normal electrocardiograms: A wide range of ΣR was also observed in the subgroup of our patients with normal electrocardiographic findings. All patients in our study were evaluated for chest pain, which in most was poorly controlled with medical management. Sixty-five percent of the population with normal electrocardiographic findings proved to have significant coronary artery disease involving at least one vessel: 56 percent had two or more vessels involved. Thus, several patients in this group had an ejection fraction of less than 50 percent with a concomitantly low ΣR. This may be accounted for, in part, by infarction, which reduced R waves but was not recognized in the resting electrocardiogram even with computer technology.

R wave voltage in group with inferior myocardial infarction: The subgroup with inferior myocardial infarction showed a lower correlation coefficient with ejection fraction and a better ejection fraction than the subgroups with infarcts in anterior and lateral locations. Anatomically the right coronary artery supplies less of the left ventricular myocardial mass than does the left anterior descending coronary artery. Occlusion of the right coronary artery may lead to an infarction whose severity is more difficult to grade because less damage

is usually involved. This view is supported by the generally better prognosis of inferior than anterior infarction.[27,28]

Implications: This study independently confirms previous work of others[4,5] who have reported that changes of the QRS complex may be used as an index of left ventricular function. The use of an orthogonal lead system allowed us to expand the area of interest to the inferior wall, whereas many previous studies were restricted to the anterior surface of the heart. Our results indicate that the orthogonal ΣR value (Rx + Ry + Qz) in our patient population is a good indicator of left ventricular function, more accurate in the presence of anterior and lateral wall damage than in inferior infarction. This measurement can be viewed as a simple noninvasive aid in prescreening candidates for coronary surgery among patients with medically treated refractory angina pectoris.

Effects of Postextrasystolic Potentiation on Systolic Time Intervals

NARASIMHAN RANGANATHAN, MBBS, FRCP(C)
VAHE SIVACIYAN, BSc, MD, FRCP(C)
ROBERT CHISHOLM, MD, FRCP(C)

Toronto, Ontario, Canada

The changes in systolic time intervals associated with postextrasystolic potentiation were studied in 48 patients whose left ventricular function was categorized angiographically into four groups—normal function (I) and mild (II), moderate (III) and severe (IV) left ventricular dysfunction. Postectopic potentiation in all groups caused a decrease in preejection period/left ventricular ejection time (PEP/LVET) ratio. The greatest potentiation and decreases in PEP/LVET ratio were noted in beats where the difference in compensatory pause and coupling interval (both expressed as percent of basic cycle length [CP percent − CI percent]) exceeded 40. The decrease in the ratio was least in the normal subjects (Group I) and maximal in Group IV patients. The pattern of response of the rate-corrected left ventricular ejection time and preejection period was also different at the four levels of ventricular function. Marked shortening of ejection time with minimal shortening of preejection period occurred in Group I, but in Group IV patients there was marked shortening of preejection period and minimal shortening of ejection time. An intermediate response was seen in Group II and III patients. The amount of shortening of ejection time exceeded that of preejection period in Group II patients; the reverse was true in Group III patients. The group responses differed with a significance of $2P < 0.001$ except when Group II was compared with Group III, when the significance was $2P < 0.025$. Thus, measurement of changes in systolic time intervals associated with postextrasystolic potentiation is of value as a noninvasive means of assessing resting left ventricular function.

Interest in postextrasystolic potentiation has been recently revived, and it has been used during angiography to determine reversible areas of left ventricular dysfunction.[1–3] Measurement of systolic time intervals, an effective noninvasive means of studying ventricular function,[4] allows detection of beat to beat changes of left ventricular performance and is uniquely suited for the study of postectopic potentiation; yet such use has never been studied in detail. Only two previous studies are available, one showing changes in left ventricular ejection time with paired electrical stimulation,[5] the other performed in patients with hypertrophic obstructive cardiomyopathy.[6] In this report we describe the effect of postectopic potentiation on the systolic time intervals during diagnostic cardiac catheterization in a group of patients with different levels of left ventricular function.

Methods

Patients: Forty-eight patients undergoing diagnostic cardiac catheterization were studied before angiography. Systolic time intervals were measured from the external phonocardiogram (200 to 400 hertz), lead II of the electrocardiogram and external carotid pulse tracing with use of a multichannel pressurized-ink direct-writing recorder at a paper speed of 100 mm/sec. The carotid pulse transducer (EMT no. 29) and the recorder had a time constant of more than 2.5

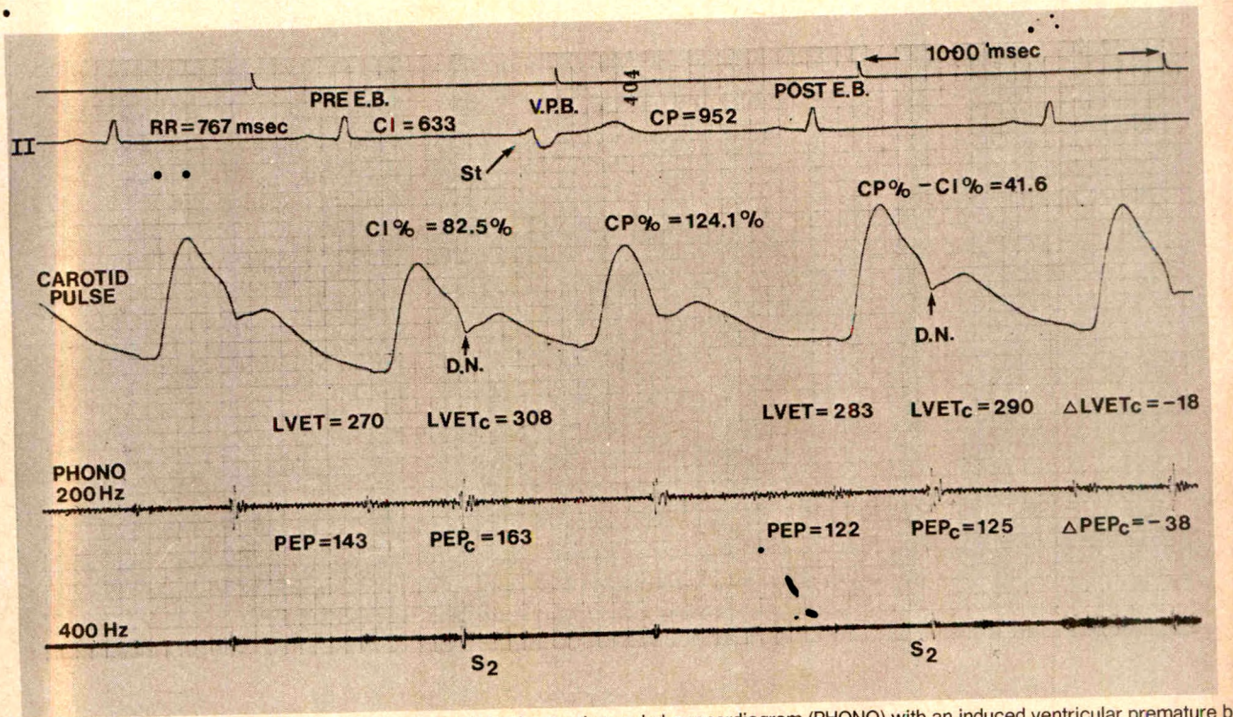

FIGURE 1. Simultaneous lead II electrocardiogram, carotid pulse tracing and phonocardiogram (PHONO) with an induced ventricular premature beat (V.P.B.). The calculated systolic time intervals for the preextrasystolic and the postextrasystolic beats (PRE and POST E.B.) are indicated in milliseconds (msec). The R-R interval (in seconds) of the cycle preceding the preextrasystolic beat is used for the rate correction of that beat. The compensatory pause (CP in seconds) is used as the R-R interval of the first postextrasystolic beat and is used for its rate correction. The coupling interval (CI) and the compensatory pause are expressed as a percent of the basic cycle length (CI% and CP%, respectively). The changes in the rate-corrected left ventricular ejection time ($LVET_c$) and rate-corrected preejection period (PEP_c) are shown as Δ values. All intervals are in msec. D.N. = dicrotic notch; LVET = uncorrected left ventricular ejection time; PEP = uncorrected preejection period; St = stimulus.

seconds. All patients had sinus rhythm. None had cardiac valve disease. Timed single premature ventricular stimulations were produced with varying coupling intervals through an electrode catheter in the right ventricle. At least 10 premature beats were produced with varying coupling intervals in each patient. Because postectopic potentiation has been shown to last for several beats, at least 0.5 minute lapsed between each induced premature beat. Systolic time interval measurements were obtained before and during the periods of induced premature beats. After premature stimulation, left ventriculograms and coronary arteriograms were obtained.

Systolic time interval measurements: Left ventricular ejection time was measured as the interval from the beginning of the upstroke of the carotid pulse to the dicrotic notch. The preejection period was obtained by subtracting the ejection time from the Q-S_2 interval (onset of the QRS complex to the first high frequency component of the second heart sound). The resting measurements were obtained by averaging the data from 10 sinus beats. Systolic time intervals of the sinus beat immediately preceding each premature complex as well as the first four postectopic beats were calculated with the aid of a Numonics digitizer in conjunction with a PDP 11 computer.

The measured intervals were corrected for rate by dividing the observed value by the square root of the preceding cycle length (in seconds).[7] The compensatory pause preceding the first postextrasystolic beat was used as the cycle length for its rate correction. The more popular regression equations obtained from normal subjects for rate correction were not used because these are derived from observations made under resting conditions for heart rates of 50 to 110 beats/min.[8] The compensatory pause representing cycle lengths equivalent to unphysiologically slow heart rates makes the applicability of the normal regression equation doubtful. *All intervals mentioned under Results and Discussion refer to these rate-corrected values.* The changes in the systolic time intervals between the pre- and the postectopic beats were calculated.

The coupling interval and the compensatory pause were expressed as a percent of the preextrasystolic sinus R-R interval (CI percent and CP percent, respectively). It has been known that the more premature the extrasystole and the longer the compensatory pause, the greater is the potentiation.[9] Therefore, the combined effects of the two variables are best expressed when the change is related to the difference between the two variables (CP percent − CI percent). Thus a large difference will indicate a long compensatory pause and a short coupling interval, whereas a small difference will indicate an inadequate compensatory pause and a late coupling interval. Figure 1 shows a sample tracing with calculation of CP percent − CI percent values and changes in rate-corrected individual systolic time intervals.

Left ventricular function (angiography): Left ventriculograms taken in the right anterior oblique projection were used to calculate ejection fraction and percent axis shortening. The recording of electrocardiographic rhythm strips during angiography with markers to indicate the onset and end of each injection facilitated analysis of the ventriculograms. For these quantitative measurements only sinus beats that did not occur immediately after an extrasystole were analyzed. Ejection fraction and percent axis shortening were measured,

as described previously.[10] The normal values for percent axis shortening in our laboratory were similar to those described by others[11] (Fig. 2).

The angiographic criteria for the classification of left ventricular function used in this study are shown in Table I. The 48 patients were separated into four groups: Group I (16 patients), normal left ventricular function; Group II (17 patients), mild dysfunction; Group III (11 patients), moderate dysfunction and Group IV (4 patients), severe dysfunction. The clinical and hemodynamic data of the four patient groups

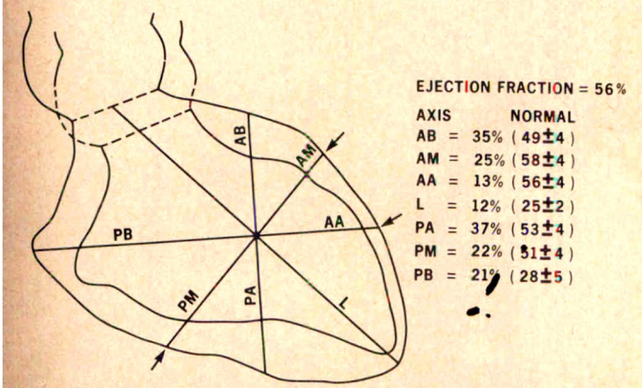

FIGURE 2. Outlines of systolic and diastolic frames of the left ventriculogram in the right anterior oblique projection taken from a patient with mild ventricular dysfunction (Group II) showing a nearly normal ejection fraction with major abnormality in shortening of axes indicated by **arrows.** AA = anteroapical; AB = anterobasal; AM = anteromedial; L = longitudinal; PA = posteroapical; PB = posterobasal; PM = posteromedial.

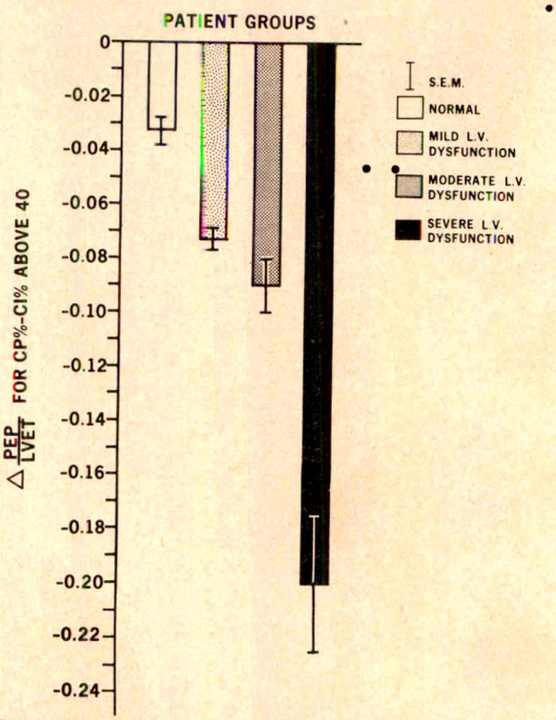

FIGURE 4. Mean change in preejection period/left ventricular ejection time ratio (ΔPEP/LVET) from beats in which the CP% − CI% value exceeded 40 between the resting and the postextrasystolic beat in the four left ventricular (L.V.) function groups. The greater the resting dysfunction, the greater is the potentiation, as shown by the decrease in PEP/LVET ratio. S.E.M. = standard error of the mean.

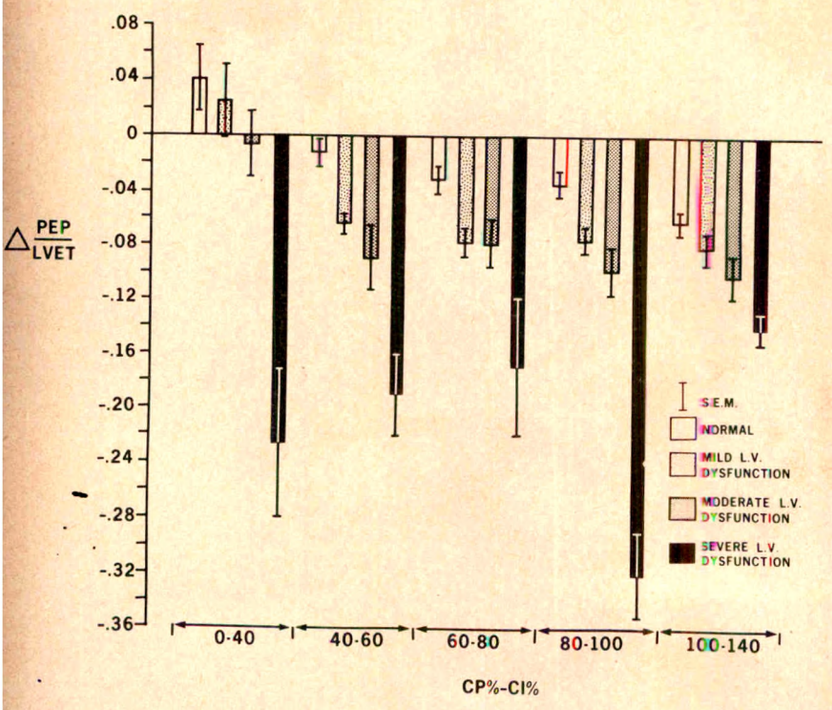

FIGURE 3. Change in preejection period/left ventricular ejection time ratio (ΔPEP/LVET) between the resting and the postectopic beats related to the difference between the compensatory pause and the coupling interval, both expressed as a percent of the basic cycle length (CP% − CI%). A significant decrease in the PEP/LVET ratio is noted in beats where the CP% − CI% value exceeded 40. Beats with a CP% − CI% value less than 40 showed an increase in this ratio in two of the four groups, indicating lack of potentiation. L.V. = left ventricular; S.E.M. = standard error of the mean.

are shown in Table II. A total of 420 observations were made. The induced ventricular premature beats had comparable degrees of prematurity in all four groups of patients. The postectopic changes in systolic time intervals for each group represent the mean of all the observations from that group. The mean postectopic changes in the systolic time intervals were then related to the resting left ventricular function.

Results

Analysis of the First Postextrasystolic Beat

Change in PEP/LVET ratio (ΔPEP/LVET) as related to the compensatory pause and the coupling interval: The change in preejection period/left ventricular ejection time (PEP/LVET) ratio was related to different ranges of difference between compensatory pause and coupling interval, both expressed as percent of the basic cycle length (CP percent − CI percent) (Fig. 3). In all patients potentiation was seen as a decrease in this ratio for all ranges of CP percent − CI percent values greater than 40, indicating adequately long compensatory pauses and relatively short coupling intervals. However, for beats with a CP percent − CI percent value less than 40, this ratio increased in Groups I and II, indicating a probable lack of potentiation in the first postextrasystolic beat. These beats (CP percent − CI percent less than 40) were therefore eliminated from the rest of the study.

Mean change in PEP/LVET ratio (ΔPEP/LVET): The mean change in PEP/LVET ratio from all beats with ranges of CP percent − CI percent values greater than 40 is shown for each patient group in Figure 4 and Table III. In all four groups potentiation is evident

TABLE I

Patient Classification According to Left Ventricular (LV) Function as Assessed With Angiography

Group	Angiographic Classification
I	Normal LV function; EF >60%; normal axis shortening
II	Mild LV dysfunction; EF = 50 to 60% and/or at least two major abnormalities* in axis shortening
III	Moderate LV dysfunction; EF = 30 to 50%
IV	Severe LV dysfunction; EF <30%

* Major abnormality in axis shortening means shortening less than 50 percent of normal.
EF = ejection fraction; LV = left ventricular.

Postextrasystolic Changes in Systolic Time Intervals in Different Left Ventricular (LV) Function Groups for CP% − CI% Values Greater Than 40 (mean ± standard error of the mean)

	Group I	Group II	Group III	Group IV
ΔPEP/LVET	−0.033 ± 0.005	−0.073 ± 0.004	−0.090 ± 0.010	−0.202 ± 0.026
$\Delta LVET_c$ (msec)	−59.5 ± 2.0	−43.0 ± 1.6	−38.0 ± 2.0	−14.0 ± 4.5
ΔPEP_c (msec)	−31.2 ± 1.3	−36.4 ± 1.1	−41.0 ± 3.0	−60.0 ± 4.3
$\Delta LVET_c - \Delta PEP_c$	−29.1 ± 2.3	−6.7 ± 2.1	3.0 ± 4.0	47.0 ± 6.4

CI% = coupling interval and CP% = compensatory pause both expressed as percent of R-R interval of the preextrasystolic sinus cycle; $\Delta LVET_c$ = change in the rate-corrected left ventricular ejection time; ΔPEP_c = change in the rate-corrected preejection period.

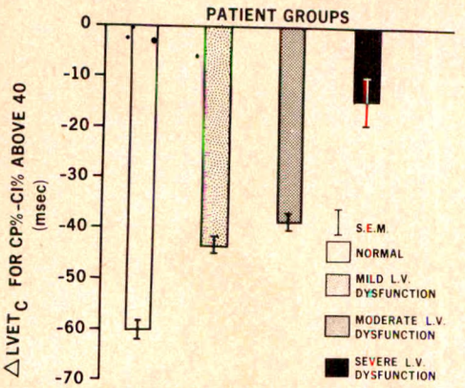

FIGURE 5. The mean change in corrected left ventricular ejection time ($\Delta LVET_c$) between the resting and the postextrasystolic beats where the CP% − CI% value exceeded 40 is shown for different left ventricular (L.V.) function groups. Marked shortening in $LVET_c$ was noted in patients with normal function, with a stepwise decrease in $LVET_c$ shortening with increasing ventricular dysfunction. S.E.M. = standard error of the mean.

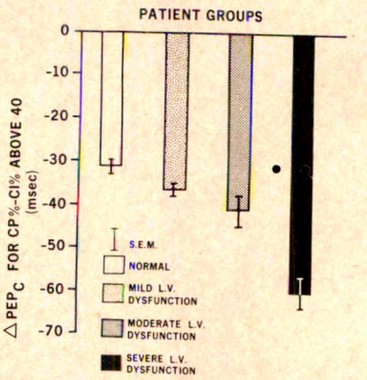

FIGURE 6. Mean change in corrected preejection period (ΔPEP_c) between the resting and the postextrasystolic beats where the CP% − CI% value exceeded 40 is shown for the four left ventricular (L.V.) function groups. The shortening of PEP_c is maximal in patients with severe dysfunction and least in patients with normal ventricular function.

as a decrease in this ratio, the maximal decrease occurring in Group IV (severe dysfunction). There is a progressive increase in the amount of potentiation as the ventricular function decreases. Minimal change in this ratio was observed in Group I patients (normal ventricular function).

Change in rate-corrected Q-S_2 interval: Although total electromechanical systole shortened in all four groups, the mean change differed little among groups.

Change in rate-corrected left ventricular ejection time (Fig. 5, Table III): The ejection time shortened in the postectopic beat in all four patient groups. Shortening was maximal (−59.5 ± 2.0 msec [mean ± standard error of the mean]) in Group I patients (normal function) and least (−14 ± 4.5 msec) in Group IV patients (severe dysfunction). In fact, one patient in this group who had an ejection fraction of 14 percent had prolongation of ejection time. In Group II and III patients (mild and moderate dysfunction, respectively) the shortening was moderate and slightly greater in Group II than in Group III.

Change in rate-corrected preejection period (Fig. 6, Table III): In contrast to the changes in ejection time, maximal shortening of preejection period occurred in Group IV patients (−60 ± 4.2 msec). A progressive decrease in shortening was noted with increasing ventricular function. Thus, the least shortening (−31 ± 1.3 msec) was seen in Group I patients (normal function).

Relation of the change in rate-corrected ejection time to the change in the rate-corrected preejection period in different functional groups: The mean change in ejection time and preejection period for different CP percent − CI percent ranges in all four groups of patients is plotted in Figure 7. The algebraic difference between the two ($\Delta LVET_c - \Delta PEP_c$ in Fig. 7), which is also plotted, further depicts this relation. Different ranges of CP percent − CI percent values indicate varying combinations of compensatory pauses and coupling intervals, the lower ranges (40 to 60) being less ideal for potentiation than the high ranges (100 or more).

In Group I the shortening of ejection time was approximately twice the amount of shortening of the preejection period. The algebraic difference between the two ($\Delta LVET_c - \Delta PEP_c$, Fig. 7) was in the negative range, indicating a greater change in the ejection time than in the preejection period. In Group II patients (mild dysfunction) changes in ejection time and preejection period were equal for low CP percent − CI percent ranges. For higher ranges, the two curves diverged, the shortening of ejection time being greater than that of the preejection period.

In Group III (moderate dysfunction) the first reversal was seen: The algebraic difference ($\Delta LVET_c - \Delta PEP_c$, Fig. 7) became positive for lower ranges of CP percent − CI percent values (40 to 60); that is, the change in preejection period was greater than the change in ejection time. In the mid ranges (60 to 100) the two intervals shortened by relatively the same amount, whereas in the higher ranges, the change in ejection time exceeded the change in preejection period. The patients in Group IV (severe dysfunction) showed a reversal of relation between changes in ejection time and preejection period in all CP percent − CI percent ranges, thus demonstrating a very positive value for the $\Delta LVET_c - \Delta PEP_c$ difference.

The relative changes in ejection time and preejection period were also evident in the *mean* difference between the two intervals in each of the four groups (Fig. 8, Table III). In Group I and II patients, the difference was in the negative range because the change in ejection time exceeded the change in preejection period, whereas in Groups III and IV, this difference was positive. The gradations of negativity and positivity reflected the resting ventricular function.

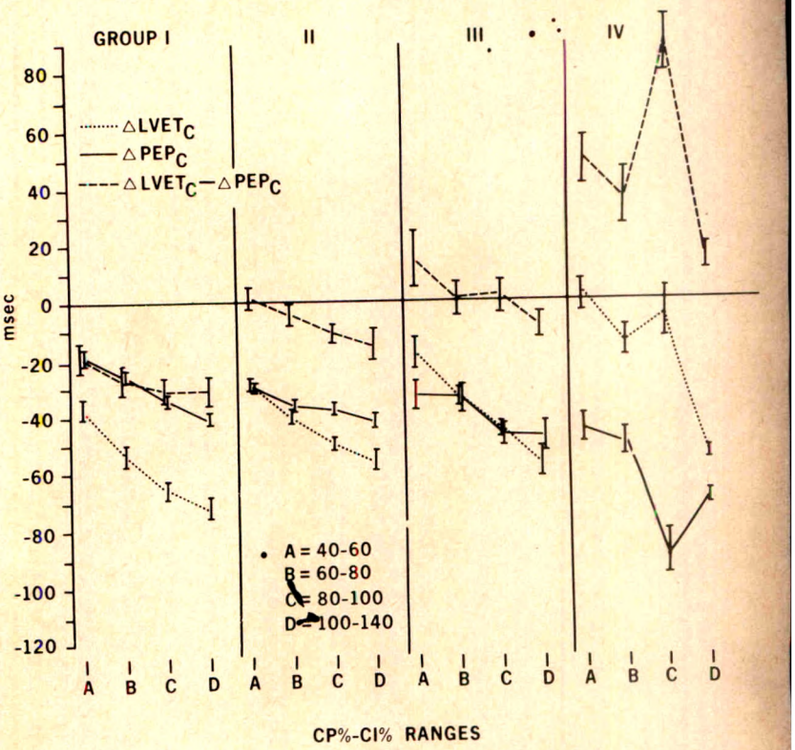

FIGURE 7. The mean change in corrected left ventricular ejection time ($\Delta LVET_c$) and corrected preejection period (ΔPEP_c) as well as the algebraic difference between the two ($\Delta LVET_c - \Delta PEP_c$) for each ventricular function group for different ranges of CP% — CI% (A,B,C,D). See text.

Comparison of the mean change in systolic time intervals among different grades of ventricular function: The results were analyzed applying an analysis of variance to each of the four variables (Table III). The variance ratios were large and clearly different among groups. The true significance level was considerably lower than the value 0.001. Because the four groups were selected a priori, we considered it legitimate to compare Group II with Group III and values in Groups I and IV with the mean values in Groups II and III. It was found that Groups II and III differed significantly only in the algebraic difference between the change in ejection time and the change in preejection period ($\Delta LVET_c - \Delta PEP_c$, Table IV). Groups I and IV differed (in opposite directions) very markedly from Groups II and III. In fact, the differences were so great that they would be highly significant even if the comparisons had been made between groups selected "a posteriori."

Comparison of resting systolic time intervals and postectopic responses in individual patients: Two patients in Group I had an abnormal resting PEP/LVET ratio (greater than 0.42). Furthermore, 21 patients in Groups II and III with mild or moderate left ventricular dysfunction had a resting PEP/LVET ratio in the normal range (13 in Group II and 8 in Group III). Thus, 23 of the total of 48 patients (48 percent) had a resting PEP/LVET ratio inconsistent with the level of ventricular function as assessed with angiography. In contrast, when postectopic responses of individual patients were related to the mean of the group to which they belonged, only 12 of 48 patients (25 percent) formed exceptions, and in all cases these were due to

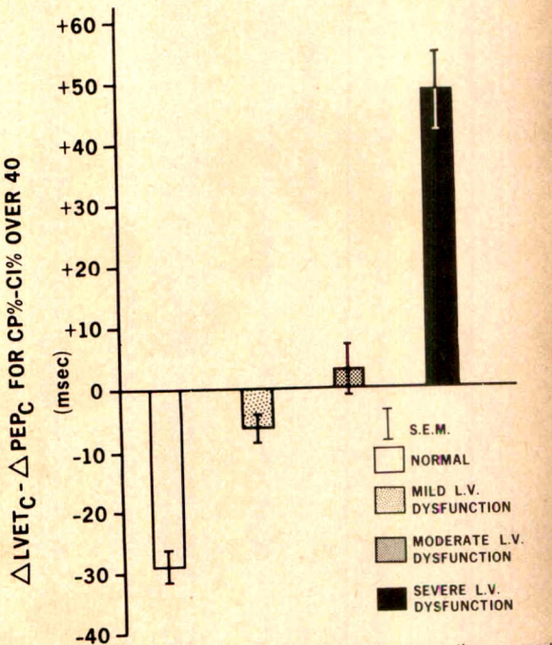

FIGURE 8. Mean of the algebraic difference between the corrected ejection time and corrected preejection period ($\Delta LVET_c - \Delta PEP_c$) observed in different left ventricular (L.V.) function groups from beats with a CP% — CI% value exceeding 40. Marked shortening in $LVET_c$ and little shortening of PEP_c in patients with normal function is reflected in the very negative values (−29 msec) whereas the opposite changes in $LVET_c$ and PEP_c in patients with severe dysfunction result in high positive values (47 msec). The mean difference is negative in patients with mild dysfunction but positive in those with moderate dysfunction although the absolute values are small. S.E.M. = standard error of the mean.

TABLE IV

Statistical Analysis of the Difference Between Mean Changes in Systolic Time Intervals in Table III

	Group I vs II (2P)	Group I vs 1/2 (II + III) (2P)	Group I vs IV (2P)	Group II vs III (2P)	Group 1/2 (II + III) vs IV (2P)	Group III vs IV (2P)

$\Delta LVET_c$	<0.001	<0.001	<0.001	NS	<0.001	<0.001
ΔPEP_c	<0.005	<0.001	<0.001	NS	<0.001	<0.001
$\Delta LVET_c - \Delta PEP_c$	<0.001	<0.001	<0.001	<0.025	<0.001	<0.001

$\Delta LVET_c$ = change in the rate-corrected left ventricular ejection time; NS = not significant; *P* = probability; ΔPEP_c = change in the rate-corrected preejection period.

variability inherent in biologic data. Two of 16 patients in Group I had a response similar to that of Group II. Of 17 Group II patients, 2 had a Group I response and 5 had a Group III response. Of 11 Group III patients, 2 had a Group II response while 1 had a Group IV response.

Analysis of the Second, Third and Fourth Postectopic Beats

The second, third and fourth postectopic beats demonstrated relative lack of potentiation as measured with systolic time intervals. In fact, in Group IV patients an alternans effect was demonstrated, with depression of left ventricular function in the second postectopic beat as shown by a significant increase in the PEP/LVET ratio (mean ΔPEP/LVET = +0.08). This returned to preectopic beat level by the fourth beat. This depression was noted to a lesser degree in Group III patients (mean ΔPEP/LVET = +0.03). By contrast, systolic time intervals in Group I and II patients returned to preectopic levels by the second beat (Table V). These observations relative to PEP/LVET ratio were also seen in the individual systolic time intervals.

Discussion

That the beat following an extrasystole shows greater than normal force of contraction has long been known.[9,12–19] The phenomenon was first described by Langendorff,[12,13] who called it "postextrasystolic compensation" because the increased force of the postectopic beat was thought to compensate for the weakness of the premature beat. Although many years later Hoffman et al.[17] renamed it "postextrasystolic potentiation," some of the crucial work with regard to the basic properties of the phenomenon were carried out around the turn of the century in isolated heart muscle preparations.[9,12–16,18,19] Woodworth[9] in particular demonstrated clearly the strength of the postectopic beat to be "closely dependent on the earliness of the extra contraction and somewhat loosely dependent on the length of the pause" and observed that the "actual stimulating effect persists on the average for about eight subsequent beats." Working with isolated perfused apical muscle preparations, he showed the potentiation to be independent of both filling and neurogenic influences. The studies of Hoffman et al.[17] and others[20–23] confirmed and extended these observations to ventricles contracting isovolumically. Although subsequently the phenomenon has been investigated by many workers,[1–3,5,6,24–29] examination of its effects on systolic time intervals has been somewhat neglected. Braunwald et al.[5] did demonstrate the shortening of ejection time to accompany potentiation in nine patients studied with paired electrical stimulation. Our study examines for the first time the effects of postectopic potentiation on all aspects of the systolic time intervals, as well as relating the findings to ventricular function as assessed with angiography.

Our observations confirm the previously known facts that postectopic potentiation is inversely related to the coupling interval and is dependent on the presence of an adequate compensatory pause that should be in excess of the basic R-R interval. Because the potentiation is best studied by combining the independent effects of the two variables, we expressed both the compensatory pause (CP) and the coupling interval (CI) as a percent of the basic R-R interval and calculated the difference. The larger the difference between CP percent and CI

TABLE V

Change in PEP/LVET Ratio Between the Preectopic Sinus Beat and the First Four Postextrasystolic Beats in the Four Patient Groups (mean ± standard error of the mean)

Group	Postextrasystolic Beats 1st	2nd	3rd	4th
I	−0.03 ± 0.01	0.02 ± 0.01	0.00 ± 0.01	0.00 ± 0.01
II	−0.07 ± 0.01	0.02 ± 0.01	0.00 ± 0.01	0.02± 0.01
III	−0.09 ± 0.01	0.03 ± 0.01	0.01 ± 0.01	0.06 ± 0.03
IV	−0.20 ± 0.03	0.08 ± 0.02	−0.02 ± 0.02	0.04 ± 0.02

percent, the shorter will be the coupling interval, the longer the compensatory pause and the greater the potentiation. Using this observation to help eliminate beats with inadequate compensatory pause, we found that beats with CP percent − CI percent ranges greater than 40 adequately demonstrated potentiation (Fig. 3).

Postectopic potentiation correlated with level of ventricular function: Postectopic potentiation was evident in all patients, as shown by a decrease in the resting preejection period/left ventricular ejection time (PEP/LVET) ratio. However, the amount of decrease was maximal in patients with severe ventricular dysfunction and minimal in those with normal ventricular function. These data are in agreement with previously noted observations that potentiation is most impressive when myocardial performance is severely compromised.[26]

Although there was a progressive increment in the decrease of PEP/LVET ratio from normal function to severe dysfunction, the pattern of response of the rate-corrected components of systolic time interval (ejection time and preejection period) was different at different levels of ventricular function (Fig. 5 and 6, Table III). In patients with normal left ventricular function marked shortening of ejection time occurred with only minimal shortening in preejection period. The order of shortening of ejection time was similar to that described by Braunwald et al.[5] Patients with severe ventricular dysfunction, on the other hand, had significant shortening of preejection period with very little shortening in ejection time. The responses in patients with mild and moderate left ventricular dysfunction were intermediate. With mild dysfunction the change in ejection time exceeded that of the preejection period, whereas with moderate dysfunction the change in the preejection period exceeded the change in ejection time. The relation of the two variables is best expressed by their algebraic difference ($\Delta LVET_c - \Delta PEP_c$) (Fig. 8, Table III). This difference was very negative in patients with normal ventricular function and very positive in those with severe dysfunction. It was mildly negative and mildly positive, respectively, in patients with mild and moderate dysfunction. Thus, the pattern of response in the first postextrasystolic beat seems to be related to the degree of resting left ventricular function. These changes in the systolic time intervals are not artificially induced by the rate correction method, because a similar relation is also seen with changes in PEP/LVET ratio, which are not influenced by rate correction.

Statistical analysis of the mean changes in the systolic time intervals showed a highly significant separation among the different groups, except between those with mild and moderate left ventricular dysfunction. However, latter two groups could be separated by using the algebraic difference ($\Delta LVET_c - \Delta PEP_c$) (Table IV). Thus, the systolic time interval responses of the first postextrasystolic beat appear to be of value in determining resting left ventricular function even when resting systolic time intervals do not reflect the true ventricular function. In fact, 13 patients with mild and 8 patients with moderate left ventricular dysfunction had normal resting intervals although their functional abnormality was demonstrated angiographically as well as with the effects of postectopic potentiation.

The systolic time interval changes of postectopic potentiation do not appear to be significant for second, third and fourth postectopic beats. In fact, the second postectopic beat showed depression of ventricular function in Group IV patients (severe dysfunction) (Table V). The second postectopic beat has been used as a control sinus beat in some angiographic studies of postectopic potentiation.[1] Our observations suggest that this beat may not be representative of the resting left ventricular function in patients with moderate to severe ventricular dysfunction.

Mechanisms of postextrasystolic potentiation effects on systolic time intervals: The mechanism underlying the changes in the systolic time intervals needs to be defined clearly although previous observations help to explain the findings.[5,24,26,27,29] The marked shortening in ejection time noted by Braunwald et al.[5] was related to an increased mean systolic ejection rate, and the potentiation was accompanied by an increase in the rate of rise of intraventricular pressure (dP/dt). Although Beck et al.,[29] in their studies on postextrasystolic ventricular pressure responses in patients with heart failure, demonstrated only a modest rise in dP/dt accompanied by a significant increase in end-diastolic pressure, others[24,27] have shown a marked rise. In all our patients there was shortening of the preejection period reflecting the increased contractility accompanying potentiation. An increase in the velocity of ejection in the postectopic beat will tend to shorten the ejection time whereas an increase in stroke volume due to the compensatory pause will tend to lengthen it. The net effect on the ejection time will depend on which factor dominates. In patients with normal ventricular function, the effect of an increased rate of ejection may overcome the opposing effect of increased stroke volume thereby causing a marked shortening of ejection time. On the other hand, patients with severe left ventricular dysfunction are unable to shorten the ejection time significantly, despite the striking potentiation as evidenced by the marked shortening of the preejection period. In these patients, the increment in stroke volume may be larger because of their large resting end-diastolic volume. Although the rate of ejection may also be increased, it may not overcome the effect of the increased stroke volume, thus resulting in a net effect of only minimal shortening of the ejection time.

Clinical applications of findings: (1) Postectopic potentiation broadens the use of systolic time intervals as a noninvasive means of assessing left ventricular function in patients with spontaneous ventricular premature beats. Furthermore, effective and safe means of mechanically stimulating the heart externally have been recently developed and can be used to produce premature beats.[30] Thus in the future it may be possible to assess ventricular function noninvasively using postectopic potentiation.

UNIVERSITY OF LOUISVILLE SCHOOL OF MEDICINE LIBRARY

(2) In patients undergoing cardiac catheterization, ventricular premature beats can be induced electrically or mechanically, thus providing an additional means of assessing ventricular function.

(3) Because postectopic potentiation is a form of positive inotropism, the effects of other inotropic agents, such as digitalis and sympathomimetic drugs, on systolic time intervals may have a similar application. Thus, such agents might be used not only to assess drug response but also to assess resting ventricular function.

(4) In left bundle branch block, in which the preejection period as well as the PEP/LVET ratio are of little use, this method, which measures the change in systolic time intervals between the pre- and postectopic beats, may be of value because an abnormal sequence of excitation is present in both, thus canceling out its effects. In fact, preliminary observations in 10 patients (5 studied with angiography) suggest this to be true.

(5) For similar reasons the method could be of value in patients with sympathetic overactivity, which tends to normalize resting systolic time intervals and mask changes of left ventricular dysfunction. Patients with acute myocardial infarction, who very commonly have ventricular premature beats,[31] would be one example.

(6) If the improvement in angiographic ejection fraction in the postextrasystolic beat is an indicator of reversibility of left ventricular dysfunction,[1–3] it is logical to assume that such improvement may have a bearing on "postectopic changes in systolic time intervals." However, this correlation remains to be proved.

The U Wave and Aberrant Intraventricular Conduction

Further Evidence for the Purkinje Repolarization Theory on Genesis of the U Wave

YOSHIO WATANABE, MD, FACC
HITOSHI TODA, MD

Toyoake, Japan

The Purkinje system repolarization theory on the genesis of the U wave was tested by correlating the incidence of aberrancy of atrial premature systoles with the timing of the U wave and other measurements in 126 electrocardiograms selected from 6,000 records. Coupling (R_s-R_p) intervals were measured from the onset of the QRS complex of a sinus (s) beat to that of the premature (p) beat, and 149 different R_s-R_p intervals were studied. Criteria used for diagnosing aberrancy were significant changes in the QRS amplitude and significant alterations in the QRS contour. The incidence of aberrancy was plotted against (1) the R_s-R_p interval; (2) the ratio between the R_s-R_p and R_s-R_s intervals (the basic cycle length); (3) the ratio between P_s-P_p (the interval from a sinus P wave to a premature P wave) and P_s-P_s (the sinus cycle length); (4) the interval from the end of the preceding T wave to the premature QRS complex (T-R_p interval); (5) the interval from the apex of the U wave of the sinus beat to the premature QRS complex (aU-R_p); and (6) the interval from the end of the preceding U wave to the premature QRS complex (eU-R_p). As expected, a decrease in either of these values tended to increase the incidence of aberrancy. However, smooth S-shaped curves were noted with aU-R_p and eU-R_p intervals only. The correlation was much poorer with the other four measurements. Aberrancy with a typical right or left bundle branch block pattern was observed only when the premature QRS complex occurred before the apex of the U wave, the left bundle branch block pattern occurring with greater prematurity. It is concluded that the U wave most likely represents phase 3 repolarization of the Purkinje system, and propagation of supraventricular impulses during this period is the cause of aberrant ventricular conduction.

The term aberrant intraventricular conduction is applied when a supraventricular impulse (an impulse originating above the so-called bifurcation of the His bundle) is accompanied by an abnormal spread of ventricular excitation compared with the excitation pattern during the basic rhythm (usually sinus rhythm, but there may be other mechanisms including atrial fibrillation).[1] This condition most commonly results from a sudden shortening of the cardiac cycle[1–3] although prolongation of cycle length and several other factors may also cause such QRS alterations.[4–6] On the basis of various electrophysiologic studies, it is now widely believed that aberrant conduction of supraventricular premature systoles is caused by the arrival of those early impulses in the His-Purkinje system before this system completely recovers its excitability from a preceding depolarization.[7–9] In terms of transmembrane potentials, encroachment of phase 3 repolarization of Purkinje fibers with resultant conduction delay or block in certain fascicles or their ramifications would produce an abnormal QRS contour.

On the other hand, the U wave is the only electrocardiographic wave form whose genesis remains controversial.[10] However, several clinical

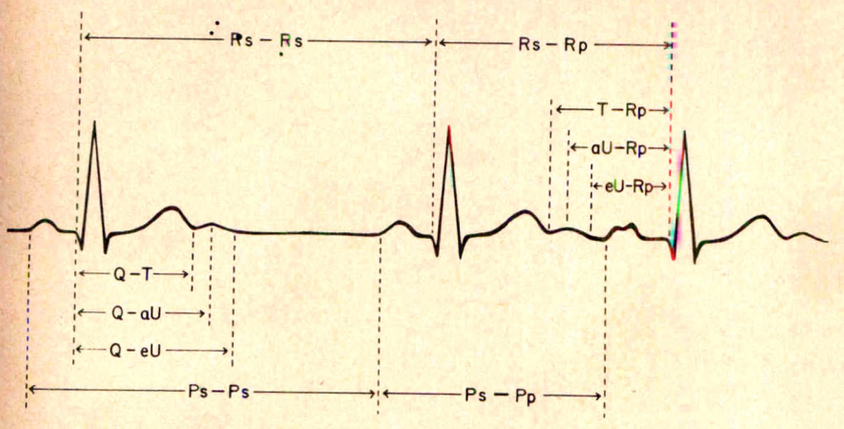

FIGURE 1. Diagram explaining the methods of measuring various time intervals.

and experimental observations led us to suggest that the U wave probably represents phase 3 repolarization of the Purkinje system.[11–13] If this hypothesis is correct, the occurrence of aberrantly conducted supraventricular premature beats should depend on their time of appearance with respect to the U wave. The present electrocardiographic study was designed to test this assumption.

It is possible to differentiate atrioventricular (A-V) junctional premature systoles from their atrial counterparts in a majority of instances by studying the P wave contour and the P-R interval as long as their QRS complex is identical to that of the sinus beats with a normal QRS duration. Once intraventricular conduction becomes aberrant, A-V junctional origin of these premature beats (or escape beats) can no longer be identified with certainty from clinical electrocardiograms alone because impulse formation in the proximal portion of a bundle branch or a fascicle immediately below the bifurcation of the His bundle could show similar QRS deformities.[14] Hence, in this study, only atrial premature systoles were used and their aberrancy was correlated with various time intervals with reference to their preceding beats.

Material and Methods

Six thousand consecutive electrocardiograms recorded in the Heart Station of the Fujita Gakuen University Hospital were reviewed for the presence of atrial premature systoles, and 126 tracings showing this arrhythmia were selected for the study. Each record consisted of four sets of three simultaneous leads (I, II, III; aVR, aVL, aVF; V_1, V_2, V_3; and V_4, V_5, V_6). The following intervals were measured to the nearest 0.01 second: (1) the basic sinus cycle length, (2) the coupling interval, and (3) the Q-T, Q-aU and Q-eU intervals of the sinus beats (Fig. 1).

The basic sinus cycle length was determined between the onset of two consecutive QRS complexes of sinus origin (R_s-R_s interval), which equals the interval between two sinus P waves (P_s-P_s interval). When there was sinus arrhythmia, the basic cycle length was measured as the mean R_s-R_s interval, usually in the particular lead set or sets where the premature systoles were observed.

The coupling interval was measured between the onset of the QRS complex of a sinus beat and that of the following premature beat (R_s-R_p interval). In the presence of several premature systoles in a given record, the coupling intervals of all the ectopic beats were determined. When variations in their coupling intervals were less than 0.04 second, only one representative premature systole was chosen, whereas individual premature beats were subjected to analysis if such variations exceeded this range. Thus, a total of 149 atrial premature systoles were studied to calculate percent incidence of aberrancy as related to various measurements.

The Q-T, Q-aU and Q-eU intervals were defined as the intervals from the beginning of the QRS complex to the end of the T wave, to the apex of the U wave (aU) and to the end of the U wave (eU), respectively. These three intervals were usually measured in precordial leads, especially in the leads showing the most prominent U waves, unless there was a significant difference in heart rate between the leads having premature systoles and those precordial leads. The Q-eU intervals were not obtained in 10 instances in which the terminal portion of the U wave was obscured by superimposition of the following P wave, usually in the presence of relatively rapid sinus mechanisms.

From these measurements, the following values were calculated: (1) the ratio between the coupling interval (R_s-R_p interval) and the basic sinus cycle (R_s-R_s interval), (2) the T-R_p interval (interval between the end of the T wave of the preceding sinus beat and the beginning of a premature QRS complex), and (3) the aU-R_p and eU-R_p intervals as measured from the apex and the end of the U wave, respectively, to the onset of a premature QRS complex (Fig. 1).

The presence of aberrant intraventricular conduction was diagnosed in the following manner: Classically, the term aberrant conduction implies significant alterations in the QRS configuration. Here, significant alterations can be defined as one of the following three changes: (1) appearance of a new deflection (Q, R or S) not present in sinus beats, (2) disappearance of a preexistent Q, R or S deflection, or (3) changes in the QRS pattern, for example, from an rS to an RS pattern, even when the QRS duration was not prolonged. One extreme of such changes in contour is the development of a typical right (or left) bundle branch block pattern with QRS widening.

In addition to these "contour criteria," we adopted the following "amplitude criteria" of aberrancy: Because beat to beat variations in the QRS amplitude of sinus beats were often noted, we first determined the maximal variation in their total QRS amplitude (ΔQRS) in leads showing atrial premature systoles. When the amplitude of a given premature QRS either exceeded that of the largest QRS complex of sinus origin or was smaller than the smallest sinus QRS complex by a

difference greater than ΔQRS, aberrancy in terms of amplitude changes was identified. In the absence of beat to beat QRS variation, a difference of 0.2 mv or greater was arbitrarily chosen to indicate amplitude aberrancy. These two criteria for contour and amplitude aberrancy were not mutually exclusive.

Results

Incidence of aberrant intraventricular conduction: Of the 149 atrial premature systoles studied, 71 were considered to have aberrant intraventricular conduction in terms of the amplitude criteria, whereas 45 showed aberrancy in terms of contour criteria. There were 34 premature beats that satisfied both of these criteria, whereas 67 premature systoles did not show any aberrancy.

The electrocardiogram reproduced in Figure 2 illustrates various degrees of aberrancy. Here, precordial leads V_2, V_4, V_5 and V_6 are shown, of which the latter three were recorded simultaneously. In lead V_2, two atrial premature systoles are noted (beats 4 and 8). Their atrial origin is readily noted from the presence of an early P wave preceding those QRS complexes at a P-R interval of approximately 0.16 second. Their coupling (R_s-R_p) intervals both measure 0.56 second, whereas the Q-aU and Q-eU intervals are 0.50 and 0.60 second, respectively, from beats 2 and 6, which terminate the basic sinus cycle. Thus, these premature QRS complexes occurred 0.06 second after the apex of the U wave and 0.04 second before its end. Their QRS configuration is almost identical to that of the sinus beats, showing an RS pattern. The maximal beat to beat variation in the QRS amplitude of sinus beats in this lead amounts to only 0.5 mm (0.05 mv), whereas these two premature QRS complexes are greater than the largest sinus QRS complex by more than 4 mm (0.4 mv). It is thus evident that the amplitude criteria for aberrancy are satisfied, but there is no aberrancy of contour.

On the other hand, there are four atrial premature systoles in leads V_4 through V_6 (beats 2, 5, 8 and 11) with variable coupling intervals. The 2nd and the 11th (last) beats have the same R_s-R_p interval of 0.48 second (and an aU-R_p interval of −0.02 second) and show a significant change in QRS amplitude (see especially lead V_6). In addition, a closer examination of their contour reveals disappearance of the small embryonic Q wave seen in the sinus beats in these leads. Hence, these premature beats also satisfy the contour criteria for aberrant conduction. Beat 5 occurring with a shorter coupling interval of 0.42 second shows a more obvious contour change, with the development of a deep and wide S wave and QRS prolongation suggesting a conduction delay in the right bundle branch system. In contrast, beat 8 has the longest R_s-R_p interval of

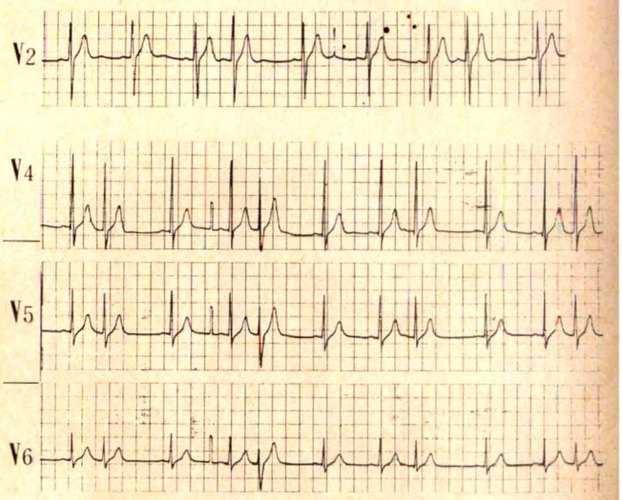

FIGURE 2. Identification of aberrant intraventricular conduction based on contour and amplitude criteria. Detailed discussion in text.

0.54 second but still occurs before the end of the U wave. Although this beat does not show any contour aberrancy, minimal amplitude aberrancy is present.

The validity of the criteria for aberrancy based on alterations in the QRS amplitude, arbitrarily set by us in this study, is supported by the electrocardiogram reproduced in Figure 3, which was obtained from a case not included in our series. In lead V_3 of this record, the presence of right bundle branch block is evident from the QRS duration of 0.13 second and the QRS-T configuration. The Q-aU and Q-eU intervals of the sinus beats measure approximately 0.54 and 0.62 second, respectively. There are two atrial premature systoles in lead V_3 (beats 3 and 8) that have a coupling interval of 0.54 second and occur almost on the apex of the U wave. The QRS complexes of these premature beats retain the right bundle branch block pattern and have a QRS duration of 0.13 second, which is identical to that of the sinus beats. However, a definite increase in their amplitude is readily noted. Thus, alterations in the QRS amplitude appear to signify aberrant intraventricular conduction even in the presence of a bundle branch block. Langendorf[15] reported a similar case although he did not specifically emphasize the change in QRS amplitude (his Fig. 5). In lead III of our Figure 3, two atrial premature systoles (beats 4 and 8) occurred with slightly longer coupling intervals of 0.58 and 0.62 second, respectively, the latter corresponding to the end of the U wave. A slight de-

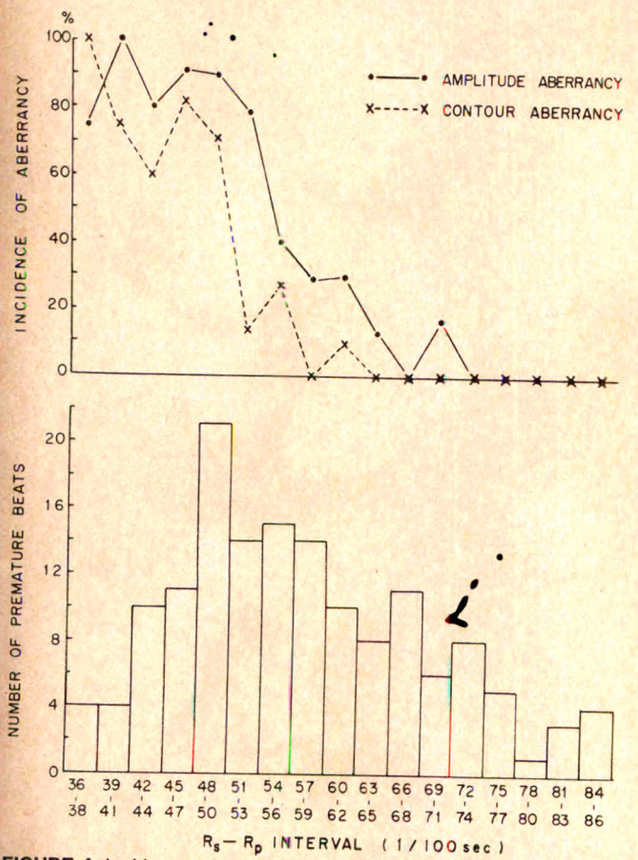

FIGURE 4. Incidence of aberrant conduction as related to the R_s-R_p interval (interval from the beginning of the QRS complex of a sinus beat to that of a coupled atrial premature systole). The histogram **(bottom)** shows the number of premature beats in individual ranges of R_s-R_p intervals; the two curves **at top** show percent incidence of aberrancy based on criteria of amplitude **(solid line)** and contour **(broken line).**

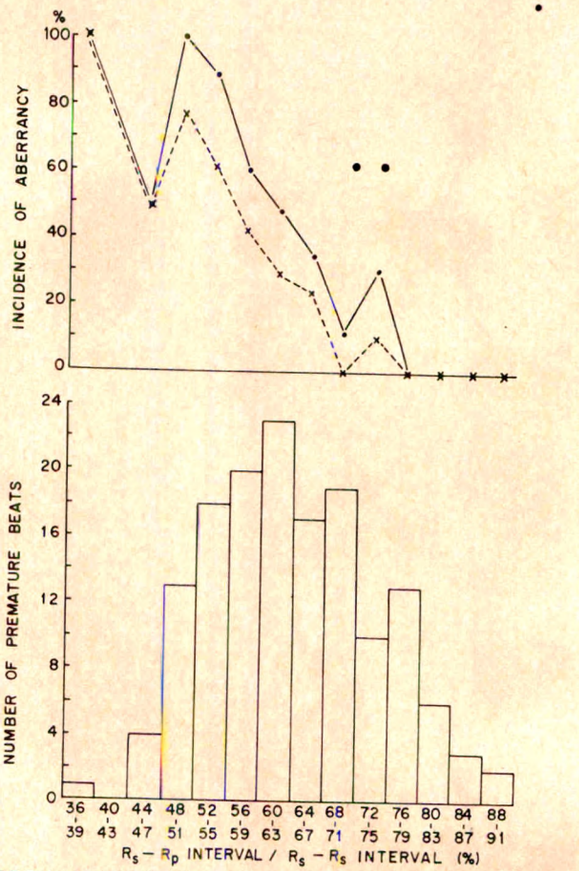

FIGURE 5. Incidence of aberrant QRS complexes as related to the ratio of the R_s-R_p/R_s-R_s intervals. The R_s-R_s interval is the basic sinus cycle length. Histograms and curves similar to those in Figure 4.

crease in their QRS amplitude is noted in beat 4, whereas the amplitude change is hardly significant in beat 8.

Aberrancy correlated with other measurements: After the presence or absence of aberrant intraventricular conduction was determined in individual atrial premature beats in the manner illustrated in Figures 2 and 3, the incidence of aberrancy was plotted against the coupling interval, the ratio between the coupling interval and the basic cycle length, and so forth.

Figure 4 shows such a correlation with the coupling intervals. The histogram at the bottom of this figure shows the number of premature beats in individual ranges of coupling intervals. For instance, the shortest coupling intervals of 0.36 to 0.38 second occurred in four instances, whereas the most common range of R_s-R_p intervals was between 0.48 and 0.50 second (21 instances). In the top diagram, the solid line connecting closed circles indicates percent incidence of aberrancy in terms of amplitude; the broken line with crosses indicates that in terms of contour. Although there is a trend toward an increased incidence of aberrant conduction with the shorter coupling intervals, these two curves are not smooth, and even the shortest observed coupling intervals were not always associated with aberrancy. Thus, the coupling interval as such does not appear to determine the development of aberrant conduction.

In Figure 5 the incidence of aberrancy is plotted against the ratio between the R_s-R_p and R_s-R_s intervals. This ratio is considered an index of sudden shortening of the ventricular cycle and has been commonly believed to play a major role in the genesis of aberrant intraventricular conduction in what is known as the Ashman phenomenon.[3] Although a general trend is again observed toward a greater probability of occurrence of aberrant QRS complexes with a smaller ratio, ratios below 50 percent are often accompanied by no aberrancy in either amplitude or contour. Furthermore, the incidence of contour aberrancy decreases to zero (0 of 19) with a shortening of the R-R cycle to 68 to 71 percent, but a lesser shortening of 72 to 75 percent is again associated with a 10 percent incidence rate (1 of 10). Thus, it appears that there is no critical degree of sudden R-R shortening that invariably causes abnormal intraventricular conduction of supraventricular impulses.

Because an atrial impulse should invade the intraventricular conduction system some time before the inscription of a QRS complex, one might argue that the R_s-R_p/R_s-R_s ratio may not accurately reflect the shortening of cycle length that is truly effective at the His-Purkinje level. Hence, an additional measurement,

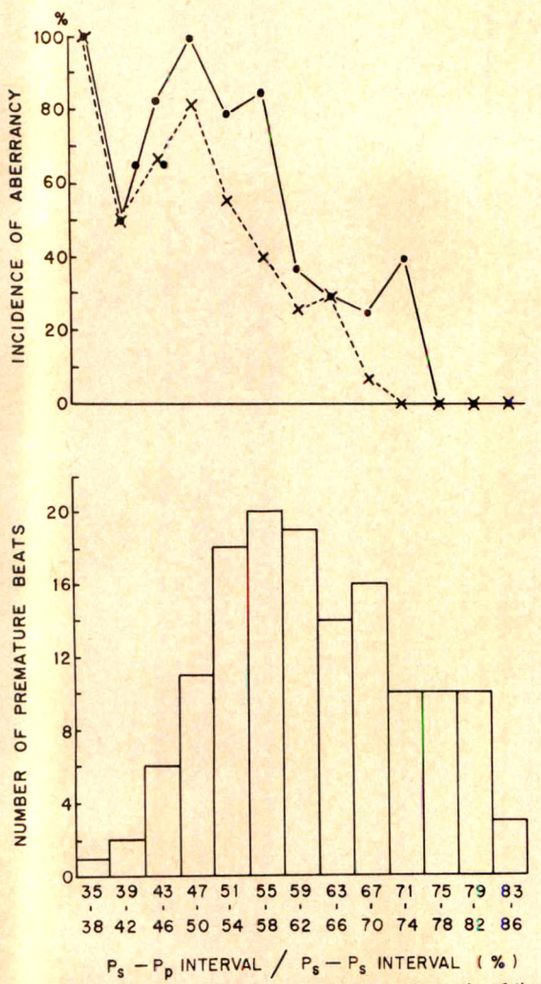

FIGURE 6. Incidence of aberrancy as related to the ratio of the P_s-P_p/P_s-P_s intervals. The P_s-P_p interval is the interval between the P waves of sinus and premature beats; the P_s-P_s interval is the interval between two consecutive sinus P waves.

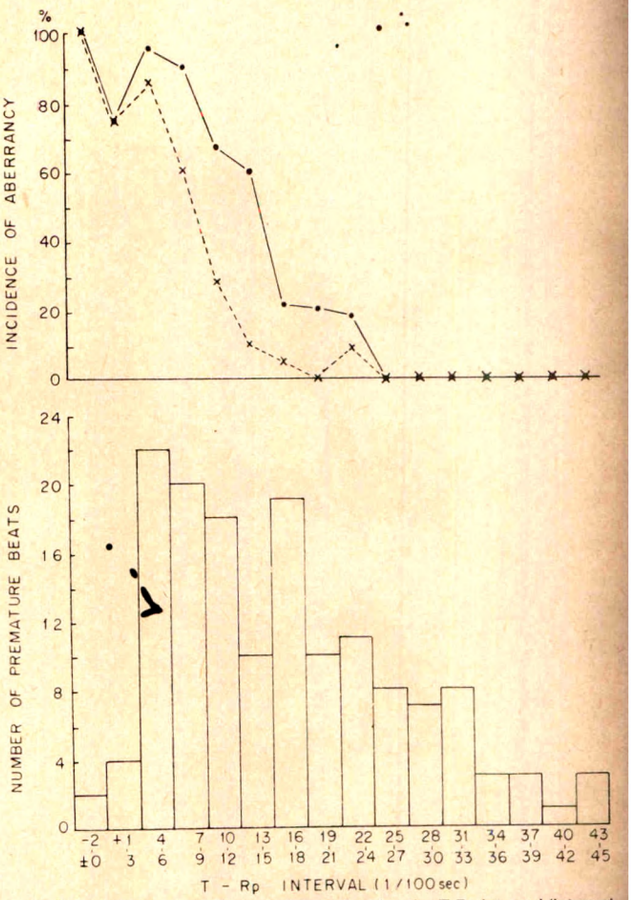

FIGURE 7. Incidence of aberrancy as related to the T-R_p interval (interval between the end of the T wave of a sinus beat and the onset of the QRS complex of an atrial premature systole).

the P_s-P_p interval (the interval between a sinus P wave and a premature ectopic P wave), was also analyzed.

Figure 6 shows the correlation of percent incidence of aberrancy and the ratio of P_s-P_p/P_s-P_s. In this figure the two curves showing aberrancy of amplitude and contour have a pattern similar to those in Figure 5 although the irregularities are somewhat more exaggerated.

Figure 7 shows the relation between the incidence of aberrant conduction and the T-R_p interval. When this interval was less than zero, or when the QRS complex of atrial premature systoles appeared before the end of the preceding T wave (this occurred in only two cases), aberrancy was present in 100 percent (2 of 2). Contrariwise, one of the four atrial premature beats having the next shortest T-R_p intervals of 0.01 to 0.03 second failed to show any signs of aberrancy, thus reducing the incidence rate to 75 percent and making the curves far from smooth.

Figures 8 and 9 illustrate much better correlations between the percent incidence of aberrancy and the timing of atrial premature systoles with reference to the preceding U waves. In Figure 8, the incidence is plotted against the aU-R_p intervals. Here, the relation of amplitude as well as contour aberrancy and the aU-R_p interval show smooth reversed S-shaped curves. Indeed, when this interval was less than −0.01 second, or when premature ventricular activation by an atrial impulse occurred before the apex of the U wave (arrow aU), the resultant QRS complex showed an abnormal amplitude in more than 88 percent and a contour change in more than 76 percent of cases. With a progressive increase in this interval, the probability of having aberrant conduction decreased rapidly. Similarly in Figure 9, the incidence of aberrancy is well correlated with the eU-R_p interval. When the QRS complexes of atrial premature systoles appeared after the end of the U wave (arrow eU), contour aberrancy was never observed and the incidence rate of amplitude aberrancy was less than 10 percent.

These relations between the development of aberrant intraventricular conduction and the timing of atrial premature systoles with reference to the U wave of the preceding sinus beat are further illustrated in Figure 10. In this case with frequent atrial premature beats, the coupling intervals showed wide fluctuations suggesting possible atrial parasystole. During the initial control period, the sinus rate was 64/min, and the Q-aU and Q-eU intervals measured 0.51 and 0.62 second, respectively, as indicated by the downward arrows aU and eU. Six of seven premature beats appeared before the end of the U wave, all of which were associated with some degrees

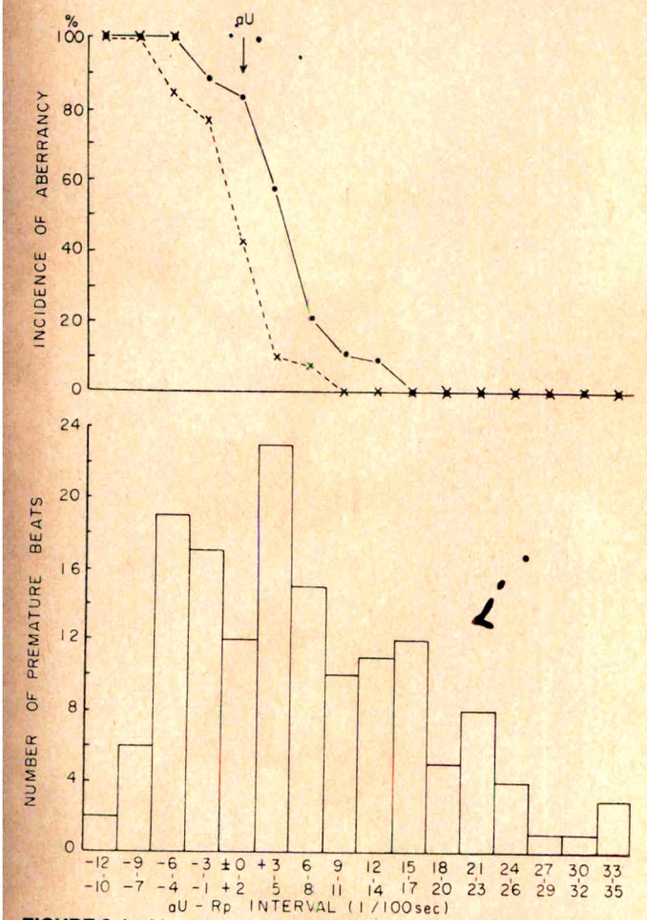

FIGURE 8. Incidence of aberrancy as related to the aU-R_p interval (interval from the apex of the U wave [aU] of a sinus beat to the beginning of the QRS complex of an atrial premature systole).

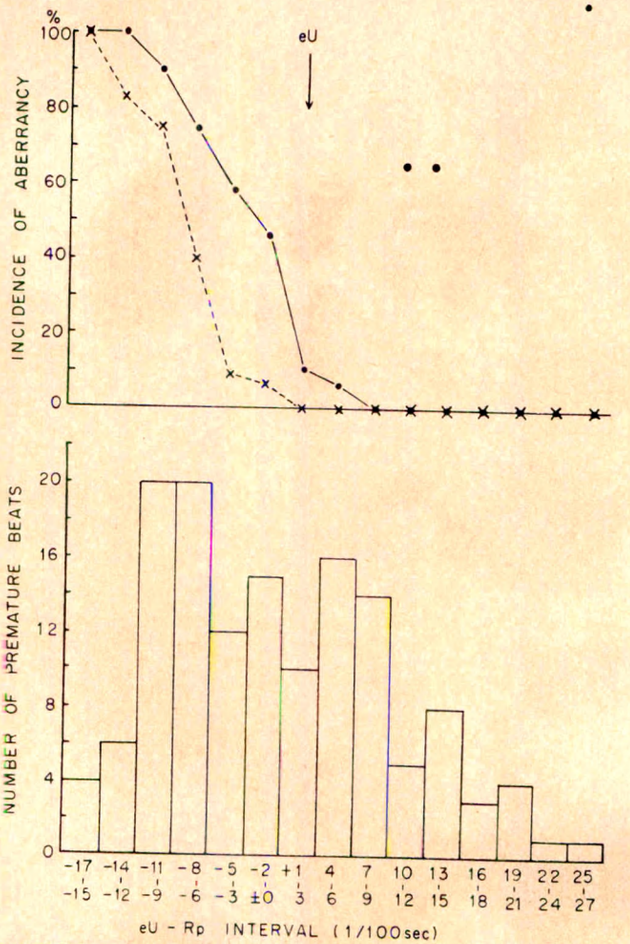

FIGURE 9. Incidence of aberrancy as related to the eU-R_p interval (interval from the end of the U wave [eU] of a sinus beat to the beginning of the QRS complex of an atrial premature beat).

of aberrant conduction (solid squares). In contrast, one premature systole occurring at a coupling interval of 0.64 second (0.02 second after the end of the U wave), did not show aberrancy (open square). When this patient performed exercises, the sinus rate increased to 82/min, with a concomitant shortening of the Q-aU and Q-eU intervals (upward arrows aU and eU). Fifteen atrial premature systoles were observed after exercise, of which 10 showed aberrant QRS complexes, whereas the remaining 5 did not. This figure again demonstrates that the end of the U wave determines the appearance or nonappearance of aberrant conduction.

Atrial premature beats showing bundle branch block: In this study, aberrant conduction showing a typical right or left bundle branch block configuration with QRS widening of 0.12 second or greater was observed in 14 instances. These atrial premature systoles were studied with regard to the aU-R_p interval as well as the ratio between the R_s-R_p and R_s-R_s intervals, and the results are shown in Figure 11.

Several comments are in order on Figure 11: (1) A right or left bundle branch block pattern of aberrancy was never observed with a positive aU-R_p interval. In other words, the occurrence of premature QRS complexes before the apex of the U wave appears to be a prerequisite to the production of a typical bundle branch block configuration. The reverse is not necessarily true because many atrial premature beats having a negative aU-R_p interval showed lesser degrees of aberrancy of contour (or amplitude). (2) On the other hand, these bundle branch block patterns of aberrant conduction were observed when the ratio between the coupling interval and the basic sinus cycle length was less than 57 percent although, again, many more atrial premature systoles with such R_s-R_p/R_s-R_s ratios showed either lesser degrees of aberrancy or no aberrancy at all. (3) There is a general trend that the right bundle branch block type of aberrancy occurs with relatively less degrees of prematurity, whereas the left bundle branch block configuration is produced with greater prematurity or only when an atrial premature systole precedes the apex of the U wave by intervals of 0.05 second or longer. Contrariwise, the values of R_s-R_p/R_s-R_s ratio do not appear to determine the patterns of bundle branch block. (4) One exception to the tendency of a right bundle branch block configuration to occur with lesser degrees of prematurity was noted when a premature QRS complex at an aU-R_p interval of −0.12 second had a right bundle branch block configuration (cross with arrow). However, this was a special case of atrial bigeminy in which the first atrial premature beat showed a left bundle branch block pattern at an aU-R_p interval of −0.09 second (closed circle with arrow), whereas the second premature systole was associated with the right bundle branch block. Such alternating patterns of aberrant ventricular conduction in the presence of atrial bigeminy were reported

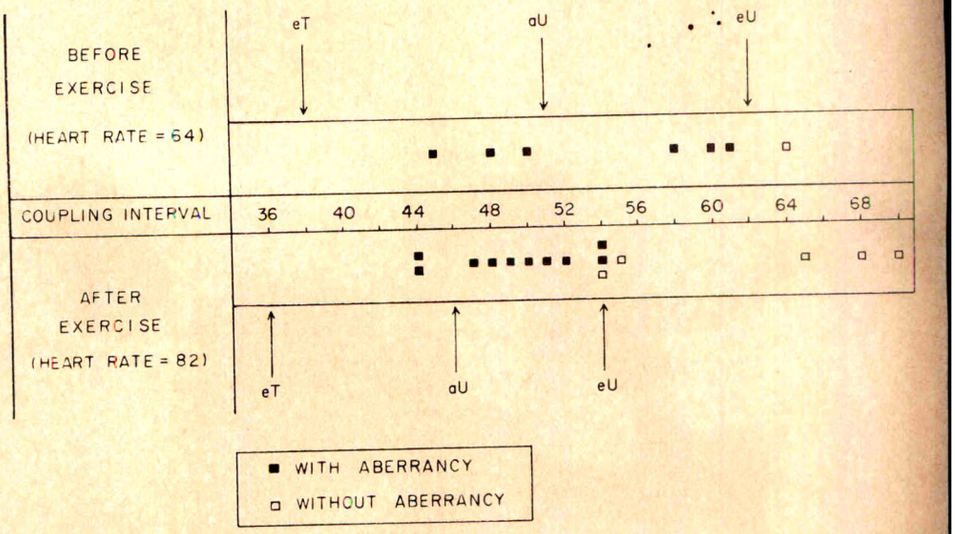

FIGURE 10. Interrelations between the time of appearance of atrial premature systoles and aberrant conduction before and after exercise (heart rate 64 and 82 beats/min, respectively) in a case of possible atrial parasystole. Coupling intervals in 1/100 sec. eT, aU and eU represent the end of the T wave, the apex of the U wave and the end of the U wave, respectively, as illustrated in Figure 1. See text for discussion.

earlier by Katz and Pick[16] and later experimentally produced in man by Cohen et al.[17] The latter discussed possible electrophysiologic mechanisms of this peculiar phenomenon.

Discussion

Disturbances of impulse transmission in myocardial tissues result from many factors that have been extensively reviewed by Watanabe and Dreifus,[18] and Singer and Ten Eick[8] have discussed the electrophysiologic mechanisms of aberrant conduction in detail. Aberrant intraventricular conduction is seen not only with a shortening of the ventricular cycle length but also with its prolongation.[4–6] The latter is probably caused by diastolic depolarization of certain Purkinje fibers, which results in a loss of membrane potential in late electrical diastole and decreased conductivity of propagated responses arising from such reduced potential levels.[19] Some investigators[20] have termed this mechanism phase 4 block. Contrariwise, aberrant conduction associated with shortened cycle lengths is caused by activation of Purkinje fibers before the completion of repolarization, which is often called phase 3 block.[20] Aberrancy of atrial premature systoles as observed in our cases probably results from this latter mechanism.

Theoretically, if conduction velocity in all the Purkinje fibers is decreased to the same extent, the resultant QRS complex may simply be widened without any alterations in contour although the QRS amplitude may well be modified. However, the time course of repolarization as well as recovery of excitability usually shows fluctuations between different fascicles or even from one Purkinje fiber to another in a given fascicle. Thus, premature stimulation of these fibers causes asynchronous spread of ventricular excitation[21] and, hence, aberrant conduction.

Aberrant conduction and transnodal (A-V) conduction: Whether the ventricular Purkinje fibers are activated during their phase 3 repolarization obviously depends on the degree of prematurity of a supraventricular impulse or the interval between the sinus and premature P waves (P_s-P_p interval). However, an extremely premature atrial impulse tends to sustain a greater conduction delay within the A-V node and may sometimes arrive in the fascicles of the intraventricular conducting system even later than certain less premature impulses that traverse the A-V node at greater velocities (so-called gap phenomenon).[22,23] Thus, several authors[24,25] have pointed out the importance of transnodal conduction time in the development of aberrant conduction. Indeed, studies using His bundle electrography have shown that the H_1-H_2 interval (or the interval between the His deflections caused by a sinus and a premature beat) plays a major role in aberrancy of atrial premature beats.[25] Although such measurements were not available in our electrocardiographic study, the effects of intranodal conduction delay were at least partially corrected by using the interval between the QRS complex of a sinus beat and that of the atrial premature systole (R_s-R_p interval) instead of the P_s-P_p interval (Fig. 4).

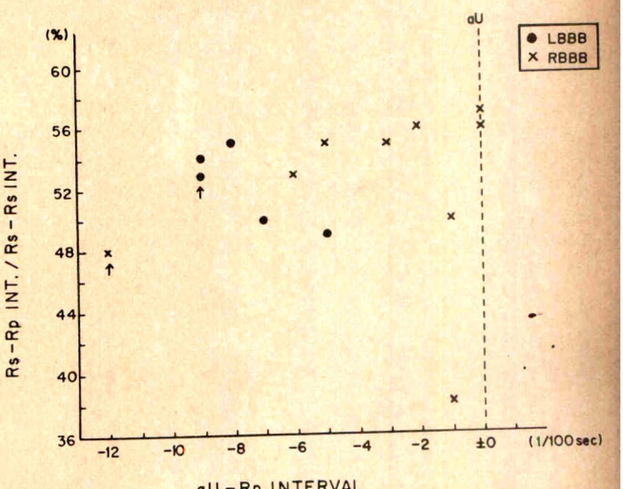

FIGURE 11. Correlation of a typical left (LBBB) or right (RBBB) bundle branch block pattern of aberrancy with the aU-R_p interval as well as the ratio of the R_s-R_p/R_s-R_s intervals. Detailed discussion in text.

Aberrant conduction, cycle length and coupling interval (Ashman phenomenon): On the other hand, the duration of both the transmembrane action potential and the effective refractory period shows a positive correlation with the cycle length of excitation.[26] Consequently, a longer preceding cycle is associated with a slower repolarization of Purkinje fibers, thus facilitating encroachment of their phase 3 by a premature impulse. It is then readily understood that the R_s-R_p interval (coupling interval) as such would not show a good correlation with the incidence of aberrant QRS complexes (Fig. 4), and the combination of a slower basic rhythm and a shorter coupling interval (or a greater degree of cycle length shortening) would definitely favor the development of aberrant conduction. This relation was first pointed out by Gouaux and Ashman[3] and is commonly referred to as the Ashman phenomenon. Many investigators have repeatedly stressed the importance of longer preceding cycles on the basis of both clinical and experimental observations.[7,8,14,15,24,25]

In our study the curves correlating the incidence of aberrancy and the ratio of the R_s-R_p/R_s-R_s intervals (this is a measure of the degree of sudden cycle length shortening) were not as smooth as might be expected from the preceding arguments for the Ashman phenomenon (Fig. 5). Such findings probably reflect variations in the time course of Purkinje repolarization from one case to another or even from one moment to the next in a same heart. Hence, a particular combination of R_s-R_p and R_s-R_s intervals (or even a particular H_1-H_2 interval) does not necessarily result in the encroachment of an identical point of phase 3 repolarization by the premature atrial impulses in two different instances, and the relation expressed by the Ashman phenomenon applies only in general terms. The lack of good correlation between the P_s-P_p/P_s-P_s ratio and the incidence of aberrancy (Fig. 6) obviously resulted from an additional involvement of intra-A–V nodal conduction time as discussed previously.[24,25]

The T wave as an index of phase 3 repolarization: It may thus be construed that if there is any good index for the phase 3 repolarization of the intraventricular conducting fibers, this index should show a much better correlation with the incidence of aberrant conduction of atrial premature systoles. Because the Purkinje fibers show a longer duration of action potential than the ventricular muscle fibers,[27] an indirect estimation of the time of Purkinje repolarization may be made from the T wave. However, the difference between action potential durations of Purkinje and ventricular muscle fibers is affected by many factors including heart rate,[13] and no fixed time values can be assigned between the T wave and phase 3 of the Purkinje system. This explains the still not smooth curves correlating the T-R_p interval (the interval between the end of the T wave and the premature QRS complex) and the incidence of aberrancy (Fig. 7) although the correlation appeared to be a little better than that obtained with the other three variables.

Aberrancy and the U wave (an index of phase 3 repolarization of the Purkinje system): When the distance of the QRS complex of an atrial premature systole from either the apex (aU) or the end (eU) of the U wave of the preceding sinus beat was correlated with aberrant conduction, the curves were quite smooth (Fig. 8 and 9). This finding suggests that the relative timing of the U wave and premature QRS complex plays a decisive role in producing aberrant intraventricular conduction, a hypothesis further substantiated in Figure 10. From these considerations, our premise that the U wave of the electrocardiogram probably represents phase 3 repolarization of the Purkinje system (or the Purkinje T wave) appears to be supported.[11–13]

It is well known that aberrant conduction of supraventricular premature systoles most commonly shows a right bundle branch block configuration.[3,6,8,28] On the basis of experimental studies in canine Purkinje preparations,[29] this finding has been attributed to the presence of longer action potential durations in the right than in the left bundle branch. If this holds true also in man, it may be suggested that repolarization of the left bundle branch fibers contributes to the initial portion of the U wave while repolarization of the right bundle branch system is responsible for the terminal portion of this wave form. The appearance of aberrancy of the left bundle branch block type only when premature QRS complexes occur 0.05 second or more earlier than the apex of the U wave, and the common production of right bundle branch block pattern when they occur toward the apex of the U wave (Fig. 11) may be in keeping with the above hypothesis. One possible explanation for the appearance of left bundle branch block in the presence of longer action potential durations in the right bundle is that conduction is only delayed in the latter while it is blocked in the left bundle entirely with such short coupling intervals; however no insight into this question is gained from our study.

So-called incomplete right bundle branch block patterns were often noted in atrial premature systoles occurring after the apex (but before the end) of the U wave (not shown). Moore et al.[30] indicated that a right bundle branch block configuration resulted from a block in the proximal portion of the right bundle and an incomplete right bundle branch block from a distal block. Cohen et al.[24] thought that a right bundle branch block pattern with the initial QRS vector identical to that of the sinus beats was due to distal Purkinje block, whereas that with a different initial vector was caused by proximal block. In vitro and in vivo experiments by Toyama[9] localized the site of conduction delay and block of premature stimuli slightly more proximal to the so-called distal gate of the right bundle. Obviously, no information on the level of conduction block is available in studies using clinical electrocardiograms alone. However, Moe et al.[7] earlier concluded that aberrant conduction was never caused by the refractoriness in ventricular muscle itself.

Other causes of aberrancy of premature beats: Several investigators[6,8] have mentioned possible causes of aberrant conduction of supraventricular premature beats other than incomplete repolarization of the Purkinje fibers. For instance, the use of certain anomalous A-V pathways by a supraventricular premature impulse

could cause an aberrant QRS complex. Although no cases with apparent preexcitation were included in our series, the presence of so-called concealed bypass tracts cannot definitely be ruled out. This or certain other mechanisms of aberrancy may have been responsible for some of the instances in which QRS complexes occurring beyond the end of the U wave showed minor degrees of aberrant conduction (Fig. 9).

Other views on genesis of the U wave: Finally, comments are in order on another prevailing theory on the genesis of the U wave. In an early panel discussion,[31] several investigators suggested that negative afterpotentials in the ventricular myocardium caused this electrocardiographic wave form. A more recent review by Lepeschkin[10] again considered this theory the most plausible and did not favor the theory of Purkinje repolarization. If one subscribes to the afterpotential theory, one might hypothetically propose that the arrival of a supraventricular impulse in the working ventricular muscle fibers at the time of a negative afterpotential may alter the upstroke velocity of their action potential and cause an abnormal spread of intramural excitation even though the bulk of evidence discussed seems to support the so-called phase 3 block in the Purkinje fibers as the cause of aberrant conduction. However, we believe that with this afterpotential mechanism one would expect the greatest degrees of aberrancy to develop when a premature QRS complex occurs on or around the apex of the U wave where the cell membrane is said to be unstable and the excitability is enhanced.[10,32] Contrariwise, aberrancy of premature QRS complexes becomes further exaggerated with their progressively early appearance with reference to the apex of the U wave (Fig. 2 and 11).

In conclusion, the Purkinje repolarization theory appears to offer more plausible explanations for at least several clinical electrocardiographic findings related to the U wave[11,12] although the validity of this concept still rests on more direct experimental studies to be carried out in the future.

Valve Origin of the Aortic Incisura

HANI N. SABBAH, BS
PAUL D. STEIN, MD, FACC

Detroit, Michigan

The occurrence and magnitude of the incisura of the central aortic pressure were shown in 66 patients to depend on the functional state of the aortic valve. In normal subjects and children with congenital aortic stenosis (with thin flexible leaflets), the incisura ranged between 6 and 14 mm Hg. With aortic regurgitation, the incisura diminished as the severity of regurgitation increased. With calcific aortic stenosis, the incisura was smaller or absent. These observations imply a valve mechanism productive of the incisura. In vitro studies of human aortic valves confirmed these observations. Additional in vitro studies with high speed cinematography (2,000 frames/sec) of a stented normal porcine valve also showed that early diastolic stretch and recoil of the leaflets occurs. These results indicate that in the presence of a normal or diseased aortic valve the aortic incisura is produced primarily by valve distension or recoil, respectively. Distension and rebound of the aortic walls do not appear to contribute significantly in the presence of a normal or a diseased valve. Because acquired aortic valve disease affects the magnitude of the central aortic incisura, inspection of the incisura may be of ancillary value in evaluating the pathologic state of the aortic valve.

The incisura of the central aortic pressure, frequently termed the dicrotic notch, has been observed since intraarterial catheterization was first introduced. However, its mechanism of production has not been fully explored. Pressure within the aorta has been thought to reflect the volume of blood contained within the vessels and the distensibility characteristics of the aortic wall.[1] This would imply that the incisura results from transient distension of the aorta. Others[2] considered the incisura the result of closure of the aortic valve, but they did not describe the method by which closure produces the incisura. The aortic incisura has been postulated to result from the rebound of the aortic blood column and walls that occurs after aortic valve closure.[3] Burton[4] described the aortic incisura or dicrotic notch as an interruption of the decrease of aortic pressure that occurs after abrupt closure of the aortic valve. He suggested that the elastic recoil of the aorta and of the valve itself creates the increase in pressure productive of the dicrotic wave. In view of the limited information upon which these speculations were made concerning the origin of the aortic incisura, we attempted to provide a more detailed view of the mechanism producing this phenomenon. Recognition of the exact cause of the aortic incisura would explain the variability of the incisura in various diseases of the aortic valve.

Methods

Clinical studies: Central aortic pressure was measured in 66 patients during diagnostic cardiac catheterization. Twenty-six patients had a normally functioning aortic valve as judged from the absence of a pressure gradient across the aortic valve, the absence of murmurs and normal cineaortograms in 10 of 26 patients with aortographic studies. Sixteen patients had pure aortic insufficiency of various degrees of severity. Aortic insufficiency in these patients was quan-

From the Departments of Medicine and Surgery, Henry Ford Hospital, Detroit, Michigan. This study was supported by Project R38820 from funds supplied by the Henry Ford Hospital via a grant from the Ford Foundation, New York, New York. Manuscript received March 11, 1977; revised manuscript received June 27, 1977, accepted June 29, 1977.

Address for reprints: Paul D. Stein, MD, Henry Ford Hospital, 2799 West Grand Boulevard, Detroit, Michigan 48202.

titated from cineaortograms on the basis of a 1+ to 4+ scale.[5] Twenty patients had mild to severe calcific aortic stenosis combined with mild to moderate aortic regurgitation. Three patients had congenital aortic stenosis, as judged from a history of a murmur since birth, their age (3, 10 and 20 years, respectively) and a pressure gradient across the aortic valve (44 to 70 mm Hg). None of these three patients had aortographic evidence of aortic insufficiency. One patient with calcific aortic stenosis was studied before and after the insertion of a porcine heterograft aortic prosthetic valve.

Aortic pressures were obtained using a Millar catheter-tip micromanometer in 24 patients and a fluid-filled catheter in conjunction with a Statham P23db pressure transducer in 42 patients. The tip of the catheter was routinely placed in the ascending aorta in proximity to the aortic valve. All recordings were made using an Electronics for Medicine photographic recorder at paper speeds of 25 to 200 mm/sec.

To determine the variability of the aortic incisura associated with various abnormalities of the aortic valve, the incisura was quantitated in two ways: (1) the magnitude of the aortic incisura was measured in millimeters of mercury from the bottom of the incisura to the top of the dicrotic wave; and (2) the ratio of the magnitude of the aortic incisura to the magnitude of the aortic pulse pressure (millimeters of mercury) was calculated.

In vitro studies: These were performed utilizing a Plexiglas® model of the root of the aorta and left ventricular chamber in which various types of valves were inserted. The dimensions of the simulated root of the aorta were based on measurements obtained from aortograms of normal subjects, and these dimensions were within the range described by others.[6] The simulated arterial circulatory system was previously described in detail.[7,8] Essentially, the system consisted of a reservoir, a hydraulic pump, a compression chamber, a laminar resistor and a variable clamp. The parts were interconnected through a series of various types of rigid and corrugated rubber tubing. A Statham P23db pressure transducer was connected directly to the model of the aortic root through a precision-drilled orifice in the Plexiglas. Systolic pressure was adjusted by varying the fluid level in the compression chamber, and diastolic pressure was adjusted with the variable clamp distal to the compression chamber. The test fluid consisted of a mixture of water and glycerin with a viscosity of 0.05 poise.

Various configurations of human valves were studied in vitro: These included a normal human valve, a thickened and deformed stenotic human valve, a stenotic valve with normally flexible and distensible leaflets and an insufficient human valve. The normal human valve was obtained at autopsy and mounted on stents. The cross-sectional area of its orifice was 5 cm^2. A second human valve was mounted in a similar fashion and was made to simulate a severely thickened and deformed valve. The leaflets were sealed and thickened with silicone adhesive, which resulted in a thickness of 0.1 to 0.3 cm. The effective orifice area was reduced to 0.7 cm^2. A valve that simulated a congenitally stenosed aortic valve with normally flexible leaflets was made from a normal human valve mounted on stents; the leaflets were sewn together with 5-0 sutures, leaving a central orifice of 0.8 cm^2. The leaflets closed completely during diastole, permitting no regurgitation. An insufficient semilunar valve was created from a stented normal human valve by suturing open one of the leaflets.

Valves were tested in the simulated arterial system at a constant pump rate of 68 strokes/min, a stroke volume of 80 ml/stroke and an aortic pressure of 120/80 mm Hg. (However, the pressure with the insufficient valve was 125/65 mm Hg.) The systolic ejection period was maintained at 0.29 second

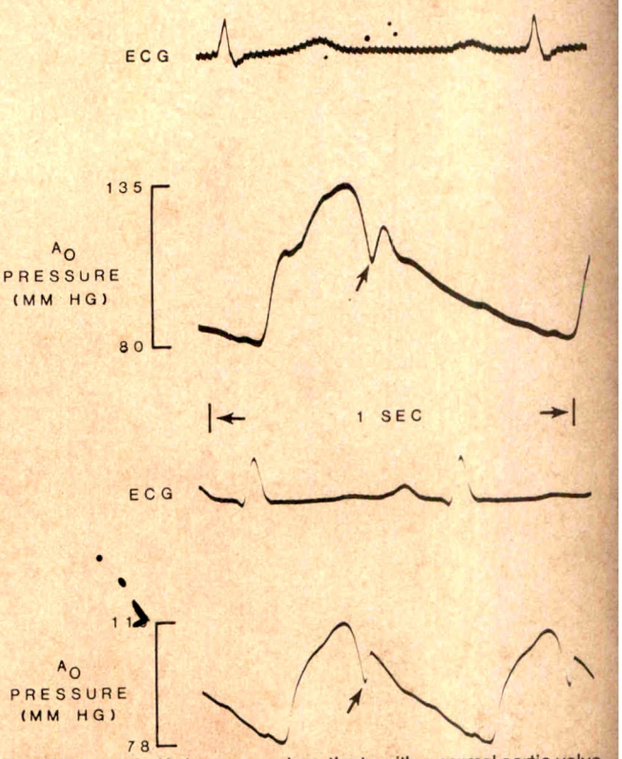

FIGURE 1. Aortic (A_O) pressures in patients with a normal aortic valve, showing prominent deeply inscribed incisuras **(arrows). Top,** pressure measured with a fluid-filled catheter. **Bottom,** pressure measured with a catheter-tip micromanometer. ECG = electrocardiogram.

with the normal valve and the insufficient valve. It was increased to 0.40 to 0.41 second with the stenosed valves to simulate the prolonged ejection that occurs in aortic stenosis.

Cinematography of the motion of the cusps of a stented normal porcine valve in early diastole was performed with a Hycam High Speed Camera (Red Lake Laboratories, Inc., Sunnyvale, California) at 2,000 frames/sec in the in vitro circulatory system that was adapted for such cine pictures. The simulated aortic pressure for these cine films was set at 160/90 mm Hg, the pump rate at 65 strokes/min and the stroke volume at 70 ml/stroke. Cine films of the motion of the valve cusps in early diastole were taken at 90° to the direction of flow.

Results

Clinical studies: *Patients with a normal aortic valve* had a prominent clearly defined sharp incisura (Fig. 1). The amplitude of the incisura varied among patients but was present and well defined in all normal subjects. There was no statistically significant difference between the magnitude of the incisura in the 13 normal subjects whose aortic pressure was measured with a catheter-tip micromanometer and the 13 subjects whose pressure was measured with a fluid-filled catheter. In patients with a normal aortic valve, the incisura ranged from 6 to 14 mm Hg (mean 9 mm Hg). The ratio of the magnitude of the incisura to the magnitude of the pulse pressure ranged from 0.13 to 0.39 mm Hg (mean 0.22 mm Hg).

The three patients with congenital aortic stenosis had a prominent aortic incisura. Both the magnitude of the incisura and the ratio of the incisura to the pulse pressure were within the range observed in patients with a normal aortic valve (Fig. 2).

Studies in patients with pure aortic insufficiency showed an aortic incisura of various degrees of magnitude (Fig. 3). The magnitude decreased (although not necessarily linearly) with an increasing severity of aortic regurgitation (Fig. 3 and 4). The incisura was completely absent in all patients with massive aortic insufficiency (Fig. 3 and 4). Similarly, the ratio of the magnitude of the incisura to the pulse pressure diminished with increasing severity of aortic regurgitation (Fig. 4).

Patients with calcific aortic stenosis and regurgitation also had an incisura of lower amplitude than that of normal subjects. Both the amplitude and the ratio of the incisura to pulse pressure diminished with increasing pressure gradients across the aortic valve (Fig. 2 and 5).

Aortic pressure measurements before valve replacement in a patient with a severely stenotic and calcified aortic valve showed no aortic incisura. After the valve was replaced with a porcine heterograft, the aortic incisura was present and well defined (Fig. 6).

In vitro studies: These confirmed the observations made in patients. A prominent aortic incisura was shown with both the stented normal human valve and the simulated congenitally stenosed human valve. Pressures obtained with the thickened and deformed stenotic valve, which simulated a heavily calcified aortic valve, showed the virtual absence of an aortic incisura.

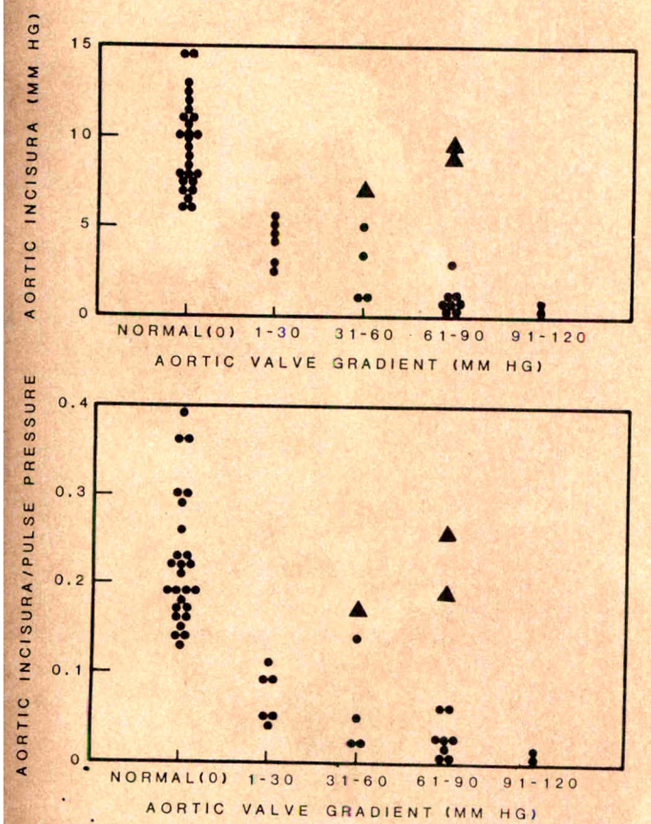

FIGURE 2. Magnitude of aortic incisura (mm Hg) **(top)** and ratio of aortic incisura to pulse pressure **(bottom)** shown in relation to the peak pressure gradient measured across the aortic valve. Both the magnitude of the incisura and the ratio of the incisura to the pulse pressure diminished with increasing pressure gradients in patients with calcific aortic stenosis. However, in young persons with congenital aortic stenosis **(triangles)**, incisuras were of the same magnitude as in normal subjects.

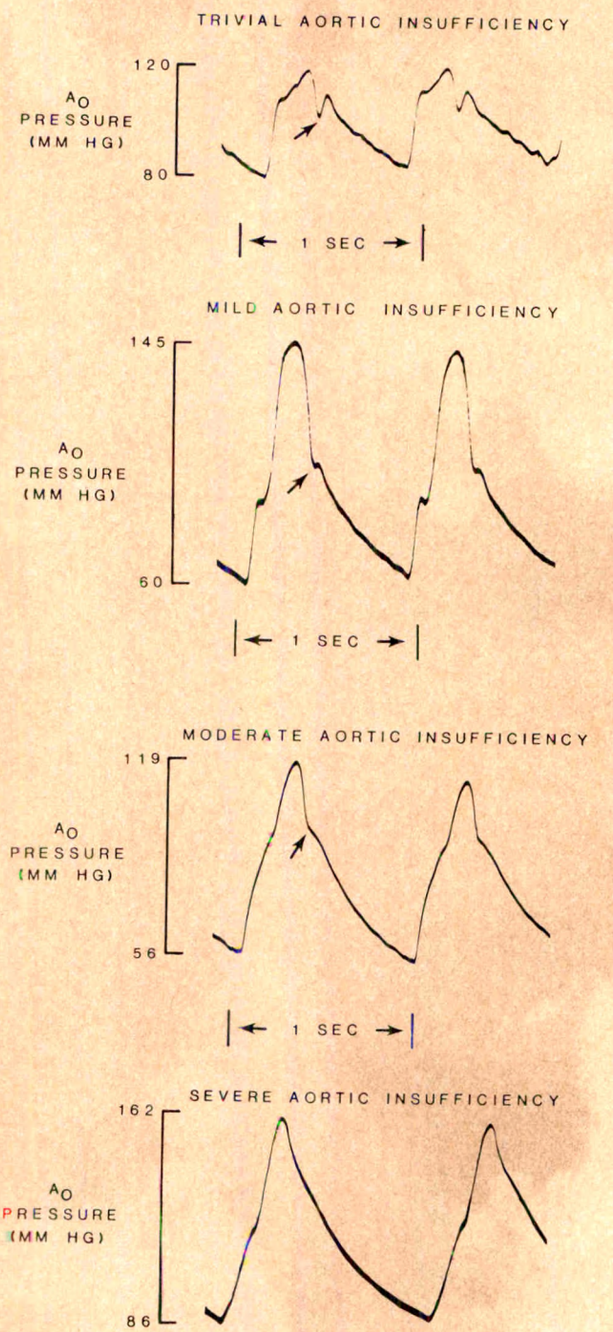

FIGURE 3. Central aortic (A_O) pressures measured in patients with various degrees of aortic insufficiency. No patient had a measurable pressure gradient across the aortic valve. The magnitude of the aortic incisura diminished with an increasing severity of insufficiency.

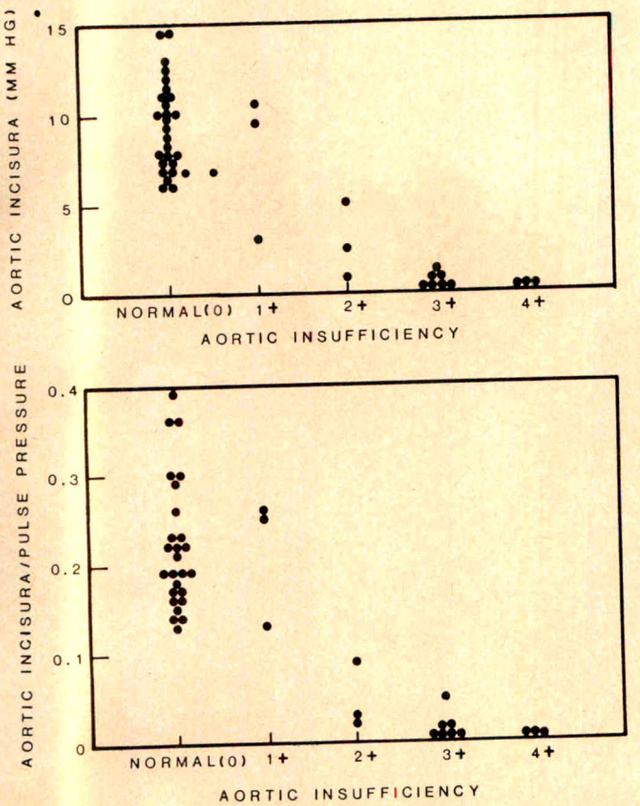

FIGURE 4. Magnitude of aortic incisura **(top)** and ratio of aortic incisura to pulse pressure **(bottom)** in normal subjects and patients with aortic insufficiency of varying degrees of severity as judged by the cineaortogram. Trivial, mild, moderate and severe aortic insufficiency are indicated as 1+ to 4+, respectively.

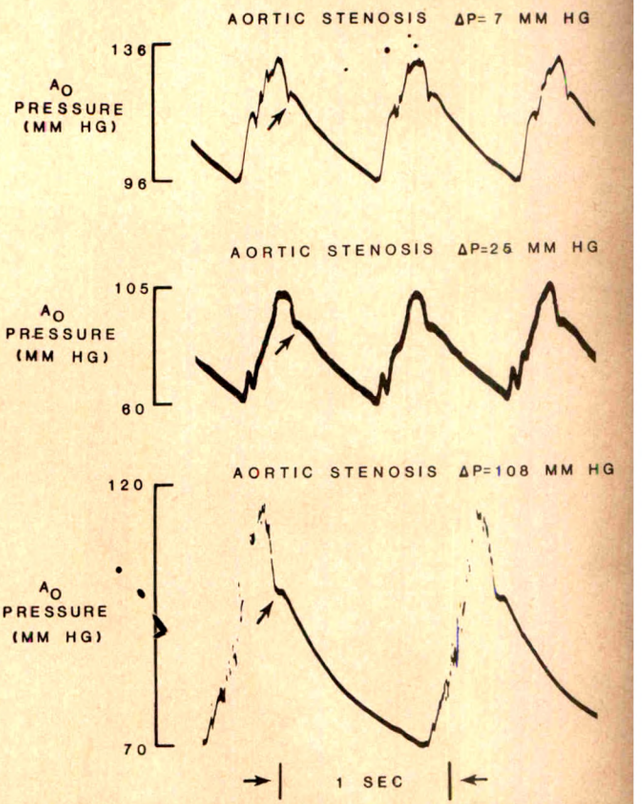

FIGURE 5. Central aortic (A_O) pressure in patients with various degrees of calcific aortic stenosis. Peak pressure gradient (ΔP) measured across the valve is shown. The incisura is indicated by **arrows.** The magnitude of the incisura was small in the patients with the higher gradients.

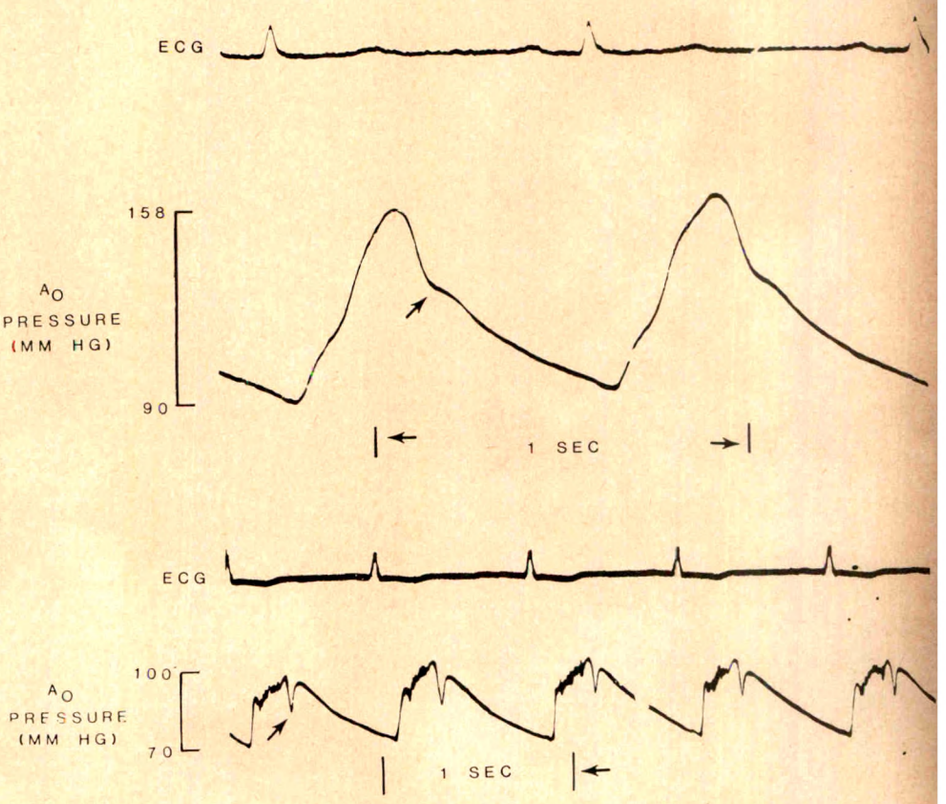

FIGURE 6. Central aortic (A_O) pressure of a patient with calcific aortic stenosis and regurgitation. **Top**, preoperatively, showing an aortic incisura of negligible size **(arrow). Bottom,** after replacement of the aortic valve with a porcine heterograft valve. A prominent deeply inscribed aortic incisura is now shown. ECG = electrocardiogram.

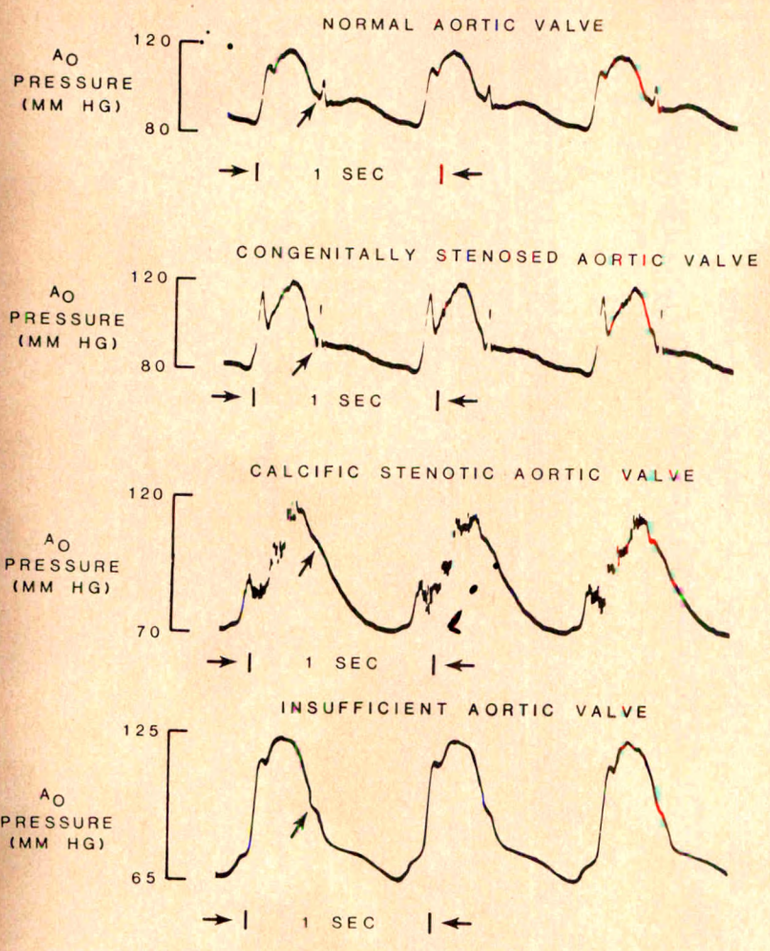

FIGURE 7. Simulated aortic (A_O) pressures, measured in vitro with a stented normal human aortic valve **(top)**, a simulated congenitally stenosed valve, a simulated human calcific stenotic valve and a simulated human regurgitant valve **(bottom)**. The incisura in each case is shown by **arrows.**

The incisura was also of negligible size in the presence of an insufficient valve (Fig. 7).

Cinematography of the aortic leaflets of a porcine valve during diastole showed distension and recoil of the leaflets after closure of the valve (Fig. 8). The center of the cusps bulged into the simulated left ventricle and recoiled toward the simulated aorta after maximal distension.

Discussion

The aortic incisura in patients with a normal or diseased aortic valve: Our results show that under normal physiologic circumstances, and even in the presence of altered physiology induced by a diseased valve, the aortic incisura appears to be produced primarily by the aortic valve. This is apparent from the varying magnitude of the incisura in association with various configurations of the valve. A prominent incisura invariably occurred with a normal aortic valve and a congenitally stenotic valve, reflecting the thin, flexible and distensible leaflets of both normal valves and congenitally stenotic valves. A pressure differential between the aorta and left ventricle at the onset of diastole could readily stretch such valves. A poorly defined and frequently negligible incisura of low amplitude occurred with calcified stenotic valves. A diminished dicrotic notch also has been observed by others[2] in carotid pulse tracings of patients with valve stenosis. This reflects the thickened, noncompliant and nondistensible nature of these valves, which are unable to stretch and respond to the rapidly increasing pressure difference across the valve during early diastole. The magnitude of the incisura diminished with higher systolic gradients across the aortic valve in patients with calcific aortic stenosis. This demonstrated further the dependence of the incisura upon valve distensibility because increased thickening and rigidity of the valve are usually associated with more severe stenosis.

The incisura was also of low amplitude in patients with pure aortic regurgitation, and its magnitude was greatly diminished with more severe regurgitation. An indistinct dicrotic notch in carotid pulse tracings of patients with severe aortic insufficiency has also been observed by others.[2] The reason for the diminished amplitude of the incisura in the presence of aortic regurgitation differs from that of calcific aortic stenosis. In aortic regurgitation, the leaflets have a diminished capacity to become tense after closure. Because such tension is an essential requirement for stretching of the valve, the valve cannot distend into the left ventricle.

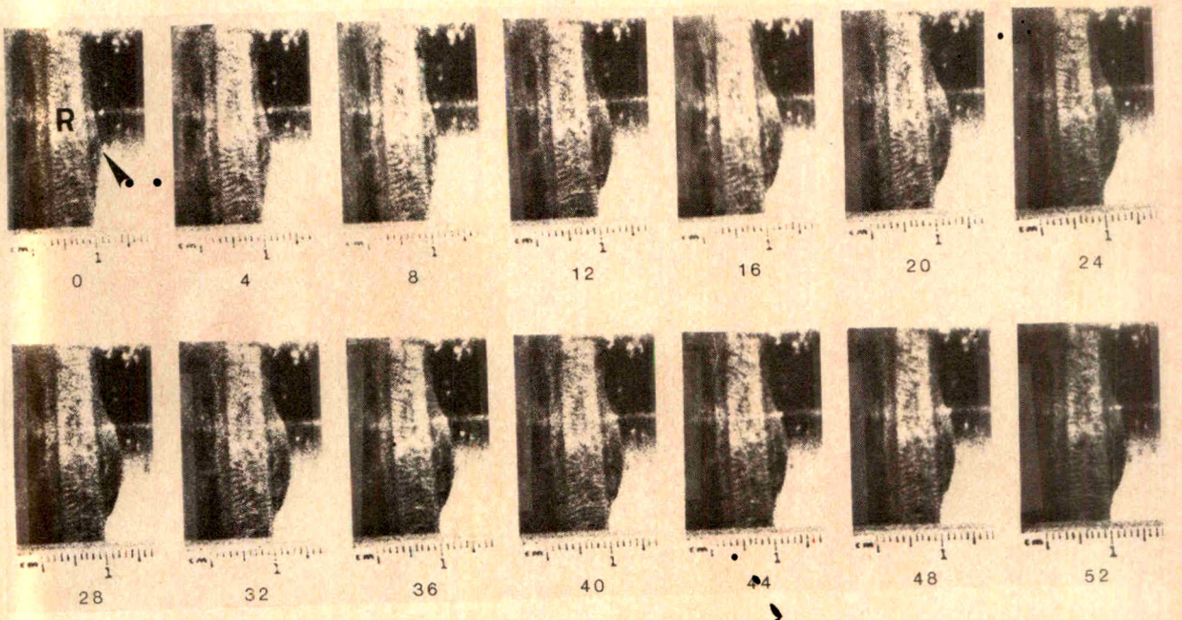

FIGURE 8. Cine films showing stretch and recoil of the closed cusps of a stented normal porcine valve in vitro. The motion pictures of the valve were taken at 90° to the direction of flow. The simulated ventricle is to the **right;** the aorta to the **left.** The sewing ring (R) of the valve is shown with the base of the cusp **(arrow)** protruding toward the ventricle. Diastolic pressure was 90 mm Hg. Every fourth frame was selected for illustration, and the frame numbers are shown. The interval between illustrated frames is 2.0 msec. At the moment of complete closure (frame 0) the base of the cusps extended 0.1 cm from the edge of the sewing ring. This corresponded to the 1.1 cm mark on the accompanying scale. Prominent stretch of the cusps is apparent on frame 24 (1.3 cm mark). Recoil is apparent on frame 44 (1.2 cm mark).

Observations related to the effects of the aortic valve upon the incisura were strengthened by the following demonstration. An incisura of negligible size was shown in a patient who had calcific aortic stenosis before surgery. The incisura was greatly increased after replacement of the valve with a heterograft porcine valve. The difference appears to be attributed to the valve.

Mechanisms contributing to the aortic incisura: The observations made in patients were confirmed in vitro under circumstances that permitted all variables to be uniform and controlled. Only the configuration of the valve was changed in these in vitro studies. With stenotic valves, the duration of systole was correspondingly changed to simulate flow in patients more closely. The incisura in vitro showed characteristics similar to those of the incisura in patients.

Stretch and recoil of the normally distensible valve leaflets thus appear to be the primary cause of the aortic incisura under normal and pathologic circumstances. Distension of the semilunar cusps into the left ventricle occurs because of a differential pressure between the ventricle and the aorta just after valve closure. Such ballooning causes a transient increase of the volume of the root of the aorta. A small amount of blood drains from the aorta into the distended cusps and causes a rapid reduction of the aortic pressure, the end point of which is the apex of the incisura. Consequent to distension, the leaflets recoil because of their inherent elastic properties. This recoil decreases the volume of the root of the aorta and causes pressure to increase. Distension and recoil of a mounted porcine valve were shown to occur in early diastole by high speed cinematography (2,000 frames/sec).

If stretch and rebound of the aorta are responsible for the incisura as some workers[1,3,4] have indicated, the diameter of the aorta would need to increase during the rapid fall of pressure and to decrease during the subsequent rise of pressure associated with the dicrotic wave. However, this does not occur.[9] During the rapid decrease of pressure at the onset of the incisura there is a simultaneous reduction in the diameter of the aorta whereas during the dicrotic wave the diameter of the aorta increases.[9] The reduction of the aortic diameter coincident with the reduced pressure during the incisura would therefore seem to be related to distension of the aortic valve into the ventricle. The increased volume of the root of the aorta, required for a reduction of pressure, occurs by virtue of the expanded volume produced by the stretch of valve leaflets into the left ventricle. With nonphysiologic valves, as with rigid disc prosthetic valves, some characteristics of valve closure differ from those of normal or even diseased human valves. The disc closes later during ejection[8] and at a different time relative to retrograde flow, and the energy of impact at the time of closure may differ from that found in normal physiologic states or pathophysiologic conditions. With such nonphysiologic valves, factors may participate in the production of an apparent incisura that do not contribute to the incisura in patients with a normal or diseased valve.

The attribution of the aortic incisura to effects of compliance of the aortic wall may have risen from data

suggesting that backward flow at the end of systole is coincident with valve closure.[10] If this were true, this flow would increase the volume of the aorta, thereby distending it. The rebound of the aorta that would follow is credited with the production of the dicrotic wave.[4] This mechanism appears to be unlikely because the aortic incisura has been shown to occur 12 to 15 msec before the nadir of backward flow.[7,11] We[7] have observed that augmentation of forward or retrograde flow did not affect the magnitude of the aortic incisura.

Clinical implications: Variations of the magnitude of the aortic incisura in various aortic valve diseases can be explained in view of the mechanism of its production postulated in our study. The absence of the incisura in severe calcific aortic stenosis appears to be related to the absence of distensibility of the aortic valve, which results from thickening and calcification of the leaflets. Because little or no stretch or recoil can occur, no variations of pressure are produced. In aortic insufficiency, the failure of the valve to close completely results in inability of the valve to distend into the left ventricle. Again, this causes a negligible incisura. In congenital aortic stenosis, the leaflets are fused but retain their flexibility and distensibility. These characteristics allow the valve to balloon into the left ventricle during early diastole and permit an appreciable recoil.

The physiologic principles relating to the valve origin of the incisura therefore may be applied clinically. A prominent aortic incisura implies that the aortic valve is normally distensible. A reduction of the amplitude of the aortic incisura implies malfunction of the aortic valve. An absent or reduced aortic incisura, in view of our findings, offers physicians another indicator of aortic valve disease.

Myocardial Scintigraphy With Technetium-99m Pyrophosphate During the Early Phase of Acute Infarction

B. LEONARD HOLMAN, MD, FACC*
MICHAEL LESCH, MD, FACC†
JOSEPH S. ALPERT, MD, FACC

Boston, Massachusetts

To determine the sensitivity of myocardial scintigraphy with technetium-99m pyrophosphate during the early phase of acute myocardial infarction, 31 patients admitted to the coronary care unit with prolonged ischemic pain underwent imaging within 4 to 8 hours and again at 24 hours after the onset of symptoms. In 11 of 15 patients with documented acute myocardial infarction, increased focal myocardial uptake was demonstrated on early myocardial scintigraphy. Focal uptake was observed in only 2 of 16 patients with unstable angina pectoris. Three of four patients with normal early scintigrams had massive transmural myocardial infarction. Normal early scintigrams in these three patients may have reflected poor perfusion because the images were abnormal at 24 hours. In four patients the extent of technetium-99m pyrophosphate uptake increased more than 20 percent at 24 hours without other evidence of infarct extension. In the other seven patients, there was no significant change in the area of the abnormal radioactive uptake between early and delayed scintiscans. This study suggests that technetium-99m pyrophosphate scintigraphy can detect acute myocardial infarction as early as 4 hours after the onset of symptoms although the sensitivity rate (73 percent) is less than that at 24 hours.

Scintigraphic techniques using infarct-avid radiotracers provide a direct method for determining the extent of acute myocardial infarction.[1–3] Previous investigators[4] have suggested that 12 hours is the earliest time after the onset of symptoms for accurate detection of infarction. With the advent of therapeutic maneuvers aimed at limiting the extent of myocardial necrosis,[5] it has become increasingly important to measure infarct size accurately during the early phase of acute infarction. We have, therefore, determined the accuracy of myocardial scintigraphy with technetium-99m pyrophosphate for detecting acute infarction and predicting its size in the first hours after onset of symptoms.

Methods

Myocardial scintigraphy using technetium-99m pyrophosphate was performed in 31 patients admitted to the coronary care unit with suspected acute myocardial infarction. Patients were selected for study only if they had a clearly defined onset of precordial chest pain occurring no more than 8 hours before imaging, an uncomplicated course during the first 24 hours after admission and no previously documented myocardial infarction.

Patients: *Acute myocardial infarction was diagnosed if the following three criteria were met:* (1) a history of typical chest pain lasting 1 hour or more, (2) the presence of a characteristic pattern of elevation in the creatine kinase (CK) serum activity above normal levels with subsequent resolution, and (3) appearance of Q waves (transmural infarction) or evolution of ST-T wave changes (nontransmural infarction) characteristic of infarction in the electrocardiogram.

Unstable angina pectoris was defined as prolonged chest pain, ischemic in character and of recent onset (less than 1 month), that had increased in frequency, severity or duration in the month before admission. Patients with this diagnosis had no electrocardiographic evidence of acute myocardial infarction and a peak serum CK value in the 3 days after admission that was less than the upper limit of normal.

Fifteen of the 31 patients had an acute myocardial infarction that was transmural in 11 and nontransmural in 4, as judged from electrocardiographic changes. The remaining 16 patients had unstable angina pectoris. Scintigraphy was performed in all patients within 4 to 8 hours after the onset of chest pain.

Myocardial scintigraphy: The procedure was performed as soon as possible after the patients' admission to the coronary care unit and was repeated 24 hours later. Imaging was performed 90 minutes after the administration of 10 mCi (5 mg) of technetium-99m pyrophosphate using an Anger scintillation camera with a low energy all purpose collimator and a pulse height analyzer window peaked symmetrically over the 140 kev photopeak of technetium-99m. Imaging was performed in the anterior, left anterior oblique and left lateral projections, collecting 400,000 counts in each view. The scintigraphic images were obtained on Polaroid® film (type 52) and were interpreted independently by two observers without prior knowledge of the clinical diagnosis. The extent of technetium-99m pyrophosphate uptake was measured from the anterior projection with use of planimetry in the patients with documented acute myocardial infarction. (The borders of the focal myocardial uptake were obscured by overlying osseous activity in the left anterior oblique and left lateral views. These projections were therefore not used to measure infarct size.) The percent change in the area of the myocardial uptake between 4 and 24 hours was then determined.

The reproducibility of the planimetric measurement was assessed in four control patients with acute infarction. Repeat scintigraphy was performed in the anterior position after the camera detector was repositioned. The area of technetium-99m pyrophosphate uptake in each of the two anterior views was measured with planimetry.

Results

Myocardial infarction: In 11 of the 15 patients with acute infarction (Patients 1 to 11, Table I), increased focal myocardial activity was demonstrated on early myocardial scintigraphy. In all cases, myocardial uptake was less intense in early scintigrams (4 to 8 hours) than in the 24 hour study. In 5 of the 11 (Cases 1 to 5), serum CK activity was within normal limits at the time scintigraphy was performed (Fig. 1).

In one case (Patient 12), diffuse myocardial uptake was evident on early scintigraphy performed 90 minutes after injection. Results of repeat scintigraphy 3 hours after injection were normal, suggesting that the initial diffuse uptake was caused by blood pool activity.

In the other three patients (Cases 13 to 15) with normal myocardial scintigrams, imaging was performed 4 hours (one patient) and 8 hours (two patients) after the onset of pain. In one patient (Case 13), serum CK was within normal limits at the time of imaging. All three patients had a massive transmural myocardial infarction. Two of these patients (Cases 14 and 15) died of pump failure within 1 week of infarction, and the third patient's course was complicated by cardiogenic shock. Subsequent scintigrams were abnormal in the two patients surviving 24 hours after infarction.

Unstable angina pectoris: Of the 16 patients with unstable angina pectoris, 12 had normal early scintigrams. Of the remaining four patients, two had focal and two had diffuse myocardial uptake (Table II). With use of focal myocardial uptake as the criterion for the diagnosis of acute myocardial infarction, the sensitivity

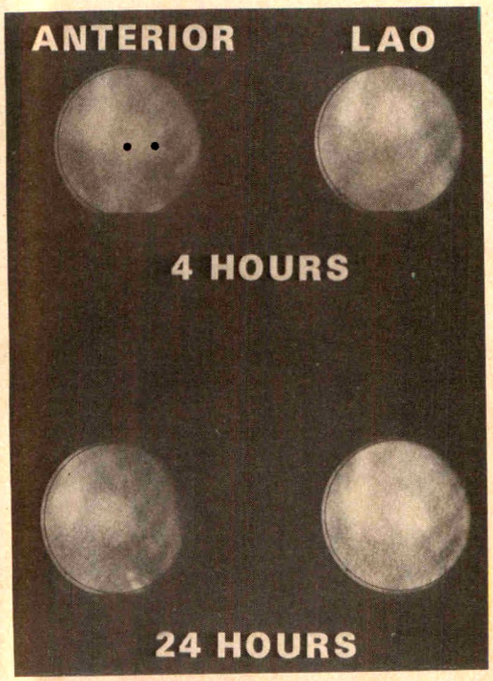

FIGURE 1. Case 1 (Table I). Scintigraphy performed with technetium-99m pyrophosphate in the anterior and left anterior oblique (LAO) projections 4 hours **(upper panel)** and 24 hours **(lower panel)** after the onset of symptoms in a patient with acute anteroseptal myocardial infarction. The serum CK level was normal at 4 hours.

rate of early scintigraphy was 73 percent and the specificity rate 88 percent.

Reproducibility: In the four control patients with documented myocardial infarction who underwent imaging twice in the anterior position, the percent change in area between the first and second measurements was 5.3 ± 1.2 percent (mean ± standard error of the mean). The change in area of the abnormal radioactive uptake between early and delayed scintiscans in 7 of the 11 patients with early focal myocardial uptake was not significantly different from the results obtained in testing the reproducibility of the method (Table I). The area of technetium-99m pyrophosphate uptake increased in eight patients between early and delayed scintigraphy. In four of these eight patients, the increase was greater than 20 percent. The area decreased slightly in the remaining three patients.

Discussion

Acute myocardial infarction can be detected with technetium-99m pyrophosphate within 4 hours of the onset of chest pain and before elevation of serum creatine kinase activity. The detection rate is somewhat lower with early compared with delayed (24 hours to 7 days) scintigraphy.[4,6] However, three of the four patients with normal early scintigraphy in this study had massive transmural infarcts and did not present diagnostic problems on admission. The specificity rate of

TABLE II

Summary of Scintigraphic Results in 31 Cases

Early Myocardial Scintigraphy	Diagnosis (no. of patients)	
	Acute Myocardial Infarction	Unstable Angina Pectoris
Normal	4 (27%)	12 (75%)
Diffuse uptake	0	2 (12.5%)
Focal uptake	11 (73%)	2 (12.5%)
Total patients	15	16

early scintigraphy was high, with normal or diffuse patterns observed in 88 percent of patients with unstable angina pectoris. Of course, we cannot rule out the possibility that focal uptake of technetium-99m in two patients with unstable angina pectoris actually represented an area of myocardial necrosis.

The failure of massive infarcts to concentrate pyrophosphate early is analogous to the normal scintigrams obtained in a canine model of infarction 7 hours after permanent coronary occlusion; in animals subjected to temporary occlusion, early scintigraphy was abnormal.[7] Because pyrophosphate uptake is flow-limited, large infarcts receive insufficient tracer to be detected with early scintigraphy. That delayed scintigraphy is abnormal in these patients suggests that the initial marked reduction in flow is followed by rapid establishment of collateral flow.

Estimating changes in extent of infarction: The substantial increase in size of the technetium-99m pyrophosphate uptake in four patients may indicate some extension of the infarct during the first 24 hours; this could not be confirmed by other criteria. Thus, the extent of technetium-99m pyrophosphate uptake appears time-dependent in at least some patients with acute infarction without other evidence of reinfarction. For myocardial scintigraphy to be useful in estimating changes in the size of infarction, the time interval between infarction and scintigraphy will have to be known and serial scintigraphy will probably be necessary. In any case, the extent of infarction can probably be determined as early as 4 hours after the onset of symptoms (assuming that there is good correlation between infarct size and tracer uptake)[7–12] although prediction of ultimate size cannot be made in many patients.

Currently no other technique is available that accurately measures the size of acute infarction during the early period, 4 to 8 hours, after the onset of symptoms. Creatine kinase clearance curves require 10 to 12 hours before accurate sizing is possible.[13] Use of myocardial perfusion scintigraphy with potassium analogs and measurements of wall motion abnormalities with radionuclide techniques cannot distinguish between alterations in function due to the acute process, ischemia or old infarction.[14] S-T segment mapping provides a qualitative index of the size of infarction and can signal directional changes in the size of the evolving infarct, but it cannot quantitate the degree of necrosis.[15]

Implications: Although infarct scintigraphy may

estimate infarct size in most cases within 8 hours of symptoms, technetium-99m pyrophosphate uptake may not reflect the degree of necrosis within the borders of the infarct. The uptake of the radiotracer in any given tissue section is related not to the degree or amount of infarction but only to the presence of necrosis.[7,8] As a result, the border zone of the infarct may concentrate pyrophosphate in small nests of necrotic tissue interspersed between zones of reversibly ischemic tissue which can be salvaged by early treatment. Conversely, at the time of early scintigraphy, the tracer may be concentrating in ischemic tissue destined for ultimate necrosis but potentially salvageable with appropriate interventions.[16] Thus, the use of early scintigraphy to provide a quantitative measure of the efficacy of drug therapy will require a clearer understanding of the mechanism of technetium-99m pyrophosphate localization.

Thallium-201 Myocardial Perfusion Scintigraphy for the Clinical Clarification of Normal, Abnormal and Equivocal Electrocardiographic Stress Tests

ELIAS H. BOTVINICK, MD*

Sixty-five patients were studied with stress electrocardiography and thallium-201 relative myocardial perfusion scintigraphy. Results were correlated with selective coronary angiography. Scintigraphy was more sensitive (85 versus 67 percent), more specific (89 versus 63 percent) and significantly more accurate (87 versus 65 percent) than stress electrocardiography for the diagnosis of significant coronary arterial lesions in patients with isoelectric S-T segments at rest. Stress scintigraphy helped clarify the equivocal stress test due to left bundle branch block, left ventricular hypertrophy, drugs, hyperventilation and other conditions and was more accurate than the stress electrocardiogram (89 versus 53 percent) even in the presence of a depressed S-T segment at rest. Thallium-201 scintigraphy is a safe and simple noninvasive method for identifying abnormal myocardial perfusion, stress-induced ischemia and, indirectly, significant coronary arterial lesions.

Methods for the noninvasive diagnosis and evaluation of coronary artery disease have been dramatically advanced by the development of relative myocardial perfusion scintigraphy.[1–3] During the last 5 years, a variety of radionuclides, including potassium-43, cesium-129, cesium-131 and rubidium-81, have been used to identify abnormalities of myocardial perfusion, regions of stress-induced ischemia and, indirectly, significant coronary arterial lesions.[2–8] Investigators have demonstrated the ability of scintigraphic methods to identify the false positive treadmill test[9] and have shown its increased sensitivity and specificity for the identification of coronary arterial disease.[2,3] Thallium-201 is a cyclotron-produced radionuclide with a small energy of emission and a 73 hour physical half-life. The intramyocardial distribution of thallium-201, similar to that of other intracell cations, has been shown to correlate with coronary blood flow after an intravenous injection.[10] Other determinants of thallium-201 distribution include the presence of myocardial scar and, possibly, altered membrane function of any cause.[11] Extracted 70 to 80 percent by the coronary circulation on its first pass,[12] thallium-201 maintains its initial localization for approximately 1 hour before gradual redistribution occurs.[13] Its rapid blood clearance, intramyocardial localization and physical characteristics make it the most promising agent now available for myocardial perfusion scintigraphy. To evaluate its clinical utility, we performed relative myocardial perfusion scintigraphy with thallium-201 in patients undergoing selective coronary angiography.

Methods

Perfusion scintigrams and stress electrocardiograms were correlated with selective coronary angiograms in 74 patients evaluated for the presence of coronary disease. All patients were referred for evaluation of chest pain suspected to be coronary in origin. None had pain at rest, but 19 had electrocardiographic Q waves 0.04 second or more in duration, confirming a history of prior myocardial infarction.

Procedure: After a baseline 12 lead electrocardiogram, an intravenous catheter was placed in the forearm and each patient underwent maximal graded treadmill stress testing until limiting symptoms prevented continuation according to a modified Bruce protocol.[14] One minute before the exercise end point was reached, 2 mCi of thallium-201 (supplied by New England Nuclear, Boston, Massachusetts) was injected through the established intravenous line. The blood pressure and a modified V_5 electrocardiographic lead were monitored during standing, hyperventilation, exercise and a 6 to 8 minute recovery period. After recovery, scintigraphy was performed with a Searle Pho Gamma IV scintillation camera. To ensure adequate evaluation of relative myocardial radioactivity, an image was taken to 200,000 counts in the anterior projection and the time noted. This was followed by images in the 45° left anterior oblique and left lateral projections, taken to equal time. All scintigrams were performed using a converging collimator, and a 20 percent window was centered at approximately 75 kev. Hepatic or splenic activity was shielded when apparent. Patients with normal stress images had no scintigraphic evidence of stress-induced coronary malperfusion or significant coronary arterial narrowing and were not restudied at rest. Patients with abnormal stress images were restudied, usually within 1 week of the initial stress scintigram. All scintigrams were performed with the patient's informed consent and in a fasting state. Always within 2 weeks and often within 48 hours of the scintigraphic study the patient underwent selective coronary angiography with use of the Sones or Judkins technique and multiple orthogonal projections.

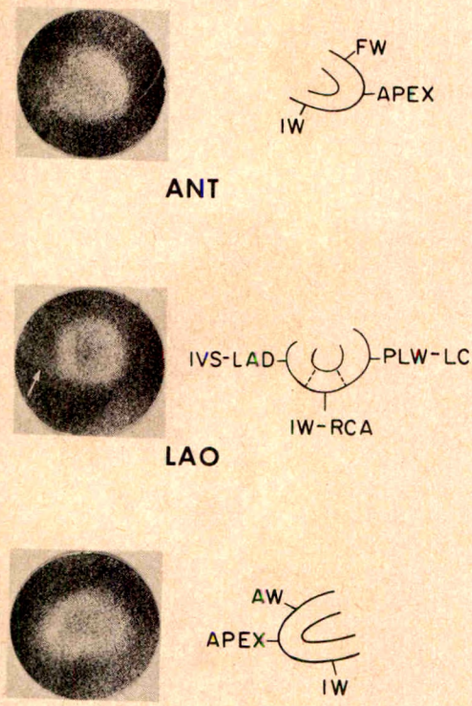

FIGURE 1. Normal thallium-201 myocardial perfusion scintigram in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections performed after peak treadmill stress in a patient with normal coronary arteries on angiography. Myocardial uptake in the left ventricle is intense and homogeneous. There is vague evidence of right ventricular activity in this example **(arrow).** The right ventricle occasionally appears as a region of faint activity anterior to the left ventricle. The diagram to the right of each image indicates ventricular as well as coronary anatomy. AW = anterior wall; FW = free wall; IVS = interventricular septum; IW = left ventricular inferior wall; LAD = distribution of the left anterior descending coronary artery; LC = common region of distribution of the left circumflex coronary artery; PLW = left ventricular posterior lateral wall; RCA = common distribution of the right coronary artery.

Interpretation of stress electrocardiograms, scintigrams and coronary angiograms: *The treadmill electrocardiogram* was considered abnormal and positive for ischemia and significant coronary artery disease if 1 mm or greater horizontal or downsloping S-T segment depression beyond an isoelectric baseline, 0.08 mm from the J point, appeared during exercise or in recovery. It was called equivocal for the diagnosis of ischemia, regardless of the degree of exercise-induced S-T depression, if the baseline S-T segment was depressed more than 1 mm. Such equivocal tests were also analyzed to determine the reliability of stress-induced S-T segment depression 1 mm below the baseline. The treadmill test was never stopped because of a specific target heart rate but negative treadmill tests in which the patient failed to reach 85 percent of the maximal predicted heart rate for age were classified as suboptimal studies.

A scintigraphic defect at rest was interpreted as evidence of prior infarction. However, only the stress scintigram with new or increased abnormalities beyond those seen at rest was considered indicative of reversible relative hypoperfusion and judged a positive study consistent with stress-induced myocardial ischemia. Stress-induced abnormalities were localized to myocardial regions and to the coronary vessels perfusing these regions.

Coronary angiograms were performed in multiple projections. Significant coronary lesions were those revealing a 75 percent or greater area of stenosis in the course of a major coronary vessel on selective coronary angiography.

Stress electrocardiograms, scintigrams and coronary angiograms were read by separate and independent observers, each without knowledge of the results of the other studies. The initial 50 scintigrams were read a second time to determine the reproducibility of image interpretation.

The ability of the stress electrocardiogram and scintigram to diagnose stress-induced ischemia and, indirectly, significant coronary stenosis was compared. Evidence of prior infarction in the resting electrocardiogram or scintigram is not in itself evidence of ongoing ischemia and was not taken as evidence of ongoing stress-induced ischemia in this study. Although commonly related to significant coronary lesions, neither significant electrocardiographic Q waves nor scintigraphic abnormalities at rest were of themselves accepted as findings positive for ischemia.

Results

Overall findings: Figure 1 shows a normal thallium-201 perfusion study with an accompanying diagram to clarify the scintigraphic anatomy. Stress-induced abnormalities involving the interventricular septum were interpreted as due to left anterior descending coronary artery disease; those involving the posterior lateral left ventricular wall were related to left circumflex coronary artery disease and inferior wall abnormalities were related to right coronary stenosis. Apical lesions could be the result of distal disease in any of the vessels and could be localized only in the presence of other accompanying scintigraphic abnormalities.

Nine patients, seven with significant coronary lesions, had no stress-induced electrocardiographic or scintigraphic abnormalities at suboptimal stress. None of these patients achieved 85 percent of the maximal predicted heart rate for age and it is possible that both tests in these nine patients were negative because of the suboptimal nature of the stress alone. These patients, four with prior infarction, were excluded from further analysis.

Sixty-five patients were studied at optimal stress or had stress-induced electrocardiographic or scintigraphic abnormalities at a suboptimal heart rate (Fig. 2). There were 48 men and 17 women with a mean age of 52 years (range 19 to 69 years). Twenty-five patients had an abnormal stress electrocardiogram, 21 a normal stress electrocardiogram and 19 an equivocal stress electrocardiogram with depressed S-T segments at rest. The latter were due to left bundle branch block in two patients, left ventricular hypertrophy in six patients, digitalis in five patients and hyperventilation in three patients; they were of unknown cause in three patients. Three patients with right bundle branch block were studied and were included in the group with normal resting S-T segments.

Positive stress electrocardiogram: Among the 25 patients with a stress electrocardiogram positive for ischemia, 17, all with significant coronary lesions on coronary angiography, had an abnormal scintigram revealing stress-induced changes. Eight of the 25 patients had a normal stress scintigram, including 7 without significant coronary lesions on angiography. Among these seven, three had chest pain in association with mitral valve prolapse, but the cause of the chest pain in all seven was unclear. One patient with a prior infarction showed no change in scintigraphic perfusion in spite of exercise-induced ischemic S-T segment depression. Figure 3 demonstrates the scintigraphic study of a patient with stress-induced abnormalities involving the left ventricular septum, apex and inferior wall. The scintigram performed 6 days later at rest revealed a normal homogeneous perfusion pattern. The electrocardiogram, suggestive of ischemia during stress, became definitely abnormal in recovery but failed to give localizing information. Angiography revealed significant lesions of the left anterior descending and right coronary arteries. Figure 4 demonstrates the normal stress scintigram of a patient with chest pain and an abnormal stress electrocardiogram. The stress electrocardiogram is said to be a false positive study in this case only with reference to its relation to the normal coronary angiogram.

Negative stress electrocardiogram: Among the 21 patients with a stress electrocardiogram negative for ischemia, 13 had a normal stress scintigram; in 3 patients both tests were negative despite the presence of a significant coronary lesion on angiography. However, eight patients with a negative stress electrocardiogram had a positive stress scintigram; six of the eight had significant coronary lesions. Two patients with a negative stress test and no coronary lesions had apparent

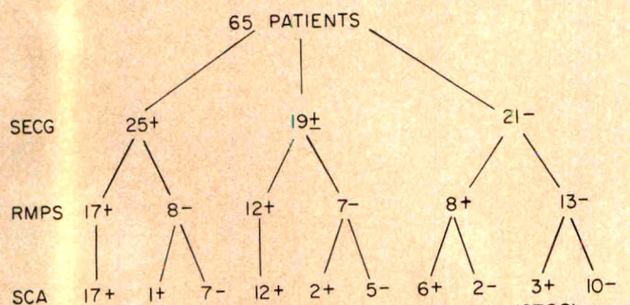

FIGURE 2. Overall results of stress electrocardiography (SECG), regional myocardial perfusion scintigraphy (RMPS) and selective coronary angiography (SCA) in 65 patients. Scintigraphy was more accurate than stress electrocardiography in identifying the presence of significant coronary artery disease. Additionally, the scintigram clarified the equivocal stress electrocardiogram. + = an abnormal study; − = a normal study; ± = an equivocal study.

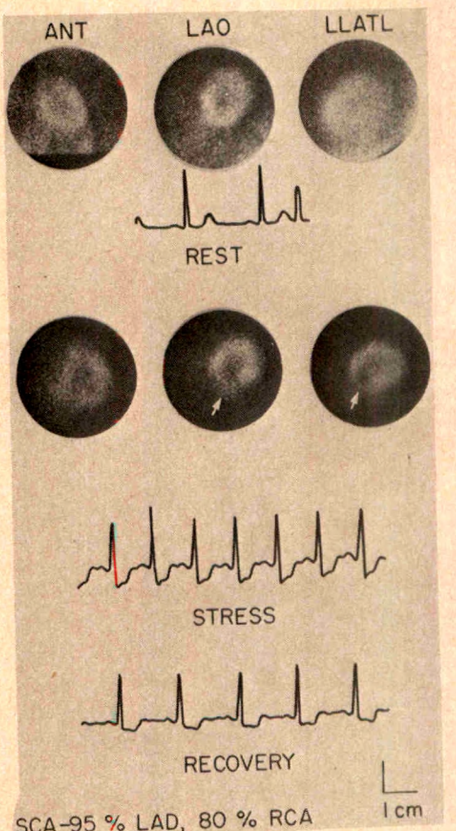

FIGURE 3. Abnormal stress electrocardiogram and scintigram. Resting **(top)** and stress **(bottom)** electrocardiogram and thallium-201 scintigram in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections performed in a patient whose selective coronary angiograms (SCA) demonstrated significant left anterior descending (LAD) and right coronary artery (RCA) lesions. The image at rest is normal; that during stress shows significant abnormalities involving the left ventricular apex and inferior wall and distal aspect of the interventricular septum **(arrows).** Although both the stress electrocardiogram and scintigram predicted the presence of significant coronary lesions, only the scintigram gave accurate localizing information.

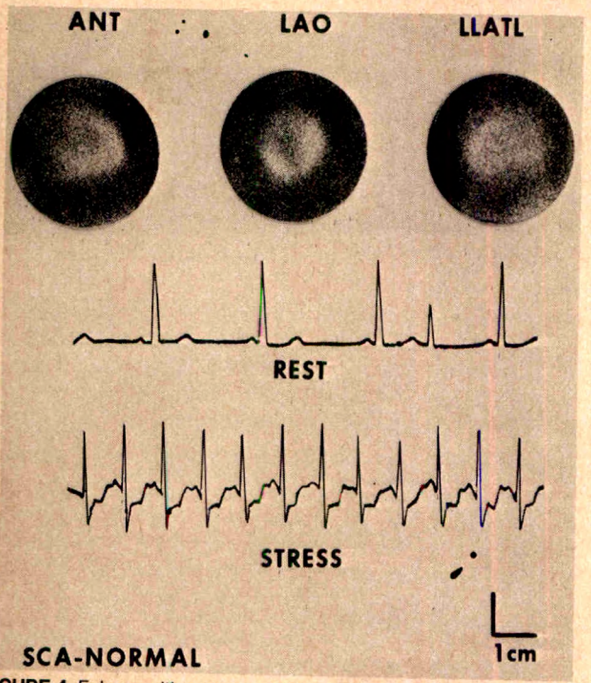

FIGURE 4. False positive stress electrocardiogram. Stress thallium-201 perfusion images in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections **(top)** and the resting and stress electrocardiograms **(bottom)** in a patient with normal coronary arteries on angiography (SCA). Radionuclide distribution was normal but the stress electrocardiogram showed distinct and significant horizontal S-T segment depression. Scintigraphy proved to be the valid clinical indicator.

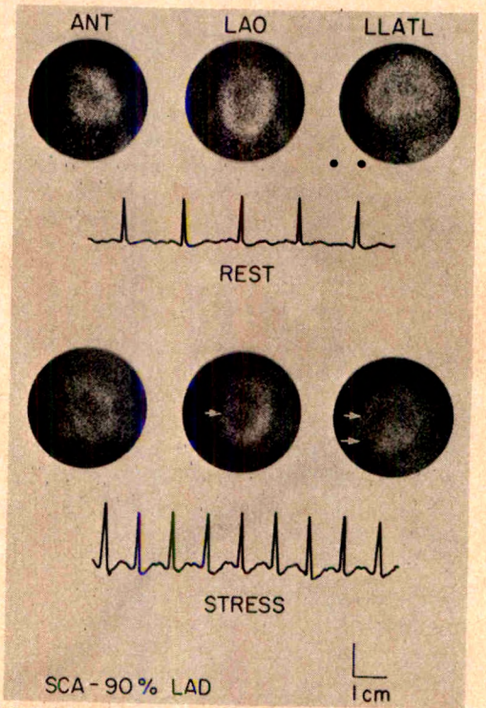

FIGURE 5. False negative stress electrocardiogram. Resting **(top)** and stress **(bottom)** electrocardiogram and thallium-201 perfusion images in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections in a patient whose selective coronary angiograms (SCA) demonstrated significant left anterior descending coronary artery disease. The resting scintigram reveals homogeneous radioactivity. With stress, the interventricular septum and anterior left ventricular wall **(arrows)**, the regions supplied by the stenotic vessel, are barely visible. The electrocardiogram shows no ischemic change on exercise.

stress-induced image abnormalities. One of these had a diffuse cardiomyopathy and an abnormal resting image; the other had no documented heart disease and a normal resting image. Four patients with a negative stress electrocardiogram at suboptimal stress had a positive stress scintigram and significant coronary lesions. No other patients had a positive scintigram at suboptimal stress. Figure 5 demonstrates an abnormal stress scintigram and a normal or false negative stress electrocardiogram in a patient with severe left anterior descending coronary artery disease. Although the distribution of radioactivity was essentially homogeneous at rest, the anterior and septal left ventricular walls show relatively decreased intensity during stress consistent with relative perfusion deficits in these regions.

Table I compares the sensitivity, specificity and accuracy of stress electrocardiography with that of relative myocardial perfusion scintigraphy in the diagnosis of significant coronary artery disease in the 46 patients with resting isoelectric S-T segments. Scintigraphy was more sensitive (85 versus 67 percent) and more specific (89 versus 63 percent) than stress electrocardiography, but because of the small number of patients studied neither difference was statistically significant at the 0.05 level. Overall, the scintigraphic method permitted the correct angiographic diagnosis much more frequently than the stress electrocardiogram, even in the presence of resting isoelectric S-T segments. The scintigraphic accuracy rate was 87 percent compared with 65 percent for stress electrocardiography (difference significant at the 0.05 level).[15] Significant coronary artery disease was present in all patients having both an abnormal stress electrocardiogram and an abnormal scintigram.

Equivocal stress electrocardiogram: Nineteen patients had a stress electrocardiogram with abnormal S-T segments at rest. Among these 19 patients, 12 with stress-induced scintigraphic abnormalities had significant coronary arterial lesions on angiography. The other seven patients had normal stress perfusion images; five of these had no angiographic evidence of coronary disease, but two had significant coronary lesions. Figure 6 illustrates the equivocal stress electrocardiogram in a patient taking digoxin. The scintigraphic study is grossly abnormal with new stress abnormalities involving the left ventricular inferior wall, the distal aspect of the posterior lateral wall, the interventricular septum and the apex. In the presence of drug-related S-T segment depression at rest, the scintigram clearly documented significant left anterior descending and right coronary artery disease and suggested probable left circumflex coronary artery disease. This patient's

TABLE I

Analysis of Results of Relative Myocardial Perfusion Scintigram Versus Stress Electrocardiogram (SECG)

Sensitivity Matrix

Scintigram	Stress Electrocardiogram TP	FN
TP	17	6
FN	1	3

Sensitivity: SECG = 0.67; scintigram = 0.85
$0.10 > P > 0.05$

Specificity Matrix

Scintigram	Stress Electrocardiogram TN	FP
TN	10	7
FP	2	0

Specificity: SECG = 0.63; scintigram = 0.89
$0.20 > P > 0.10$

Accuracy Matrix

Scintigram	Stress Electrocardiogram TP + TN	FP + FN
TP + TN	27	13
FP + FN	3	3

Accuracy: SECG = 0.65; scintigram = 0.87
$0.05 > P > 0.02$

A true positive test (TP) refers to abnormal electrocardiographic or scintigraphic studies performed in patients with documented significant coronary lesions. A true negative test (TN) refers to a normal electrocardiographic or scintigraphic study in patients with documented normal or insignificantly narrowed coronary arteries. A false positive test (FP) refers to an abnormal electrocardiographic or scintigraphic study in patients with documented normal or insignificantly narrowed coronary arteries. A false negative test (FN) refers to a normal electrocardiographic or scintigraphic study in patients with documented significant coronary lesions. In evaluating our results only the findings in 46 patients with a definitely positive or definitely negative stress electrocardiogram could be compared with the results of scintigraphy. The 27 patients with a positive coronary angiogram are considered under the sensitivity matrix, whereas the 19 with a negative coronary angiogram are considered under the specificity matrix. The accuracy matrix attempts to evaluate simultaneously sensitivity and specificity and is a compilation of the preceding two matrixes. Results were analyzed with use of McNemar's test[15] (see text).

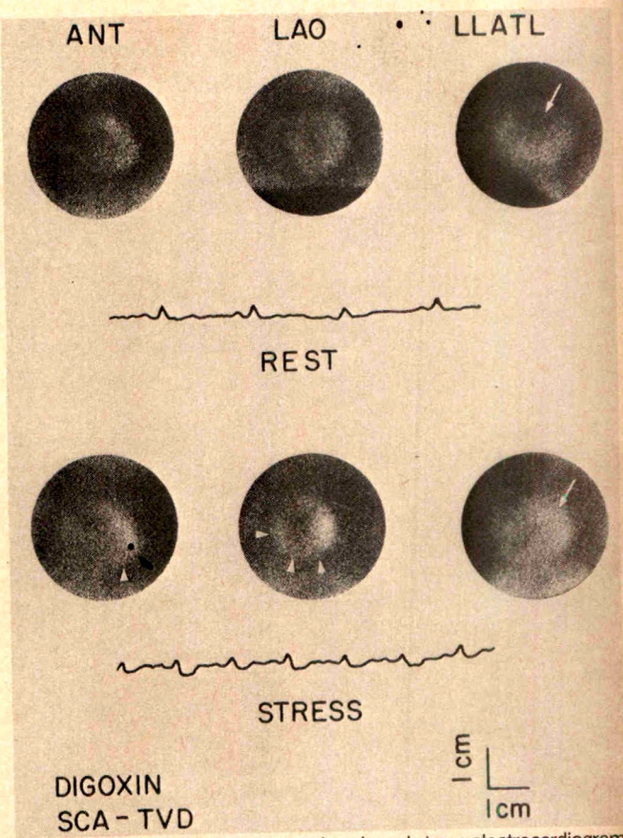

FIGURE 6. Abnormal scintigram and equivocal stress electrocardiogram in a patient with coronary artery disease. Resting **(top)** and stress **(bottom)** electrocardiogram and scintigram in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections in a patient whose coronary angiograms (SCA) revealed severe triple vessel disease (TVD). The patient was taking digoxin. The electrocardiogram showed S-T segment depression at rest that became somewhat deeper during stress. Such drug-related S-T segment depression made interpretation of the electrocardiogram difficult. However, the image showed clear stress-induced perfusion abnormalities involving the left ventricular inferior wall, distal aspect of the posterior lateral wall, interventricular septum and apex **(arrow points)** attesting to the severity and extent of coronary disease documented angiographically. The redistribution of radioactivity is also prominent in the left lateral projection where the regions of the ventricular base and lateral wall, relatively unlabeled at rest, become the most intense regions with stress **(arrows)**, indicating "best" perfusion of the basal or proximal aspects of the ventricle and widespread distal abnormalities. The perfusion scintigram clarified the equivocal stress electrocardiogram.

coronary angiogram revealed triple vessel disease. Figure 7 illustrates the resting and stress electrocardiogram and scintigram in a patient with severe left ventricular hypertrophy. Again, conduction abnormalities associated with left ventricular hypertrophy made electrocardiographic interpretation hazardous. The stress scintigram was entirely normal in this patient with normal coronary arteries. Another patient (Fig. 8) had an abnormally depressed resting electrocardiographic S-T segment and a history of atypical chest pain. The stress electrocardiogram showed significant S-T segment depression, but definite interpretation was difficult because of the abnormality at rest. The stress scintigram clearly shows new perfusion abnormalities in the region of the left ventricular posterior lateral wall, the septum and the apex, indicating significant lesions in the left anterior descending and left circumflex coronary arteries. The region supplied by the right coronary artery shows the best relative perfusion. Coronary angiography revealed severe triple vessel disease.

When the 19 equivocal tests were further analyzed, 9 of the 12 patients with significant coronary lesions had further stress-induced S-T segment depression of 1 mm or more; however, 6 of the 7 patients without significant coronary lesions also had such stress-induced S-T changes. In this latter group, the scintigram tended to demonstrate greater specificity than the stress electrocardiogram, but the trend was not significant because of the small number of patients studied. However, when the total of 19 patients was considered, the stress scintigram again predicted the correct angiographic diag-

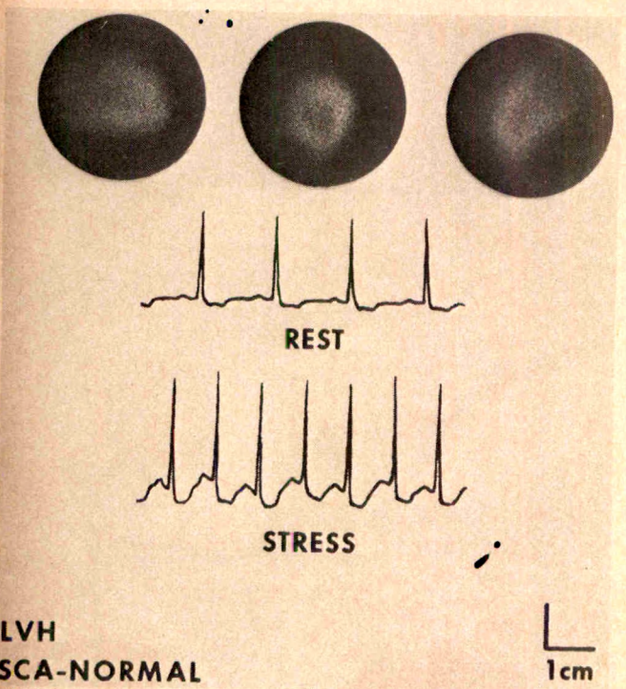

FIGURE 7. Normal scintigram and equivocal stress electrocardiogram in a patient with normal coronary arteries on angiography (SCA). Resting **(top)** and stress **(bottom)** electrocardiogram and stress scintigram in the anterior **(left),** left anterior oblique **(center)** and left lateral **(right)** projections in a patient with troublesome atypical chest pain and a history of hypertension. The full resting electrocardiogram revealed severe left ventricular hypertrophy (LVH). The monitored lead showed S-T segment depression that deepened with stress and was difficult to interpret in view of the depression at rest. The perfusion image was normal and clarified the stress electrocardiogram.

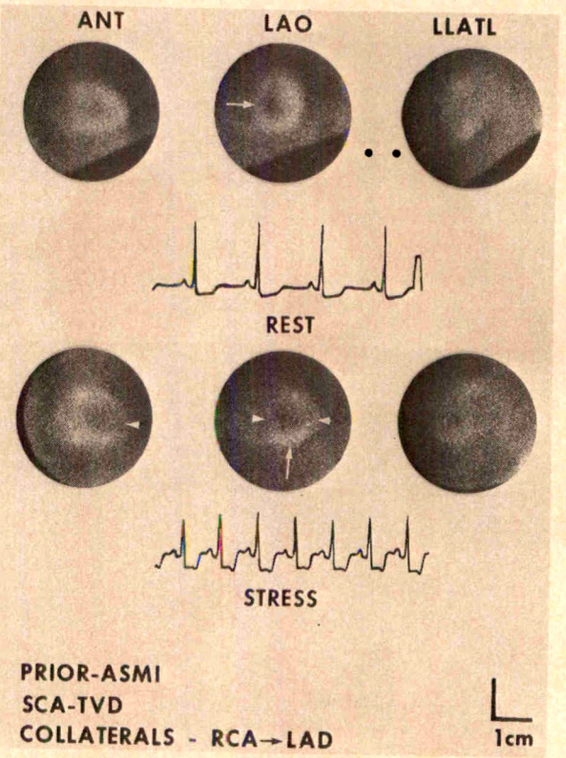

FIGURE 8. Perfusion scintigram and triple vessel disease. Resting **(top)** and stress **(bottom)** electrocardiogram and scintigram in the anterior (ANT), left anterior oblique (LAO) and left lateral (LLATL) projections in a patient with atypical chest pain. The resting scintigram showed subtle diminution in relative septal activity suggestive of a prior anteroseptal myocardial infarction (ASMI) in this region **(arrow).** Radionuclide distribution changed drastically with stress, exposing gross abnormalities of the left ventricular posterior lateral walls, septum and apex **(arrow points).** The study is consistent with severe coronary disease and stress-induced malperfusion involving at least two vessels, the left anterior descending and the left circumflex coronary arteries. The region of right coronary perfusion appears "best" perfused **(vertical arrow in stress scintigram).** Because this is a relative study, it is not necessarily true that the region of "best" perfusion is the region of normal perfusion. Here, the right coronary artery had severe localized stenosis in the presence of severe triple vessel disease (TVD). The stress electrocardiogram was difficult to interpret in the presence of resting S-T segment abnormalities in this patient taking digoxin. Abbreviations as in Figure 3.

nosis more frequently than the stress electrocardiogram. The scintigraphic accuracy rate of 89 percent was significantly better ($P < 0.05$) than the 53 percent accuracy rate of the stress electrocardiogram in patients with S-T segment depression at rest.[15]

Prior myocardial infarction: Forty-one of the 65 patients studied had significant coronary artery disease, including 15 with documented historical and electrocardiographic evidence of prior transmural infarction. All 15 patients with prior infarction had an abnormal resting scintigram, and 12 of these had new stress-induced image abnormalities that in 8 were in regions remote from the site of infarction. The stress electrocardiogram was abnormal in 7 of these 12 patients, equivocal in 3 and normal in 2. One patient with prior infarction had stress-induced electrocardiographic abnormalities in the absence of stress-induced scintigraphic change.

Scintigraphic localization, overall sensitivity and reproducibility: Correlation of the location of image abnormalities with the coronary anatomy was excellent. Scintigraphic defects corresponded well with the distribution of coronary arterial lesions. With one exception, all patients who had a significant scintigraphic septal abnormality had left anterior descending coronary artery disease; the single exception had significant stenosis in a dominant right coronary artery. Except in the two patients with a false positive scintigram, inferior wall abnormalities were always associated with right coronary arterial lesions and posterior lateral wall abnormalities were always associated with left circumflex lesions.

Although the presence of a perfusion defect on scintigraphy correlated well with a stenotic lesion in the appropriate coronary artery, the absence of a perfusion defect in a given myocardial region did not exclude a coronary lesion in the vessel perfusing that segment, especially in patients with multivessel disease. The image identified lesions in only 41 of 89 significantly affected vessels (46 percent). Thus, although scintigraphic sensitivity identified the presence of coronary

disease in a given patient, it did not identify all sites of coronary involvement.

Our results according to the degree of arterial involvement are shown in Table II. Among the 65 patients studied, 41 had significant coronary arterial lesions, including 8 with single, 18 with double and 15 with triple vessel disease. The scintigram was abnormal in 6 of 8 patients (75 percent) with single vessel disease, 16 of 18 patients (88 percent) with double vessel disease and 13 of 15 patients (86 percent) with triple vessel disease. If one excludes the 19 patients with an equivocal stress test, the stress electrocardiogram was abnormal in 1 of 4 patients (25 percent) with single vessel disease, 10 of 14 patients (71 percent) with double vessel disease and 7 of 9 patients (77 percent) with triple vessel disease.

Fifty scintigrams were interpreted by the same reader in a blinded fashion for a second time. There was total agreement with the initial reading in 45 cases (90 percent). Differences in interpretation in the other five cases were generally minor, resulting in differences only in localization but not in presence of scintigraphic abnormalities. The second reading resulted in an altered diagnosis in only two cases.

TABLE II

Test Results According to the Degree of Coronary Arterial Involvement in 41 Patients With Significant Lesions

Vessels Involved (no.)	Patients (no.)	Stress Electrocardiogram		Positive Scintigram
		Positive	Equivocal	
1	8	1	4	6
2	18	10	4	16
3	15	7	6	13
Totals	41	18	14	35

Discussion

Methods of diagnosing coronary disease: The standard for diagnosis of coronary artery disease remains the indirect anatomic evidence of selective coronary angiography. In a rough, imprecise manner, the degree of coronary stenosis is assessed and assumptions are made concerning its effect on myocardial blood supply and its pathologic significance. No effort is made to evaluate objectively myocardial demands. The stress electrocardiogram attempts to assess in a noninvasive manner both components of the oxygen supply/demand ratio. Presumably this test is abnormal when a decrease in this ratio reaches pathologic significance regardless of the observed coronary arterial anatomy. Potentially this eliminates our need to quantitate visually the coronary lesion involved. However, stress electrocardiography has problems of insensitivity and nonspecificity.[16,17] A variety of conditions, including conduction defects, left ventricular hypertrophy, drugs, hyperventilation and electrolyte abnormalities, make interpretation of the stress electrocardiogram hazardous.[18–21] Even the female sex has been invoked as a potential cause of the false positive stress test.[22]

Relative myocardial perfusion scintigraphy using thallium-201 is another noninvasive method of diagnosing pathologically significant coronary lesions without direct anatomic assessment. As an indicator of relative myocardial perfusion, scintigraphy evaluates coronary supply and identifies the heterogeneity of myocardial blood flow evoked by increasing coronary flow demand in vessels with varied and limited abilities to accommodate this demand and having an altered "coronary flow reserve."[23] Although flow through stenotic vessels may be normal at rest, exercise stimulates a less than normal increment in the flow through vessels with a diminished flow reserve.[23] The results of such altered reserve among normal, partially stenotic and occluded vessels is stress-induced heterogeneity of coronary flow, appreciated in the scintigram as "hot and cold" regions.

Advantages of scintigraphy: The anatomic correlation between thallium-201 scintigraphic defects and lesions on angiography was excellent in our study and in general agreement with the findings of Bailey et al.[24] Such localization of coronary lesions is not possible with single lead electrocardiographic monitoring systems and would probably present difficulties for multiple lead systems.[2,3,25] The ability of relative perfusion scintigraphy to identify multiple lesions in a given patient has not previously been reported. Although scintigraphy quite sensitively identified patients with coronary lesions, it identified only 46 percent of all involved vessels. In the presence of an adjacent scintigraphic defect, the image could not exclude a coronary lesion in an apparently normally perfused region. In patients with isoelectric S-T segments at rest, perfusion scintigraphy is more accurate and probably more sensitive and specific than stress electrocardiography for the identification of coronary disease. Even in patients with depressed S-T segments at rest, scintigraphy was probably more specific and certainly more accurate than stress electrocardiography. Four patients with significant coronary lesions had a normal stress electrocardiogram and an abnormal stress scintigram at suboptimal stress, thus indicating another level where the stress scintigram has greater sensitivity than the stress electrocardiogram. The presence of both an abnormal stress electrocardiogram and an abnormal stress scintigram guaranteed the presence of significant coronary disease in our study. These findings agree with and extend our observations and those of others in studies using rubidium-81[2,3] as well as the preliminary data from studies using thallium-201.[26,27] However, although others have shown that scintigraphy adds to the diagnostic sensitivity of stress electrocardiography, increased accuracy of scintigraphy alone has not previously been documented and Bailey et al.[24] could only approximate image specificity because most of their "normal" subjects did not undergo cardiac catheterization. We have shown that scintigraphic evaluation maintains its accuracy even in the setting of S-T segment depression at rest, a condition that often is related to sensitive but nonspecific results and that may prevent or cloud stress test interpretation in as many as one fourth to one third of patients with potential coronary artery disease.[28,29] This finding

supports the preliminary results of Bailey et al.[24] in patients with equivocal treadmill results. However, whereas they noted that scintigraphy improved sensitivity for coronary diagnosis in such patients, our study indicates that it improved specificity. Similar to our experience with the stress scintigram and similar to the results of others,[30] we found that scintigrams obtained at rest were extremely sensitive for identifying and localizing prior transmural infarction in the few cases studied.

We monitored only a single electrocardiographic lead. Although it has been shown that monitoring inferior as well as anterior leads may increase the sensitivity of the electrocardiographic technique, it would probably also decrease the specificity and probably would not help to resolve the equivocal test.

Clinical implications: Our standard for the diagnosis of coronary artery disease was based on assessment of coronary angiographic results. Although scintigraphic correlation with angiographic data was clear, the true indicator of significant disease remains unclear. Cases of false positive or false negative scintigrams may in part reflect only our difficulty in assessing the anatomic degree and significance of coronary stenosis. In fact, three patients with "significant" lesions on angiography had normal findings on stress electrocardiography and scintigraphy. Alternatively, the latter two methods may be insensitive to subtle ischemic changes. Similarly, the exact meaning of the abnormal stress electrocardiogram in the absence of significant coronary lesions remains unclear. It is likely that scintigraphic and electrocardiographic indicators of myocardial ischemia measure different variables. The stress-induced scintigraphic abnormalities largely reflect perfusion changes,[3–9,11,25,26,30] whereas stress-induced electrocardiographic changes probably reflect hypoxic, metabolic and electrophysiologic alterations resulting from changes in perfusion. Metabolic evidence of ischemia due to small vessel coronary disease or other cause was not available. However, other possible causes of myocardial ischemia do not carry the dire prognosis of significant large vessel coronary disease.[31] Scintigraphy is more accurate than stress electrocardiography in diagnosing large vessel coronary disease. This increased accuracy of perfusion scintigraphy is probably the reason for its success thus far in differentiating coronary artery disease from other noncoronary causes of ischemia.[32,33] More definite assessment and resolution of these problems may occur with combined angiographic, scintigraphic and metabolic studies.

Initial fears of the inability of the scintigraphic method to identify the presence of severe triple vessel disease due to generalized and uniform diminution of coronary flow reserve appear unrealized. Whereas Bailey et al.[24] found increased scintigraphic sensitivity with increased arterial involvement, we found that the scintigram was equally sensitive in single, double or triple vessel disease. However, the stress electrocardiogram showed a tendency toward increased sensitivity with increased arterial involvement, as previously documented.[23,34] We studied only two patients with left bundle branch block, both with a correct scintigraphic diagnosis, and can make no specific conclusion concerning recent observations[35] on resting membrane abnormalities and their scintigraphic effects in this condition.

Perfusion scintigraphy did not identify all involved coronary vessels. Using the technique as an indicator of relative coronary flow, one would expect the region of greatest flow to appear most intense. Regions of normal flow could not be differentiated from regions of absolutely reduced yet "best" flow in a patient with multivessel disease. The regions best visualized in the stress scintigrams shown in Figures 6 and 8, both from patients with triple vessel disease, were perfused by severely stenotic vessels. Indirect evidence that the region of greatest image intensity is indeed best perfused may come from future evaluation of the coronary collateral circulation. Similarly, regions perfused by significantly stenotic vessels may appear normally or "best" perfused if they are in proximity to more severely stenotic lesions or regions of dense infarction.[3] This may explain the single patient with prior infarction and significant coronary disease who had a positive stress electrocardiogram in the absence of stress-induced image abnormalities.

Technical considerations: Perfusion scintigraphy with thallium-201 is simple to perform, safe and reproducible.[3,27] The 73 hour thallium-201 physical half-life permits a storage shelf life of 1 week, and imaging is facilitated by the radionuclide's small energy of emission (70 to 80 kev) compared with the larger emission energy of agents such as potassium-43 and rubidium-81. However, a potential hazard of the smaller energy of emission of thallium-201 is that tissue attenuation may hamper myocardial resolution, especially in the resting image and in the obese patient where target to background ratios are lowest. Probably because of image attenuation, the myocardium was most poorly resolved in the left lateral projection. Scintigraphic defects seen only in this projection were not interpreted as abnormal unless associated with defects in other projections. We encourage use of the highest resolution scintillation camera. The prolonged half-life of thallium-201 may hamper rapid performance of repeat studies and the radionuclide's present high cost is another disadvantage. Although computer methods of enhancing images may aid scintigraphic interpretation, there is as yet no such established method that improves sensitivity without increasing the false positive rate. Although Bailey et al.[24] demonstrated good scintigraphic results using processed images, such findings have little relevance to centers seeking to apply the study clinically without computer assistance. Our study demonstrated excellent results without computer enhancement.

Hemodynamics at Rest and During Supine and Sitting Bicycle Exercise in Normal Subjects

UDHO THADANI, MBBS, MRCP, FRCP (C)*
JOHN O. PARKER, MD, FRCP (C), FACC

Kingston, Ontario, Canada

To assess left ventricular function and to compare mean pulmonary wedge pressure and left ventricular end-diastolic pressure in the supine and sitting positions, 10 patients without demonstrable cardiovascular disease underwent hemodynamic studies at rest and during exercise in the two positions. At rest the values for heart rate were higher and the values for cardiac index, stroke index, left ventricular stroke work index, mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure were lower in the sitting position. During both supine and sitting exercise left ventricular end-diastolic pressure, cardiac index, stroke index and left ventricular stroke work index increased significantly from the resting values. Comparison of data during exercise revealed higher values for heart rate and rate-pressure product and lower values for pulmonary capillary wedge pressure, left ventricular end-diastolic pressure and stroke index in the sitting position; systolic and mean systemic pressure, cardiac index and left ventricular stroke work index were similar during the two exercise periods. When absolute changes from rest to exercise were compared, the increase in heart rate, systolic blood pressure, pulmonary capillary wedge pressure, left ventricular end-diastolic pressure, cardiac index, stroke index, and left ventricular stroke work index were similar in the two positions. There was a good correlation between left ventricular end-diastolic pressure and pulmonary capillary wedge pressure at rest and during exercise in the two postures.

Recent studies in patients with coronary artery disease[1] have shown marked differences in the hemodynamic patterns in the supine and upright positions both at rest and during exercise. In these patients, left ventricular filling pressures were substantially lower during upright exercise than during exercise in the supine position. Comparative hemodynamic data are available in normal subjects at rest and during exercise in supine and upright postures,[2–13] and the normal values for left ventricular filling pressure during supine exercise have been defined.[14,15] However, no information is available regarding left ventricular filling pressure either at rest or during exercise in the upright posture.

This communication presents hemodynamic data including left ventricular end-diastolic pressure and pulmonary capillary wedge pressure measurements obtained at rest and during supine and upright exercise in patients without demonstrable cardiovascular disease.

Methods

Subjects: Hemodynamic investigations with subsequent selective coronary cinearteriography and left ventriculography were performed in 10 men aged 32 to 58 years (average 46 years). All were leading a sedentary life and were referred for investigation of chest pain. The majority of of these patients had been considered to be suffering from coronary artery disease and had been advised by their family physicians to restrict their level of activity. All had sinus rhythm and were normotensive. Cardiac examination was normal and no subject had

clinical or radiologic evidence of cardiomegaly or cardiac failure. None manifested chest pain or S-T segment depression during treadmill exercise testing. Despite the atypical nature of symptoms in many patients and the negative stress test it was felt advisable to perform angiographic studies to determine whether coronary artery disease was present. None had been taking medications for at least 7 days before the investigation.

Protocol: On the day before the investigation, the patients were taken to the laboratory, the study explained and informed consent obtained. Each patient then exercised on a bicycle ergometer in both the supine and sitting positions. During the supine exercise, the ergometer was positioned over the catheterization table, the axle being 12 inches (30.5 cm) above the table level. The work load that would induce mild fatigue while permitting exercise to be continued for 4 to 6 minutes was determined for each subject. These work loads (range 300 to 1250 kilopond-meters per minute) were recorded and were subsequently utilized in the definitive studies.

Patients were studied in the fasting state 2 hours after receiving an oral dose of 10 mg of diazepam. Under local anesthesia, the brachial artery and a vein were isolated in the right antecubital fossa. A no. 7 Swan-Ganz catheter was passed to one of the branches of the pulmonary artery supplying the right lower lobe. The position of the catheter was considered satisfactory only if good quality pulmonary capillary wedge pressure measurements were obtained after balloon inflation. A no. 8 Lehman ventriculographic catheter was inserted into the left ventricle from the right brachial artery, and the left brachial artery was cannulated with a Teflon® needle using the Seldinger technique.

Each patient was studied in both the supine and sitting positions at rest and during bicycle exercise at the predetermined work loads. A rest period of 15 minutes followed the instrumentation and a 30 minute rest period was interspaced between the two periods of exercise. The order of exercise was randomized; five patients exercised first in the upright position and five patients first in the supine position. Great care was taken in moving patients from the supine to sitting positions with continuous electrocardiographic and left ventricular pressure monitoring.

The electrocardiogram (modified lead V_5) and intracardiac and intravascular pressures were recorded at 5 minute intervals during a 10 minute control period at rest in both the supine and sitting postures, and during the final 2 minutes cardiac output was measured in duplicate with the dye-dilution technique using indocyanine green. During exercise, the electrocardiogram and pressures were monitored continually and recorded at 1 minute intervals. Cardiac output was measured in duplicate between 3 and 5 minutes of exercise and then the final pressure measurements were made and exercise discontinued.

Measurements and recordings: Pressures were measured with P23 DB Statham strain gauges from a zero reference level 5 cm below the level of the angle of Louis in the studies in the supine position, and from the fourth intercostal space at the sternal border in the sitting position. Pressures were measured over at least two respiratory cycles, and the mean pressures in the brachial artery, pulmonary artery and pulmonary capillary wedge positions were obtained electronically. Recordings were made on a photographic recorder at a paper speed of 25 mm/sec; however, for determination of left ventricular end-diastolic pressure and pulmonary capillary wedge pressure, a speed of 100 mm/sec was employed and these pressures were measured at a high level of sensitivity.

Left ventricular stroke work index (g-m/m^2) was calculated using the formula LVSWI = SI × (BAm − LVEDP) × 13.6/1000, where SI = stroke index (ml/beat per m^2), BAm = brachial arterial mean pressure (mm Hg) and LVEDP = left ventricular end-diastolic pressure (mm Hg). *Systolic ejection rate index* (ml/sec per m^2) was calculated using the formula SI/SEP where SEP = systolic ejection period in seconds obtained from the brachial arterial tracings at a speed of 100 mm/sec. In two patients, left ventricular end-diastolic pressure was not measured in the sitting position because of ventricular irritability, and in these patients values of pulmonary capillary wedge pressure were substituted for left ventricular end-diastolic pressure in the calculations for both the supine and sitting position. *The rate-pressure product* (mm Hg/min × 10^{-2}) was calculated as the product of systolic arterial pressure and heart rate × 10^{-2}. The first derivative of the left ventricular pressure curve (dP/dt [mm Hg/sec]) was obtained using an electronic differentiator.

After completion of these hemodynamic studies, selective

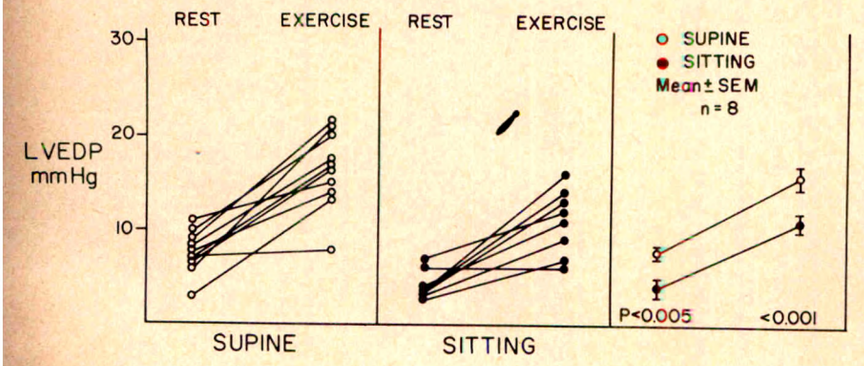

FIGURE 2. Individual and group mean values of left ventricular end-diastolic pressure (LVEDP) in the supine and sitting positions at rest and during exercise. Left ventricular end-diastolic pressure in the sitting position was recorded in only eight subjects.

coronary cineangiography and left ventriculography were carried out in all patients. For the statistical analysis of data, Student's paired t test was used.

Results

The hemodynamic and angiographic studies were completed without complications. None of the patients experienced chest pain or manifested S-T segment depression during exercise. Two subjects performed greater work loads in the sitting position and another performed a greater work load in the supine position. The remaining seven subjects performed similar work loads during the two exercise periods. The work loads required to induce fatigue during upright exercise (590 ± 289 kilopond-meters per minute) (mean ± standard deviation) and during supine exercise (589 ± 211 kilopond-meters per minute) were similar. Left ventriculography and selective coronary angiography revealed normal findings in all subjects.

Studies in the Supine Position (Table I)

Resting hemodynamics: In the supine studies, mean pulmonary capillary wedge pressure averaged 6 mm Hg (range 3 to 8), and left ventricular end-diastolic pressure averaged 8 mm Hg (range 4 to 11) (Fig. 1 and 2). These differences were significant ($P < 0.01$) and the correlation coefficient was $r = 0.94$ (Fig. 3). Cardiac index averaged 3.5 liters/min per m^2 (range 3.0 to 5.0), stroke index averaged 50 ml/m^2 (range 32 to 84) and left ventricular stroke work index averaged 61 $g\text{-}m/m^2$ (range 47 to 108).

Exercise hemodynamics: During exercise there were significant increases from resting values in heart rate; systolic, diastolic and mean systemic arterial pressure; rate-pressure product; mean pulmonary arterial pressure and pulmonary capillary wedge and left ventricular end-diastolic pressures (Fig. 1, 2, 4 and 5). The group mean values were heart rate 128 ± 6 beats/min (mean ± standard error of the mean), systolic blood pressure 178 ± 6 mm Hg and mean pulmonary arterial pressure 24 ± 2 mm Hg. The mean pulmonary capillary wedge pressure, 13 ± 1 mm Hg, was less than the left ventricular end-diastolic pressure, 16 ± 2 mm Hg ($P < 0.01$); the correlation coefficient between the two pressures was $r = 0.96$ (Fig. 3). During exercise, increases in cardiac index, stroke index, left ventricular stroke work index and systolic ejection rate index were observed in all subjects (Fig. 6 to 8).

Studies in the Sitting Position (Table I)

Resting hemodynamics: In the sitting position, mean pulmonary capillary wedge pressure averaged 4 mm Hg (range 1 to 6) and left ventricular end-diastolic pressure, recorded in eight patients, averaged 4 mm Hg (range 3 to 7); the correlation coefficient between the

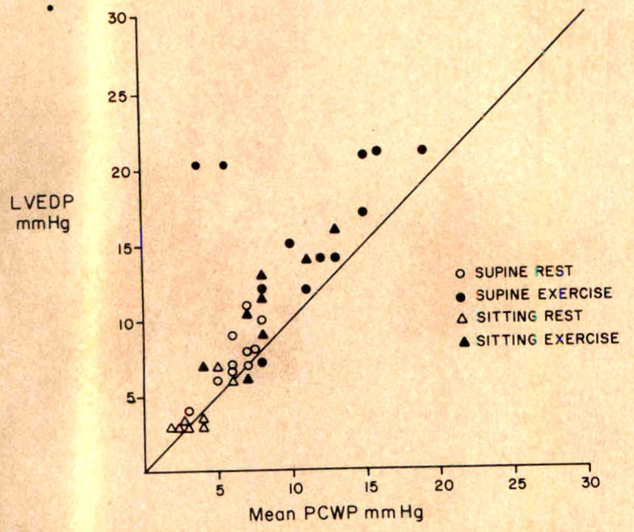

FIGURE 3. Relation between mean pulmonary capillary wedge pressure (PCWP) and left ventricular end-diastolic pressure (LVEDP) at rest and during exercise. There is a good correlation between the two pressures at rest ($r = 0.94$ supine and 0.92 sitting) and during exercise ($r = 0.96$ supine and 0.91 sitting).

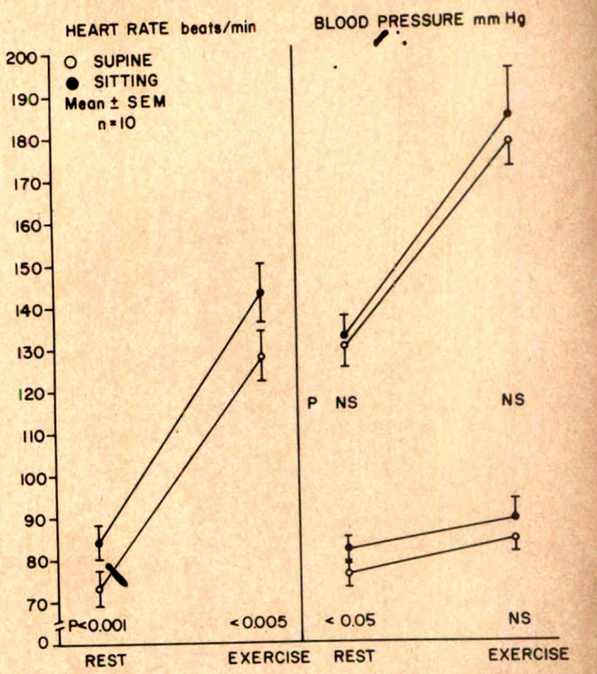

FIGURE 4. Group mean values for heart rate and systemic arterial blood pressure at rest and during exercise. NS = not significant.

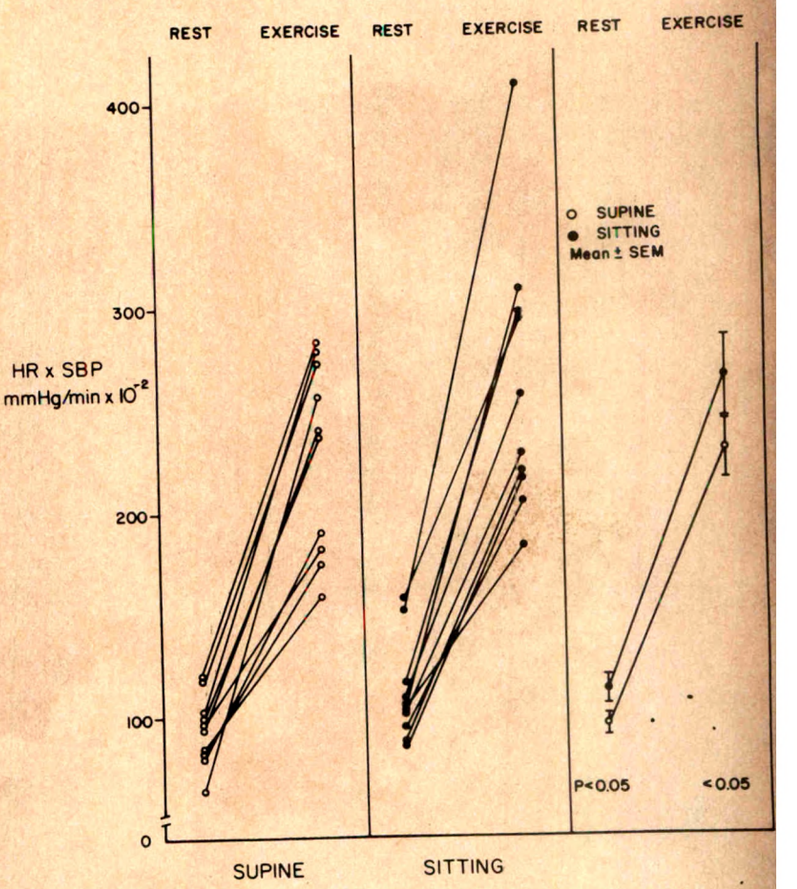

FIGURE 5. Individual and group mean changes in rate-pressure product from rest to exercise. Both at rest and during exercise, group mean values of rate-pressure product were significantly higher in the sitting position. HR × SBP = rate-pressure product (heart rate × systolic blood pressure [mm Hg/min × 10^{-2}]).

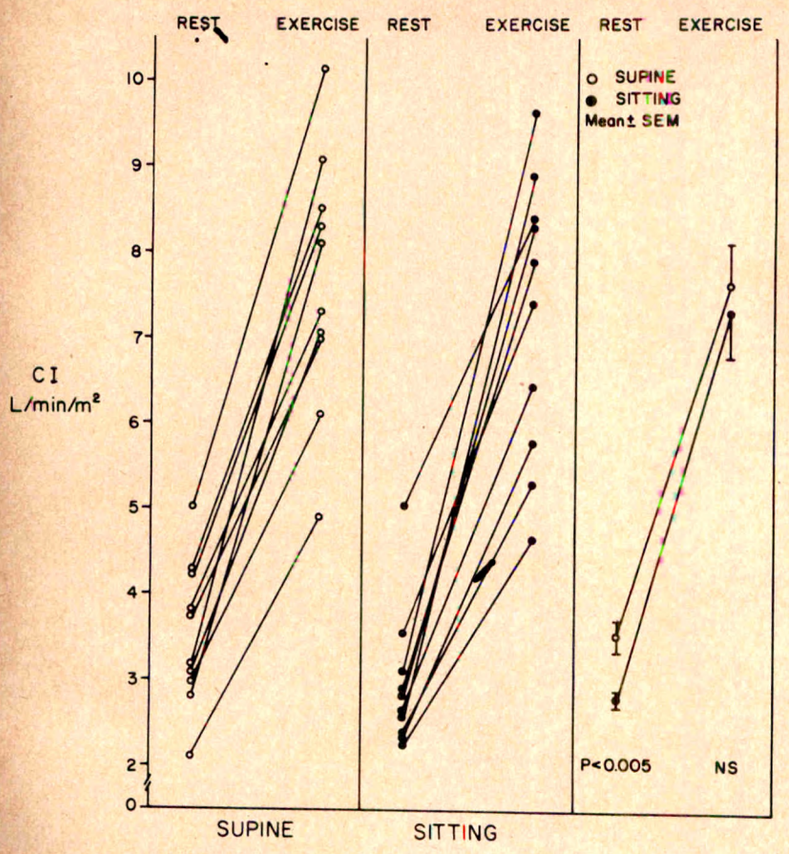

FIGURE 6. Individual and group mean values for cardiac index (CI) at rest and during exericse. At rest, cardiac index is significantly lower in the sitting position.

two pressures was $r = 0.92$ (Fig. 3). The cardiac index averaged 2.8 liters/min per m^2 (range 2.4 to 3.7), stroke index averaged 35 ml/m^2 (range 24 to 52) and left ventricular stroke work index averaged 44 g-m/m^2 (range 32 to 57).

In comparison with the resting values in the supine position, the values for heart rate and diastolic arterial pressure were higher and those for mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure were lower in the sitting posture (Fig. 1, 2 and 4). In the sitting position, mean cardiac index was 2.8 ± 0.2 liters/min per m^2 and was significantly lower than in the supine position (3.5 ± 0.3 liters/min per m^2) ($P < 0.001$) (Fig. 6). Similarly, stroke index (35 ± 3 versus 50 ± 5 ml/beat per m^2) ($P < 0.001$) and left ventricular stroke work index (44 ± 3 versus 61 ± 6 g-m/beat per m^2) ($P < 0.001$) were lower in the sitting position (Fig. 7 and 8).

Exercise hemodynamics: During exercise in the sitting position, there were increases in heart rate, systolic and mean systemic arterial pressures, mean pulmonary arterial pressure and pulmonary capillary wedge and left ventricular end-diastolic pressures (Fig. 1, 2, 4 and 5). The mean values were heart rate 146 ± 7 beats/min, systolic blood pressure 184 ± 7 mm Hg, mean pulmonary arterial pressure 22 ± 1 mm Hg, mean pulmonary capillary wedge pressure 8 ± 1 mm Hg and left ventricular end-diastolic pressure 11 ± 1 mm Hg. There was a tendency for left ventricular end-diastolic pressure to be greater than the mean pulmonary capillary wedge pressure ($P < 0.05$); the correlation coefficient between the two pressures was $r = 0.91$ (Fig. 3). During exercise, increases in cardiac index, stroke index, left ventricular stroke work index and systolic ejection rate index were observed in all subjects (Fig. 6 to 8).

Comparison of values obtained during supine exercise showed that in the sitting position there were significantly higher values for heart rate and rate pressure product (Fig. 4 and 5), similar values for systolic and mean systemic arterial pressures, mean pulmonary arterial pressure, cardiac index, left ventricular stroke work index and systolic ejection rate index (Fig. 4, 6 and 8) and lower values for mean pulmonary capillary wedge pressure, left ventricular end-diastolic pressure and stroke index (Fig. 1, 2 and 7).

However, when changes from rest to exercise in the sitting and supine postures were compared, it was observed that the increases in the variables measured were similar in the two positions: heart rate (59 versus 55 beats/min), systolic blood pressure (52 versus 47 mm Hg), mean systemic arterial pressure (22 versus 23 mm Hg), rate-pressure product (145 versus 134 mm Hg/min $\times 10^{-2}$), mean pulmonary arterial pressure (9 versus 11 mm Hg), mean pulmonary capillary wedge pressure (4 versus 7 mm Hg), left ventricular end-diastolic pressure (7 versus 8 mm Hg), cardiac index (4.5 versus 4.2 liters/min per m^2), stroke index (17 versus 11 ml/beat per m^2) and left ventricular stroke work index (36 versus 26 g-m/beat per m^2). On the other hand, increases in systolic ejection rate index were greater in the sitting position than during supine exercise (94 versus 66 ml/sec per m^2) ($P < 0.05$).

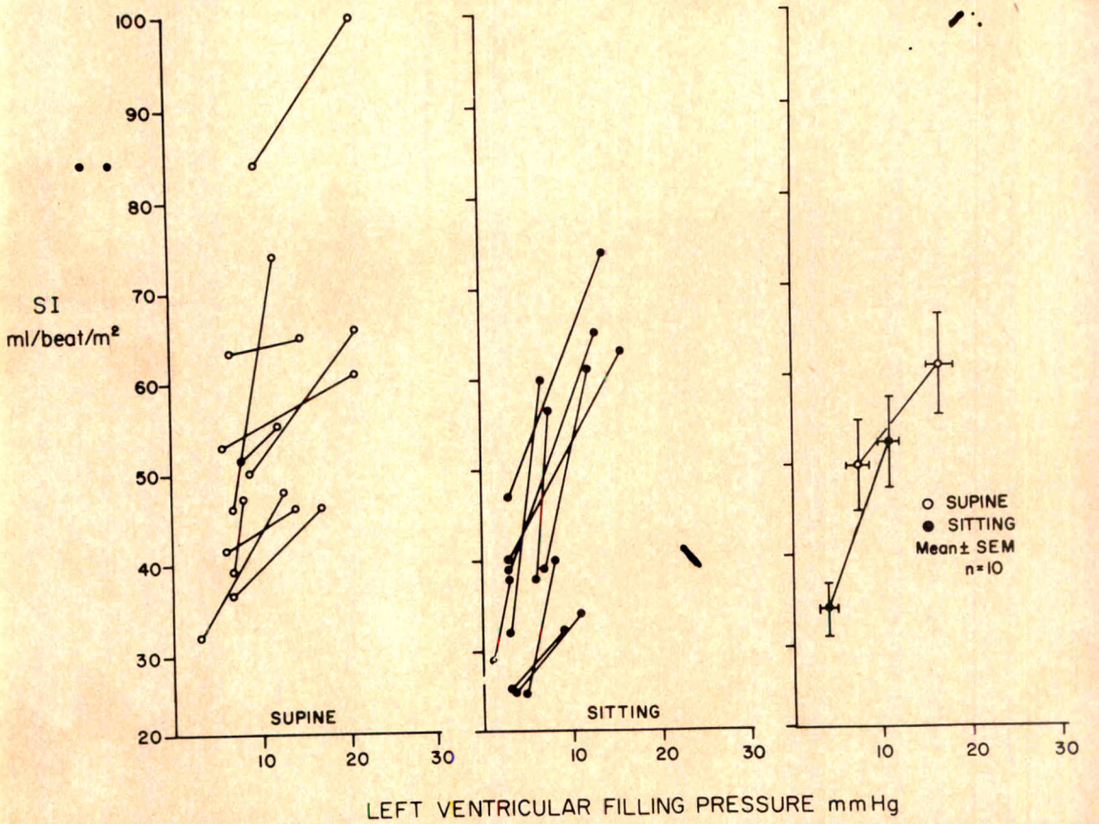

FIGURE 7. Relation between left ventricular filling pressure and stroke index (SI) at rest and during exercise in the two positions. The lines joining the points in the left and middle columns represent individual values at rest and during exercise, respectively. The group mean values for stroke index and left ventricular filling pressure were significantly lower both at rest and during exercise in the sitting position.

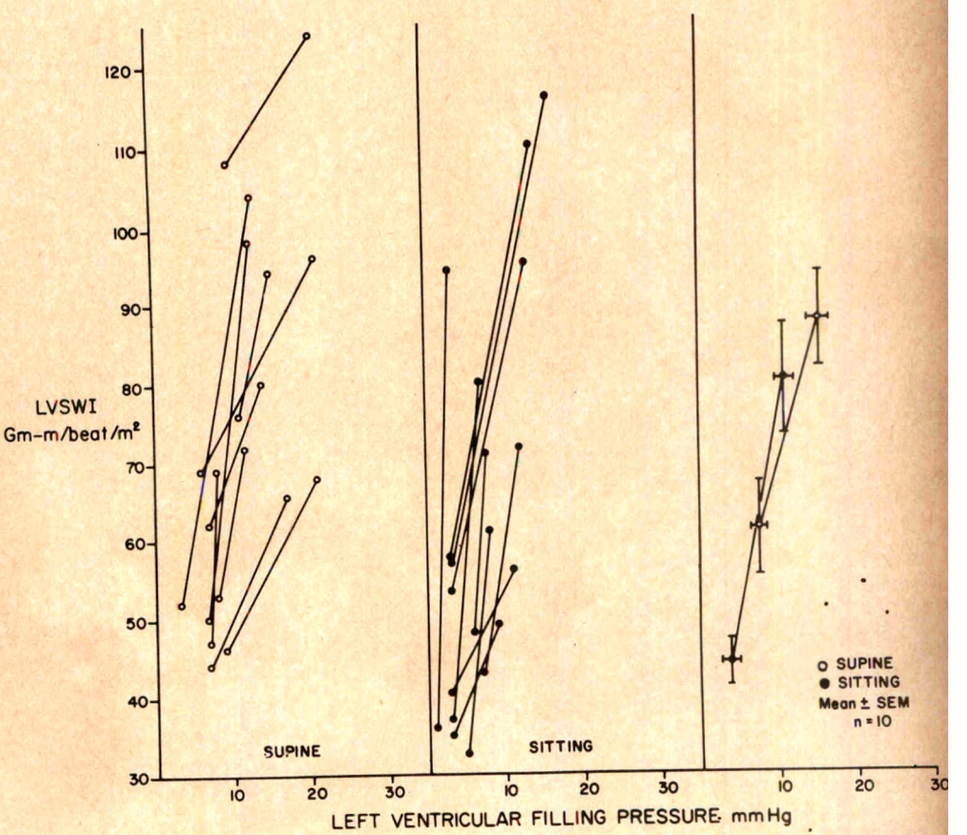

FIGURE 8. Relation between left ventricular filling pressure and left ventricular stroke work index (LVSWI) (g-m/beat per m^2) at rest and during exercise in the two positions. The lines joining the points in the left and middle columns represent individual values at rest and during exercise, respectively. At rest, the group mean values for left ventricular stroke index and left ventricular end-diastolic pressure were significantly lower in the sitting position. However, during exercise, the group values for left ventricular stroke index were similar in the two postures.

Discussion

Hemodynamics at Rest in Supine Versus Sitting Posture

This study has shown that in normal untrained subjects, the hemodynamic profile in the supine and sitting postures is different both at rest and during exercise. At rest in the supine position the left ventricular filling pressure was normal in all subjects. In normal subjects, no information is available regarding left ventricular end-diastolic pressure or pulmonary capillary wedge pressure in the upright position. Mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure averaged 4 mm Hg in the upright posture; these values were significantly lower than those obtained in the supine posture. It should be pointed out that the zero reference levels for pressure measurement were different in the two positions. The standard technique for measuring pressures in the supine position in our laboratory is from a zero reference level 5 cm below the level of the angle of Louis, whereas for studies in the sitting position we chose a reference level at the fourth intercostal space at the border of the sternum. In the sitting position, it was not possible to define exactly the location of the catheter in the ventricular chamber. The mid portion of the left ventricle in the sitting posture often lies in the fifth or sixth intercostal space and it is possible that the pressures recorded from this chamber in the sitting position were somewhat underestimated.

The resting values for cardiac index, stroke index and left ventricular stroke work index were significantly lower in the sitting position and these observations are in keeping with previous reports in normal human subjects and in patients with coronary artery disease.[1–13] In the present study, the heart rate in the sitting position was higher than in the supine posture and it would appear that the lower cardiac index and stroke index in this position were due primarily to diminished venous return.

Hemodynamics During Exercise in Supine Versus Sitting Posture

Left ventricular pressure: During supine exercise, both the mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure increased significantly. The increase in left ventricular filling pressure during supine leg exercise observed in our study and in previous reports[14,15] is at variance with some published data in normal subjects.[16–18] In the latter reports, left ventricular filling pressure and volumes during supine exercise either did not change or actually decreased from the resting values. These differences may well be due to varying methods of carrying out exercise in the supine posture. In our studies, the bicycle ergometer was placed so that the legs were elevated above the chest during supine exercise. Thus, increased venous return might have been responsible for the increased left ventricular filling pressures. This seems unlikely, however, because the left ventricular end-diastolic pressure in the same patient increased by a similar amount during upright bicycle exercise.

There are no previous data relating to left ventricular end-diastolic pressure or pulmonary capillary wedge pressure during exercise in the sitting position in normal subjects. In our study during exercise in the sitting position, both the mean pulmonary capillary wedge and left ventricular end-diastolic pressures increased. Although the absolute values for these pressures during exercise were lower in the sitting than in the supine posture, the increases in these pressures from rest to exercise in the two postures were similar. In contrast, previous studies in patients with coronary artery disease[1] demonstrated significantly smaller increases in left ventricular filling pressure during sitting than during supine bicycle exercise.

Cardiac output: In normal human subjects, the cardiac output during supine leg exercise increases as a linear function of oxygen consumption.[11] However, the changes reported in stroke volume during exercise have been variable. A review of published findings by Rushmer[19] in 1959 showed that in normal subjects the stroke volume changed only slightly over a wide range of exercise. Ten healthy men studied by Bevegård et al.[5] more than doubled their cardiac output during supine leg exercise with increases in stroke volume averaging less than 5 percent. Ross and co-workers[18] studied patients with no evidence of impaired cardiac reserve. During supine exercise, these subjects attained a cardiac index of up to 10 liters/min per m^2, whereas the stroke volume was unchanged in four and increased in two subjects and decreased in one subject. In our study, cardiac output during supine leg exercise increased significantly in all subjects; stroke volume increased in nine and was unchanged in the remaining subject. Cardiac output increased an average of 120 percent during supine exercise and stroke volume an average of 22 percent. These observations are in agreement with previous reports in normal subjects from this laboratory.[14] Thus, it would appear that in normal subjects there is a wide individual variation in the changes in stroke volume during supine leg exercise. It is difficult to reconcile the differences in results from different laboratories, but these may well be due to differences in the study population or the leg position during exercise. In our study, an increase in left ventricular stroke work index was observed during supine exercise in all subjects. These observations are in accord with previous reports in normal subjects,[14] but are different from those reported in patients with coronary artery disease.[1,14] In the latter group, the cardiac index increased but there was no significant increase in stroke index or left ventricular stroke work index during exercise in the supine posture.[1,14]

During exercise performed in the sitting position, the cardiac output also increases linearly with oxygen consumption.[11] In our study, the cardiac output during bicycle exercise in the sitting position increased by 160 percent from the resting values in this position. However, the values obtained during supine and sitting exercise were similar despite significantly lower resting values in the sitting position.

Stroke volume: When a person sits or stands, the stroke volume and heart volume consistently dimin-

ish.[4,20,21] Beginning at this lower baseline, the stroke volume increases promptly at smaller work loads and approaches the values obtained during supine rest.[4,6,7,22–24] In our study, during exercise in the sitting position, stroke index increased by 71 percent from the resting values in this posture. However, this value during upright exercise was similar to the resting stroke index in the supine posture but was significantly lower than the stroke index during exercise in the supine posture. Left ventricular stroke work index during sitting bicycle exercise increased in all subjects and both the absolute values of this variable during supine and sitting exercise and the increase from rest to exercise were similar in the two postures.

Pulmonary capillary wedge pressure as an index of left ventricular diastolic pressure: Numerous studies in the supine position have confirmed that in the absence of severe pulmonary hypertension or obstruction at the level of the pulmonary veins or left atrium, the mean pulmonary capillary wedge pressure corresponds approximately to the left atrial pressure, which itself is approximately equal to the diastolic pressure in the left ventricle.[1,25,26] Our study shows that the wedge pressure provides a good index of left ventricular end-diastolic pressure at rest and during exercise in both the supine and upright postures. Thus, it should be possible to explore left ventricular hemodynamics in the upright posture using the flotation catheter technique, which is safer than obtaining direct left ventricular pressures.

Abnormal Platelet Survival Time in Men With Myocardial Infarction and Normal Coronary Arteriogram

PETER STEELE, MD
JOSEPH RAINWATER, MD
ROBERT VOGEL, MD

Denver, Colorado

Platelet survival time was measured in eight men who had an acute transmural myocardial infarction and were subsequently found to have a normal coronary arteriogram. Platelet survival (chromium-51 labeling) was shortened in all men (2.4 ± 0.11 days; average half-time ± standard error of the mean) and different from that in eight age-matched normal men (3.7 ± 0.08 days) ($P < 0.001$). Three patients had recurrent venous thromboembolism and one had had iliofemoral arterial thromboembolism. Platelet survival was shortened (2.9 ± 0.12 days) in 11 of 16 age-matched men with transmural infarction who had arteriographic evidence of coronary obstructive disease. These results suggest that platelet survival time is shortened in patients with infarction who subsequently are shown to have a normal coronary arteriogram and that arterial thrombosis may be responsible for the infarction.

Although myocardial infarction is usually associated with arteriographic evidence of atherosclerotic coronary obstruction, examples of infarction in the absence of coronary artery disease have been reported.[1–10] Arterial thrombosis, small vessel coronary disease and arterial spasm are several possibilities that have been considered in the pathogenesis of this problem.[11] A few patients have been described who had thromboembolic occlusion and myocardial infarction at the time of cardiac catheterization.[3,12,13] Coronary arteriograms obtained several months after the infarction were normal, suggesting that complete resolution of thromboembolic coronary arterial occlusion can occur.

In this study platelet survival time was measured in eight men with a transmural myocardial infarction who subsequently were found to have a normal coronary arteriogram. Platelet survival time was also measured in eight age-matched men with a normal arteriogram who had had no infarction and in 16 men with a history of infarction and arteriographic evidence of coronary obstructive disease.

Material and Methods

Patients: Eight men with a myocardial infarction and a normal coronary arteriogram were studied. All had sustained an acute transmural infarction (new Q waves in at least three electrocardiographic leads with evolving S-T changes) 6 to 20 months before study. These men included all patients that we recognized to have this clinical entity. To qualify for study a patient was required to have electrocardiographic evidence for evolving transmural infarction and to have had subsequent coronary arteriography. In addition, all the men had impaired wall motion of the infarcted segment demonstrated with cineventriculography. Six had an anterior wall infarction and two an inferior wall infarction (Table I). Three men had a history of recurrent venous thrombosis and were started on anticoagulant therapy at the time of their infarction. One other patient had a sudden occlusion of the right common femoral artery 5 months before sustaining an acute infarction; embolectomy yielded a thrombus, and a subsequent arteriogram was normal. None of these patients had cardiac valve disease.

Platelet survival time was also measured in eight normal men. These men had a normal coronary arteriogram and had not had a myocardial infarction. They

TABLE I

Men With Infarction and a Normal Coronary Arteriogram

Case no.	Age (yr)	Location of Infarction	Other Thrombosis	Platelet Survival Time (t 1/2) (days)
1	28	Anterior	None	2.6
2	29	Anterior	RVTE*	1.9
3	32	Inferior	RVTE	2.7
4	33	Inferior	Femoral occlusion	2.4
5	34	Anterior	RVTE	2.3
6	38	Anterior	None	2.1
7	40	Anterior	None	2.5
8	42	Anterior	None	2.8
Average ± SEM				2.4 ±0.11

* RVTE = recurrent venous thromboembolism; SEM = standard error of the mean.

were selected from a larger group of normal men by age-matching with the men with infarction. In addition, 16 men in pairs, age-matched with the eight men with infarction, were studied. These 16 men had had a transmural infarction and had arteriographic evidence of coronary obstructive disease.

Platelet survival time: This was measured by labeling the platelets from about 400 ml of the patient's venous blood with 100 to 150 μCi of chromium-51.[14,15] Platelet survival half-time was obtained by computer-assisted least squares fit of a single exponent to 7 days of platelet count-rate data.

Results

Men with myocardial infarction and a normal coronary arteriogram: Platelet survival time was shortened (half-time less than 3.3 days) in all eight men with a myocardial infarction and a normal coronary arteriogram (2.4 ± 0.11 days; average ± standard error of the mean) (Table I). None of these men had hyperlipoproteinemia. Patients 4, 6, 7 and 8 smoked cigarettes (between 1/2 and 2 packs a day) at the time of their infarction and through the measurement of platelet survival time. The coronary arteriogram was normal in all but two men. Patients 4 and 8 had minor luminal irregularities in the right coronary artery and Patient 8 had a minor lesion (less than 20 percent luminal narrowing) in the left anterior descending coronary artery.

Men with a normal coronary arteriogram without infarction: Platelet survival time was normal in all eight of the age-matched normal men and the average was different from that of the men with infarction and a normal arteriogram (3.7 ± 0.08 days) ($P < 0.001$) (Fig. 1). None of the normal men had had thrombosis, none had hyperlipoproteinemia and three smoked cigarettes at the time of study. All underwent coronary arteriography for evaluation of chest pain and the arteriograms were normal in each patient. All had a normal resting 12 lead electrocardiogram. Platelet survival time averaged 3.7 ± 0.04 days in 18 other normal men. Selection of any eight normal men for comparison with the men with infarction would not alter the differences between these two groups. None of the 26 men had a platelet survival time of less than 3.3 days.

Men with myocardial infarction and obstructive coronary disease: Platelet survival time was shortened (2.9 ± 0.12 days) (Fig. 1) in 11 of the 16 men (69 percent) with a history of infarction and abnormal coronary arteries (more than 60 percent obstruction) on arteriography. Average platelet survival time for these 16 men was significantly shorter than in the normal men and significantly longer than in the 8 men with infarction and normal coronary arteriograms. Five of these men had inferior infarction and 11 had anterior, anterolateral or superior-lateral infarction. Nine men had total occlusion of the coronary artery that supplied the infarcted segment and all nine had a shortened platelet survival time. The other seven men had high grade obstructive lesions in the coronary artery to the infarcted segment and five of these had normal platelet survival time.

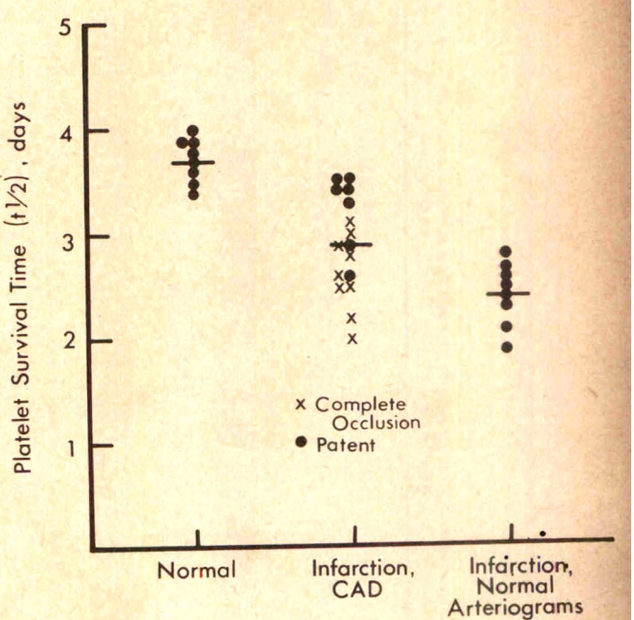

FIGURE 1. Platelet survival time in eight normal men **(left)**, 16 men with a history of myocardial infarction and arteriographic evidence of coronary artery disease (CAD) **(center)**, and eight men with a history of infarction and a normal coronary arteriogram **(right)**. For men with coronary disease, **crosses** represent complete occlusion and **closed circles** represent obstructed but patent coronary arteries.

Discussion

The present study describes eight men who had sustained a transmural myocardial infarction and subsequently were shown to have a normal coronary arteriogram. In all men platelet survival time was shorter than in age-matched control subjects, and this finding suggests that coronary arterial thrombosis occurred and resulted in infarction. Presumably the thrombus had completely recanalized by the time of coronary angiography. Of interest is the finding of recurrent venous thromboembolism in three men and of femoral arterial thromboembolism in one other.

Platelet function and coronary thrombosis: Myocardial infarction has resulted from coronary arterial thromboembolism when this occurred at the time of cardiac catheterization.[3,12,13] Coronary arteriography subsequently undertaken in these patients showed recanalization of the occluded coronary artery. Thus, coronary arterial thrombotic occlusion can recanalize with time. Bruschke et al.[6] described five patients with infarction and a subsequent normal coronary arteriogram. One of these (Case 2) on three occasions underwent coronary arteriography; the films demonstrated first a normal, then an occluded coronary artery and finally restoration of a normal arterial lumen.[6] These reports seem to confirm the idea that coronary thrombosis can cause infarction and that coronary arterial patency can be restored.

Salky and Dugdale[16] studied three patients with infarction and a normal coronary arteriogram and observed shortened platelet survival in all three. One of the young women with infarction and a normal angiogram studied by Glancy et al.[5] and the women described by Ciraulo[10] were taking oral contraceptive agents. Two of the nine patients described by Khan and Haywood[9] were taking amphetamines. Kimbiris et al.[8] observed a platelet count in excess of 600,000 per mm^3 in one of their three cases. Thus, in addition to our patients, a number of patients with infarction and normal arteriograms had abnormalities of platelet reactivity, thrombocytosis or were taking a drug that possibly could have precipitated thrombosis.

Platelet function and atherosclerosis: Shortened platelet survival time was also observed in our patients with coronary arteriosclerotic obstruction and a history of myocardial infarction. Although controversy exists in respect to the contribution of platelets to the pathogenesis of atherosclerosis, platelets play an important role in arterial thrombosis and may be important in the progression of existing lesions and the complications of atherosclerosis.[17,18] It is interesting that platelet survival time was shortened in all of our patients with complete occlusion of the coronary artery to the infarcted segment.

Perhaps our patients with infarction and normal arteriograms represent one end of a continuum in which thrombosis has occurred on a minimally abnormal arterial surface. These patients all have shortened platelet survival time. The other end of the continuum would include patients with infarction, high grade obstructive lesions and, perhaps, without thrombosis. Platelet survival time in these patients is less often abnormal.

Other possible causes of infarction in absence of obstructive disease: In our patients we did not perform at cardiac catheterization any maneuver designed to provoke coronary spasm, and no patient had "spontaneous" coronary spasm at catheterization. Controversy continues to surround the idea that coronary spasm can result in myocardial infarction.[11] Our study does not provide any information relevant to the view that small vessel coronary disease can cause myocardial infarction. The data do provide some information to suggest that coronary thrombosis can cause infarction in patients subsequently shown to have a normal coronary arteriogram.

In Liquid Potassium Therapy

A GREAT NEW WAY TO START THE DAY

ONE TABLET ONCE-A-DAY

Announcing

K-LYTE® DS DOUBLE STRENGTH EFFERVESCENT TABLETS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate.

And in good-tasting orange and lime flavors

- Easy dosage to remember in preferred liquid form—50 mEq potassium/tablet.
- Eliminates multidose confusion when taken concurrently with other drugs.
- A record of safety...no reports of GI ulceration in over a decade of use of original K-LYTE®*
- Cost is less than a diet of potassium-rich foods.

*See Prescribing Considerations

Prescribing Considerations

Indications: K-LYTE DS, is an oral potassium supplement for therapy or prophylaxis of potassium deficiency. It is particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 tablet completely dissolved, 1 to 2 times daily, depending upon the requirements of the patient: 1 tablet (50 mEq. potassium) in 6 to 8 ounces of cold or ice water. The normal adult daily requirement is approximately 50 mEq. of elemental potassium.

NOTE: It is suggested that K-LYTE DS be taken with meals and sipped slowly over a 5-10 minute period.

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 individually foil-wrapped tablets. **Also available,** K-LYTE (25 mEq. potassium) effervescent tablets (orange or lime flavors) in cartons of 30 and 250.

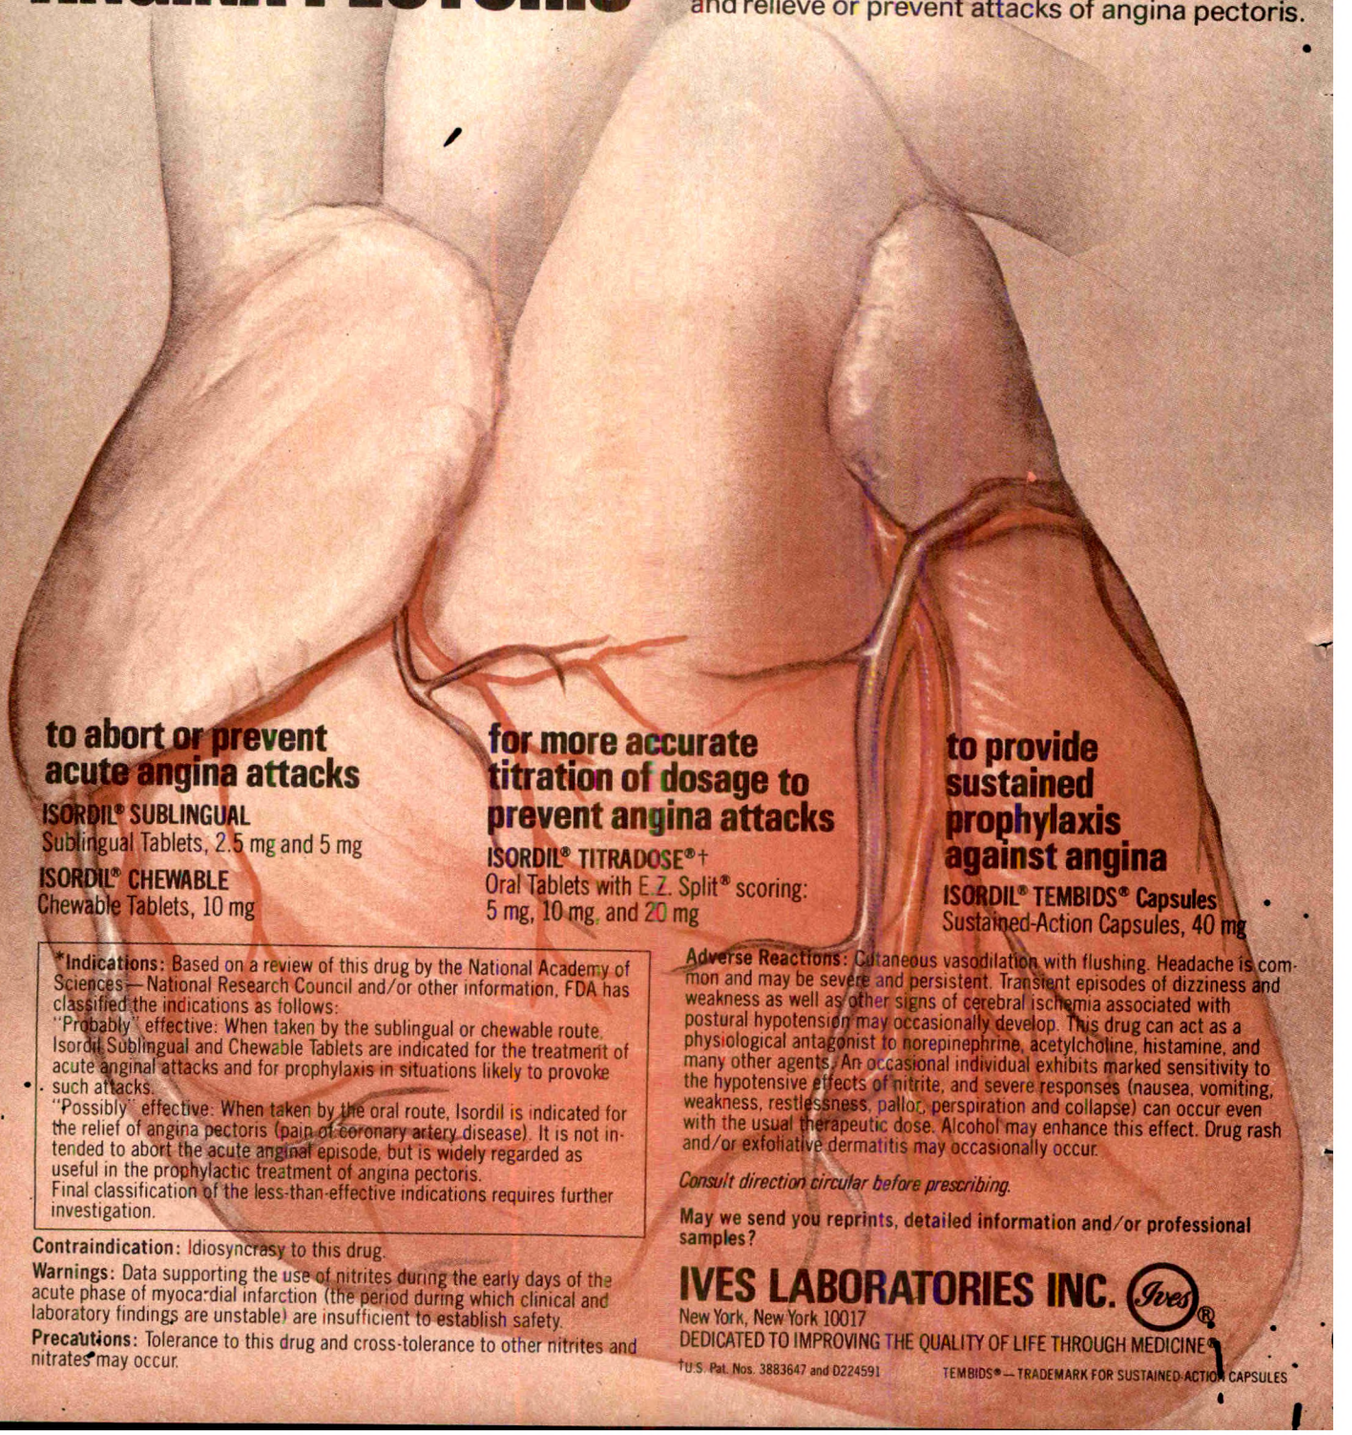
ISORDIL®
(isosorbide dinitrate)

HELPS THE HEART IN THE CONTROL OF ANGINA PECTORIS*

The established use of Isordil in the management of angina pectoris for more than two decades has often been ascribed only to the vasodilatation it produces in the coronary arteries. Recent investigations, however, suggest that an even more important effect of this agent is to dilate peripheral arteries and veins. Arterial dilatation lowers impedance to left ventricular ejection, reducing afterload. Venous dilatation leads to venous pooling and a fall in right and left ventricular filling pressure, thus reducing preload.

With afterload and preload reduced, the amount of energy expended and oxygen consumed by the heart should be decreased. Isordil can thus reduce myocardial oxygen requirements and relieve or prevent attacks of angina pectoris.



to abort or prevent acute angina attacks

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg and 5 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

for more accurate titration of dosage to prevent angina attacks

ISORDIL® TITRADOSE®†
Oral Tablets with E.Z. Split® scoring:
5 mg, 10 mg, and 20 mg

to provide sustained prophylaxis against angina

ISORDIL® TEMBIDS® Capsules
Sustained-Action Capsules, 40 mg

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

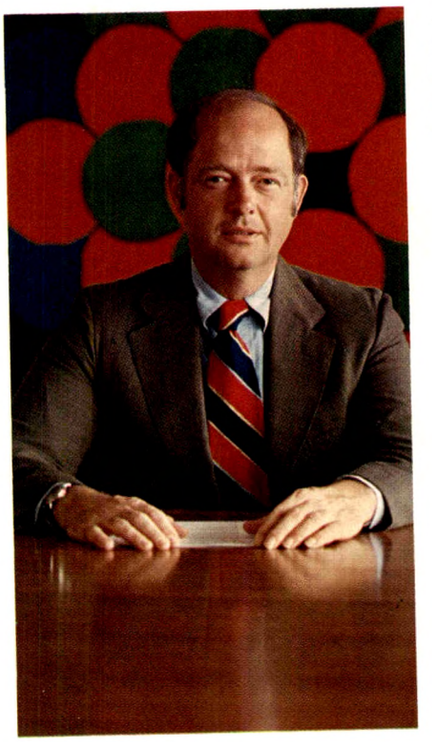
TEMBIDS® — TRADEMARK FOR SUSTAINED-ACTION CAPSULES

"How ARCO Medical Products Company is improving the predictability of cardiac pacing."



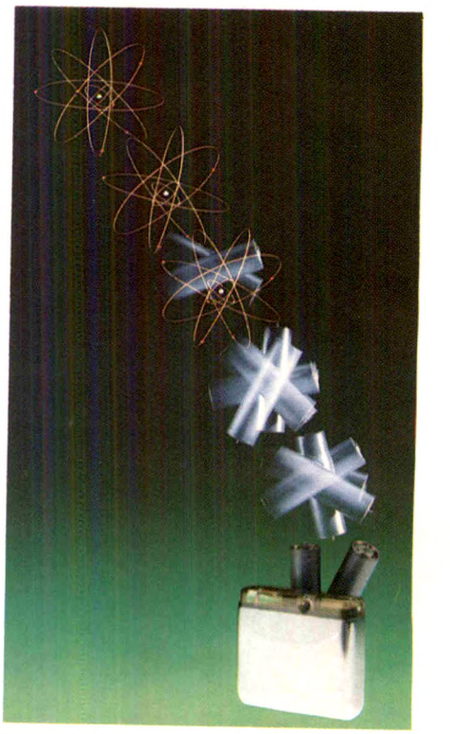
—an open letter to physicians and other members of the medical community from Page Thompson, President, ARCO Medical Products Company.

"ARCO Medical Products Company, a subsidiary of Atlantic Richfield Company—the 12th largest corporate entity in the United States, known principally for its chemical, petroleum and mineral operations—is now emerging as a leader in the highly specialized field of cardiac pacemaker systems. And we would like you to be sure that there are substantial benefits accruing to you and your patients due to our solid and rapidly growing position in this field.

"**To highlight a few of the benefits for you** we'd like to call your attention to the fact that ARCO Medical Products Company now provides:

- Pulse generators substantially improved in predictability
- A lithium thionyl chloride power source with highly desirable characteristics
- Significantly increased research and development to provide improved and new products in the near future
- A responsible attitude toward selling whereby we will not offer for sale what we cannot deliver—within 48 hours—anywhere in the free world
- Realistic, 'no-nonsense' product guarantees

"**To understand how it all began** look back to the early 1960s. Our people were then encapsulating nuclear materials used in the naval nuclear submarine program and the Apollo space program. As a result of this experience, we were awarded the first AEC contract for the encapsulation of nuclear material to be implanted in the human body. That was the beginning of the first nuclear-powered pulse generator.



"The precision and expertise put into the manufacture of those first nuclear-powered units is apparent when you see they have been functioning effectively for ten years, with a long life expectancy still ahead of them.

"**The nuclear experience evolved** into the development of pacemaker technology that utilized the nuclear-precise production and quality assurance techniques perfected when working on the AEC contract.

"ARCO Medical Products Company helped develop the advanced and exclusive lithium thionyl chloride power cell, which does not build up internal pressure. ARCO Medical

Products Company developed the triple encapsulation process which virtually solved the problem of invasion and migration of moisture within the generators.
ARCO Medical Products Company developed both a component and a total unit 'burn-in' process which virtually eliminates initial failures.
In these ways, and in many others, ARCO Medical Products Company has succeeded in significantly improving the predictability of the pulse generator.

"**We are a concerned company,** and this concern has led us to a commitment that no other pulse generator company matches: improved pulse generators

supported by a 'no-nonsense' product guarantee. In essence:

1. In the event an ARCOlith™ pulse generator becomes defective for any reason up to and including 60 days following implant, ARCO Medical Products Company will furnish a replacement pulse generator at no charge and pay *all* surgical and hospital costs as established by third-party insurance company pay schedules.*
2. In the event an ARCOlith pulse generator becomes defective for any reason after 60 days following implant up to the end of the warranty period,* ARCO Medical Products Company will furnish a replacement pulse generator at no charge and pay up to a total of $200 for surgical and hospital costs over third-party insurance company pay schedules.*

"**Be involved.** Take a stand by communicating your thoughts to us. Whatever your concerns may be regarding our products, our business philosophy, or your hopes for the future of pacemaker technology, we would like to hear from you. Kindly use the form on the following page to jot down your thoughts and mail them to me. It will be a pleasure to share your ideas."

Page Thompson

*Refer to warranty for complete details.

ARCOlith™ 12, 6, and 4 are now the trade names for pulse generator models LI-2, LI-4 and LI-3.

We'd like to hear from you.

ARCO Medical Products Company invites you to communicate your thoughts regarding implantable pulse generators or manufacturer-physician relationships.

Get involved. Take a stand. Tell us what's on your mind so we can be of better service to you and your patients in the future:

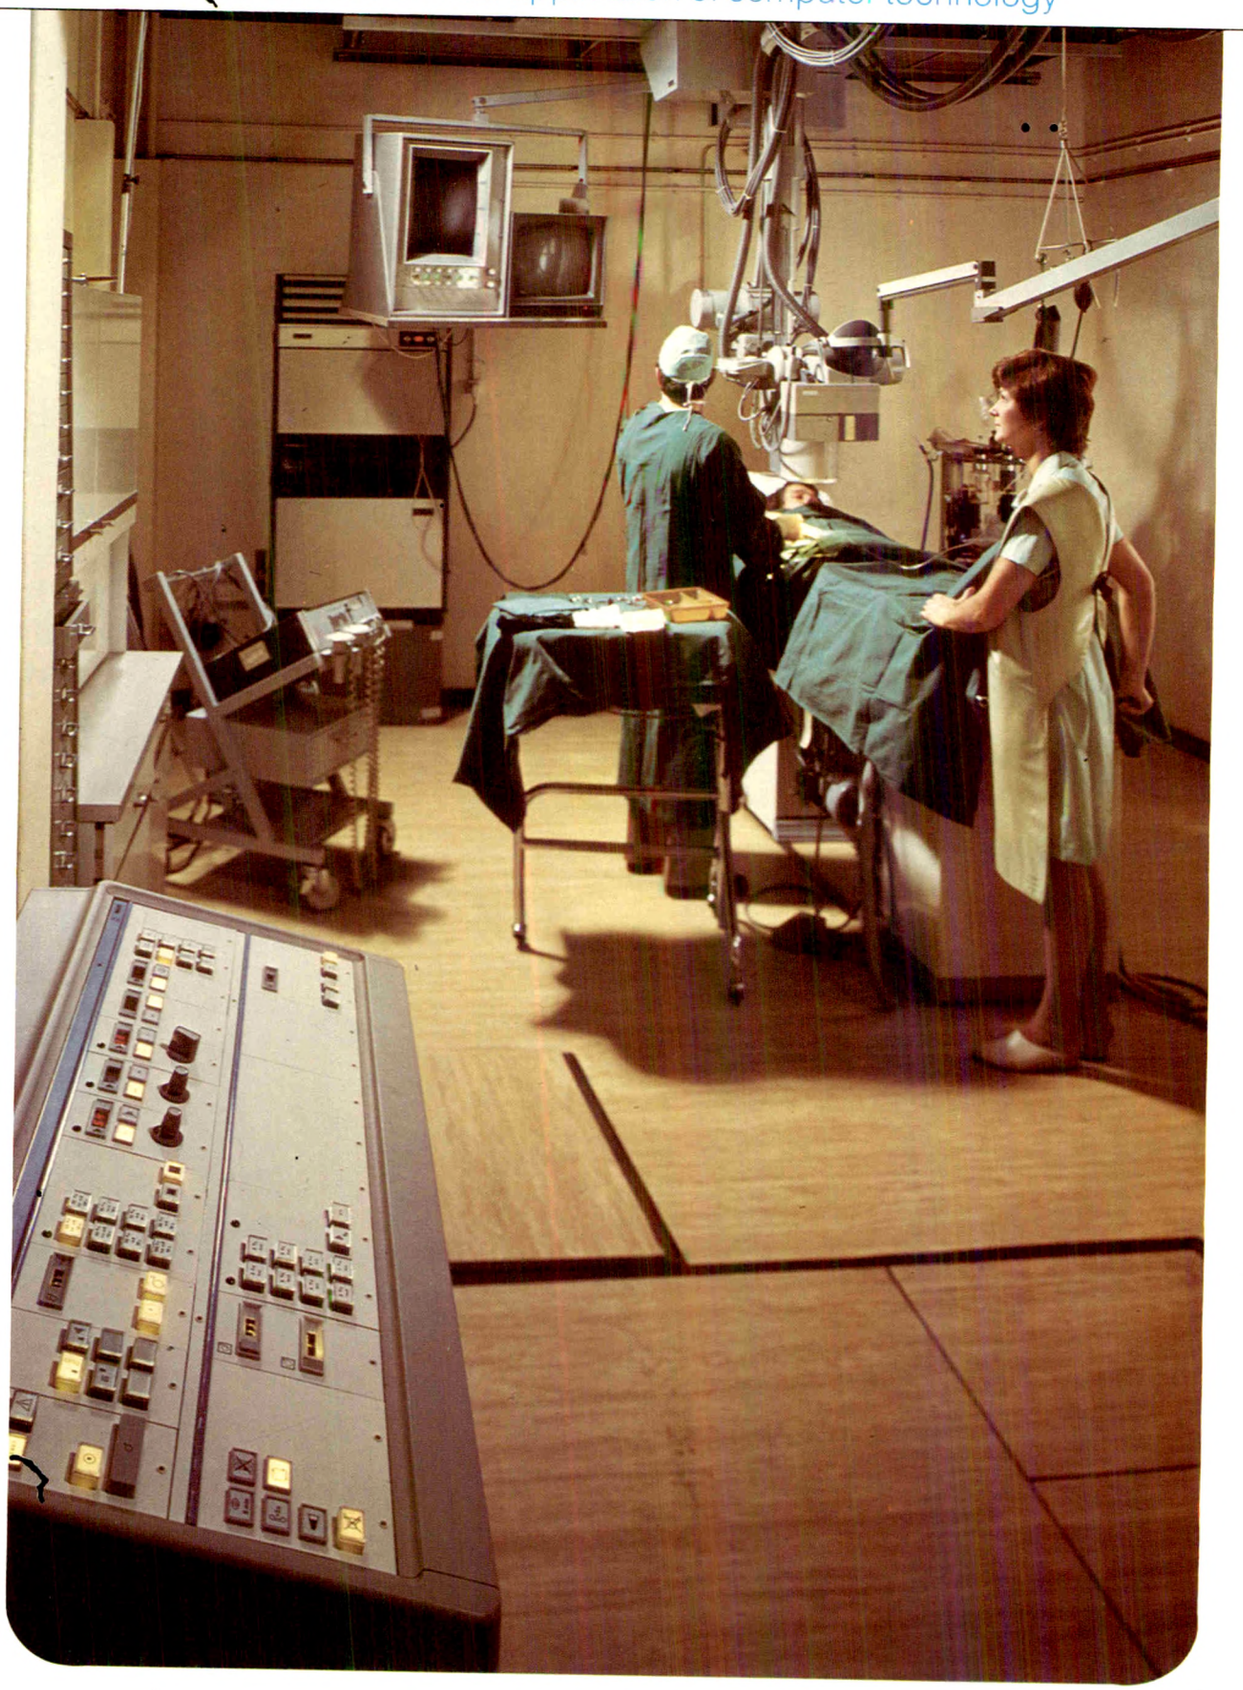
Philips Computerized X-ray Generator Guarantees Optimum Technique for Every Exposure!

PHILIPS **Optimus** M200:

the ultimate clinical application of computer technology



PHILIPS

PHILIPS®

® T.M.S.V. Philips of Holland

The Computer: Medical Language, Medical Results
Consider computer technology completely dedicated to cardiovascular diagnostics...micro-circuitry that thinks and operates in your language according to your parameters and your procedure needs. Consider technology advanced to a degree that guarantees the perfect exposure for every run on every patient, regardless of age, size or weight. *This* is the OPTIMUS.

Full automation makes such accuracy simple for you. A range of programs covering every examination technique is built into the generator at installation. You select the medical parameters for each program. For examination, simply turn on the generator and press one button for the program you want. The OPTIMUS does the rest.

Patient Measuring Shots: Your Instant Preview
Automatically (in 5 milliseconds), the OPTIMUS measures the absorption characteristics of the patient and then the computer selects the exact factors for an ideal exposure. Factors are selected in discrete mA/kV steps. Your technique is always the highest mA and the lowest kV.

In a fraction of a second, all other technical parameters are calculated and set by the generator. You're insured perfect results before the cine run starts. The measuring shots can be engaged at any time to determine optimum technique for any projection.

Measuring shots drastically reduce the radiation dose required by less automated systems to determine technique factors. In the time equivalent to one cine frame, you know exactly what the results will be.

Procedure interruptions due to factor adjustment or "trial and error test shots" are eliminated. You and the technician devote minimum attention to technique selection and maximum attention to your patient.

A New Standard of Image Quality
The OPTIMUS' high output permits short exposures with low tube tensions. As a result, images are rich in contrast and detail. Low kV lets you visualize extremely small vessels with unprecedented ease. And not only are geometric unsharpness and motion unsharpness both minimized, but the OPTIMUS automatically weighs one against the other in selecting the technique which optimizes image quality.

From Maximum to Minimum Instantly
The OPTIMUS' secondary tetrode system switches exposures on and off *and also regulates the kVp level.* Now it's possible to change technique from maximum to minimum instantly. This is the same basic concept Philips' cine pulse has used successfully for the past twenty years!

Full Generator Use
More than any other system on the market, the OPTIMUS gives you the *full* capability of a generator. Over 100 hospitals throughout the world are enjoying that OPTIMUS capability right now! It's the product of all Philips' experience in both generators and computer technology...the logical result of progress from Philips' cine pulse to automated Modular Generators to Anatomically Programmed Radiography. The OPTIMUS: it's the most logical choice for you, too.

Press one button for optimum technique for every exposure.

A built-in memory lets you change technique and return to the initial program with no operator changes—for every patient!

Secondary tetrodes—another first from Philips . . . 20 years ago!

The OPTIMUS: computerized because it does a job only a computer can do!

New Insights into the ECG for Diagnosis and Prognosis

CLINICAL ELECTROCARDIOGRAPHIC CORRELATIONS

Jorge C. Rios, MD, Guest Editor
Associate Professor of Medicine, George Washington University Medical Center

New book / 270 pages / 162 illustrations / Approx. $35.00

Dependent as the cardiologist is on the electrocardiogram, it is still at best an imprecise yardstick of disease. In this up-to-the-minute review of electrocardiography, the procedure is approached not as an isolated informational source but as part of an overall clinical picture. The findings of 32 eminent contributors are presented—in 20 separate and complete chapters covering the most clinically prevalent forms of heart disease plus related disorders with subsequent cardiac manifestations. They show how electrocardiographic data can be correlated along with clinical, anatomic and physiologic observations to help the physician reach a rational diagnosis and prognosis.

The clear presentation of the material and its clinical practicality make the book especially appealing to the active practitioner.

This book is the latest addition to our widely acclaimed Cardiovascular Clinics Series, Albert N. Brest, Editor.

CONTENTS

Clinical-electrocardiographic correlations: prologue
— *Jorge Rios and Albert Brest*

Physiologic and biologic variants of the electrocardiogram
— *Gerard Gaughan and H. Joel Gorfinkel*

Diagnostic Accuracy of the electrocardiogram
— *Jennifer Johnson, Leo Horan and Nancy Flowers*

Clinical implications of atrioventricular and intraventricular conduction abnormalities I
— *Jacob Haft*

Clinical implications of atrioventricular and intraventricular conduction abnormalities II; Acute myocardial infarction
— *Jacob Haft*

Angina pectoris: a clinical-electrocardiographic-angiographic correlative study in 510 patients
— *Robert Hamby*

Electrocardiographic-angiographic correlations in coronary heart disease
— *Jorge Rios, Thomas Sinderson and Samuel Goldberg*

Stress electrocardiography
— *John Naughton*

Electrocardiography in hypertensive heart disease
—*Syed Zafar*

Clinical-electrocardiographic correlations: aortic valve disease and hypertrophic subaortic stenosis
— *Pravin Shah*

Electrocardiographic assessment of valvular heart disease
— *Jorge Rios and Christopher Leet*

Electrocardiogram in adults with congenital heart disease
— *Alden Gooch and P. M. Kini*

Clinical-electrocardiographic correlations in diseases of the myocardium
— *Daniel McMartin and Nancy Flowers*

Pathogenesis and clinical correlations of the electrocardiographic abnormalities of pericardial disease
— *David Spodick*

Clinical-electrocardiographic correlations in pulmonary heart disease (cor pulmonale)
— *M. Irene Ferrer*

Electrocardiogram in neoplastic and hematologic disorders
— *Joseph Lindsay, Jr., Samuel Goldberg and William Roberts*

Electrocardiogram in endocrine and metabolic disorders
— *Borys Surawicz and Maria Mangiardi*

Drugs and the atrioventricular conducting system
—*Antonio Caracta and Anthony Damato*

XYZ electrocardiography: correlation with conventional 12 lead electrocardiogram
— *A. Castellanos, R. Sung, S. Richter and R. Myerburg*

Future trends in electrocardiography
— *Hubert Pipberger and Rosalie Dunn*

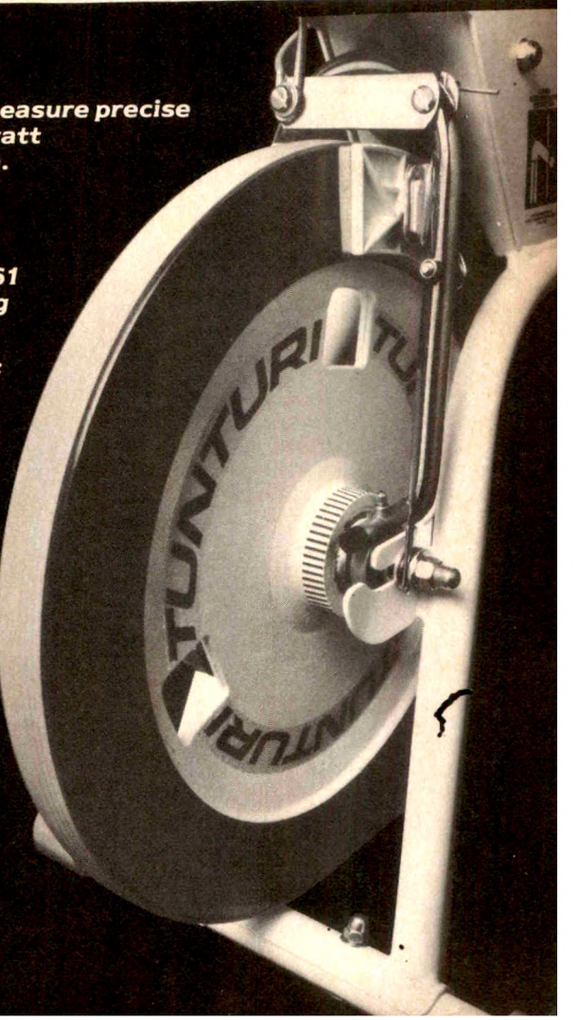
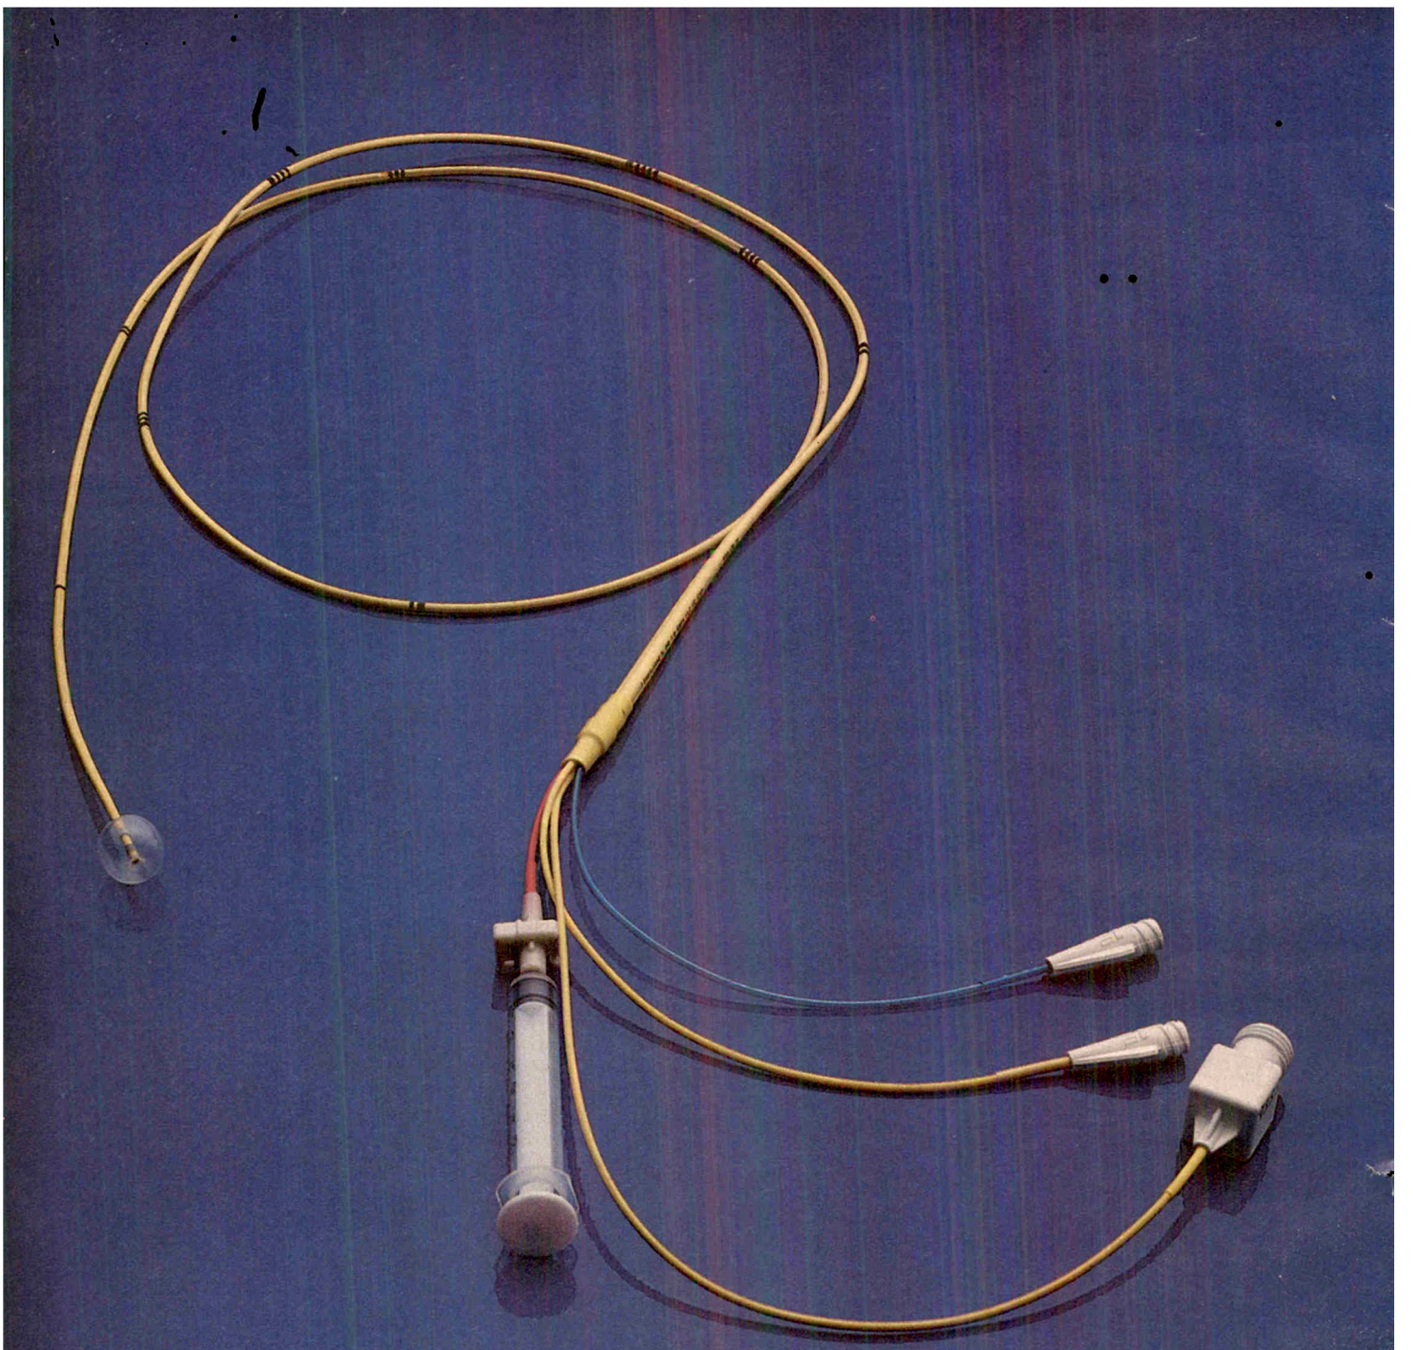
Distribution Centers in Seattle, Los Angeles, Chicago, Houston and Baltimore.

Tunturi Ergometer:

At home rehabilitation you can prescribe from your office.





We recommend this.

Data obtained with the SWAN-GANZ® Flow-Directed Balloon-Tipped Catheter allows you to diagnose and treat the critically ill patient with a high level of confidence.

Consequently, in patients where large volumes of fluid are required or where marginal cardiovascular reserve is suspected, fluid management decisions (such as treatment with plasma protein, dextrose solution, albumin, etc.) can be made more aggressively.

Moreover, SWAN-GANZ Catheters can be used to determine many patient conditions.

For example, pulmonary hypertension can be substantiated hemodynamically, and the state of congenital heart disease determined.

Hypovolemic shock can be differentiated from cardiogenic shock. Myopericardial disease can also be confirmed by the characteristic pressure changes.

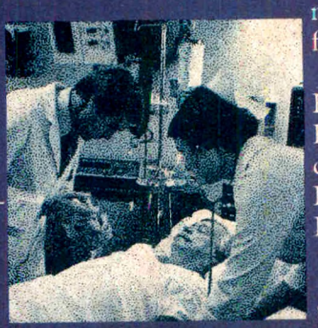
Following acute myocardial infarction, the degree of myocardial depression can be better quantitated using the cardiac

before you prescribe these.

output and wedge pressure.

The diagnosis of heart failure, particularly left heart failure, in the presence of adult respiratory distress syndrome, can be quantified.

SWAN-GANZ Catheters—a complete description, details on insertion, placement and complications, are described fully in journal reprints and technical data available from Edwards.



Ask your local Edwards' Technical Representative for copies, or contact: Edwards Laboratories, Division of American Hospital Supply Corporation, 17221 Red Hill Avenue (Irvine), P.O. Box 11150, Santa Ana, CA 92711, 714/557-8910, Cable Address: EDSLAB, Telex: 68:5567

EDWARDS LABORATORIES
Division of American Hospital Supply Corporation

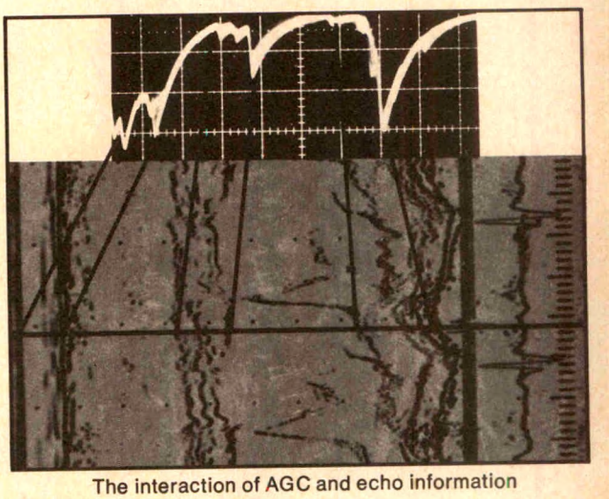
SWAN-GANZ® is a register trademark, Edwards Laboratories.

Automation solved one of their problems.

Let it solve one of yours.

Automatic Gain Compensation

Automatic Gain Compensation (AGC) circuitry has been designed to automatically analyze and determine the optimum display of each returning echo, so that heart structures are clearly delineated. As moving structures change depth and angle, the real-time flexibility of AGC permits the display to remain true and accurate throughout the examination. The result: more clinical information and an extremely high percentage of interpretable exams.

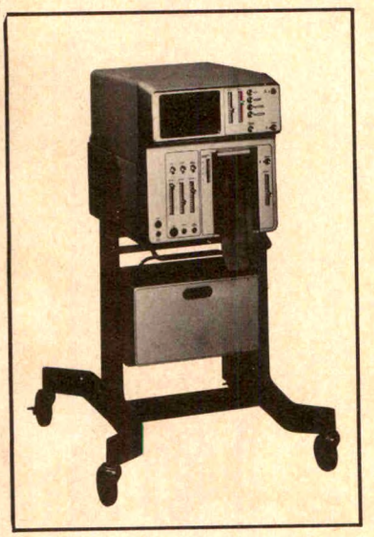


The interaction of AGC and echo information

Price Breakthrough
Incorporating new 1977 state of the art technology, the ECHOMATIC is extremely lightweight (approx. 50 lbs.) and is priced about 30% less than its next higher-priced competitor. Standard phono, carotid and ECG channels are included at this same price.

Service Support
A nationwide network of service offices is maintained to permit us to regularly meet our goal of on-site repair within 48 hours of your call. With over 30 service offices, our factory support staff, and the reliability we have built in, you can expect minimum downtime with the ECHOMATIC.

Basic Training Program
To assist in the establishment of your echocardiography service, the Metrix Teknika Echocardiography Basic Training Program has been prepared. This program includes 35mm slides, tape cassette and extensive textbook material.



☐ Please send the full story about the ECHOMATIC and Automatic Gain Compensation (AGC).

☐ Please send more information about the Basic Training Program.

INTROPIN®
(dopamine HCl)

In the shock syndrome:

Selectively redirects blood to vital organs

Increases vital organ perfusion

In the shock syndrome, perfusion pressure usually does not meet the metabolic needs of the vital organs. When volume replacement fails to reverse this process, additional therapy must be initiated to increase cardiac output and blood pressure and to increase blood flow to vital organs.

Intropin (dopamine HCl) is the only drug that both increases cardiac output and blood pressure while specifically redirecting the blood flow.

Maintains kidney function

The unique ability of Intropin to act on the "dopaminergic" receptors in the mesenteric and renal vasculature causes vasodilation in these beds and leads to increased renal blood flow, glomerular filtration rate and urine output. At low dose levels (less than 5 mcg/kg/min), when cardiac stimulation is not usually observed, these increases are independent of increased cardiac output.

In comparison, norepinephrine causes vasoconstriction in these beds, further compromising vital organ function.[1] Isoproterenol causes generalized systemic vasodilation (thereby requiring greater cardiac output to increase vital organ perfusion) and does not increase the renal fraction of the increased cardiac output.[2]

Increases cardiac output

At higher doses (above 5 mcg/kg/min), Intropin begins to increase myocardial contractility, stroke volume and cardiac output by direct positive inotropic effect while maintaining much of the unique dopaminergic effect. In certain patients such as refractory congestive failure patients, the increase in cardiac output may be seen at doses of less than 5 mcg/kg/min.

Norepinephrine, on the other hand, has a similar inotropic effect, but the expected increase in cardiac output is often diminished due to the increased systemic vascular resistance (afterload) resulting from norepinephrine's alpha adrenergic activity. Isoproterenol increases cardiac output in part through a chronotropic effect.[3] Its use results in a greater increase in myocardial oxygen consumption than does the inotropic effect of Intropin. It also results in a greater potential for arrhythmias.[3] The increased cardiac output obtained with isoproterenol is delivered to the total systemic vasculature due to general vasodilation while the selective vasodilation of Intropin directs more blood supply to the areas in need of vital perfusion.

Increases blood pressure

Intropin doses of over 20 mcg/kg/min will usually result in an alpha adrenergic (vasoconstriction) response in the peripheral vasculature. This usually raises the pressure and also redirects blood flow through the vasodilated vasculature of the renal and mesenteric beds. Thus, Intropin can increase blood pressure through an inotropic cardiac response or at doses above 20 mcg/kg/min through an additional peripheral vasculature response.

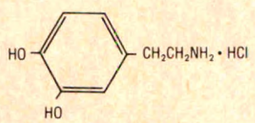
INTROPIN® (dopamine HCl)

(See last page of this advertisement for full prescribing information.)

INTROPIN® (dopamine HCl)

5 ml. AMPUL/FOR I.V. INJECTION

DESCRIPTION: INTROPIN (dopamine HCl) is 3, 4-dihydroxyphenethylamine hydrochloride, a naturally-occurring biochemical catecholamine precursor of norepinephrine. The chemical structure is:



$C_8H_{11}NO_2 \cdot HCl$ Mol. Wt. 189.65

Dopamine hydrochloride is a white, odorless crystalline powder, freely soluble in water and soluble in alcohol. It is sensitive to light, alkalis, iron salts and oxidizing agents.

Each milliliter of sterile, pyrogen-free INTROPIN Injection contains 40 mg. of dopamine hydrochloride (equivalent to 32.96 mg. of dopamine base) in Water for Injection, USP, containing 1% sodium bisulfite as a preservative.

ACTIONS: INTROPIN exerts an inotropic effect on the myocardium resulting in an increased cardiac output. INTROPIN produces less increase in myocardial oxygen consumption than isoproterenol and its use is usually not associated with a tachyarrhythmia. Clinical studies indicate that INTROPIN usually increases systolic and pulse pressure with either no effect or a slight increase in diastolic pressure. Total peripheral resistance at low and intermediate therapeutic doses is usually unchanged. Blood flow to peripheral vascular beds may decrease while mesenteric flow increases. INTROPIN has also been reported to dilate the renal vasculature presumptively by activation of a "dopaminergic" receptor. This action is accompanied by increases in glomerular filtration rate, renal blood flow, and sodium excretion. An increase in urinary output produced by dopamine is usually not associated with a decrease in osmolality of the urine.

INDICATIONS: INTROPIN is indicated for the correction of hemodynamic imbalances present in the shock syndrome due to myocardial infarctions, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation as in congestive failure.

Where appropriate, restoration of blood volume with a suitable plasma expander or whole blood should be instituted or completed prior to administration of INTROPIN.

Patients most likely to respond adequately to INTROPIN are those in whom physiological parameters, such as urine flow, myocardial function, and blood pressure, have not undergone profound deterioration. Multiclinic trials indicate that the shorter the time interval between onset of signs and symptoms and initiation of therapy with volume correction and INTROPIN, the better the prognosis.

Poor Perfusion of Vital Organs – Urine flow appears to be one of the better diagnostic signs by which adequacy of vital organ perfusion can be monitored. Nevertheless, the physician should also observe the patient for signs of reversal of confusion or comatose condition. Loss of pallor, increase in toe temperature, and/or adequacy of nail bed capillary filling may also be used as indices of adequate dosage. Clinical studies have shown that when INTROPIN is administered before urine flow has diminished to levels approximately 0.3 ml./minute, prognosis is more favorable. Nevertheless, in a number of oliguric or anuric patients, administration of INTROPIN has resulted in an increase in urine flow which in some cases reached normal levels. INTROPIN may also increase urine flow in patients whose output is within normal limits and thus may be of value in reducing the degree of pre-existing fluid accumulation. It should be noted that at doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage. Concurrent administration of INTROPIN and diuretic agents may produce an additive or potentiating effect.

Low Cardiac Output – Increased cardiac output is related to INTROPIN's direct inotropic effect on the myocardium. Increased cardiac output at low or moderate doses appears to be related to a favorable prognosis. Increase in cardiac output has been associated with either static or decreased systemic vascular resistance (SVR). Static or decreased SVR associated with low or moderate increments in cardiac output is believed to be a reflection of differential effects on specific vascular beds with increased resistance in peripheral beds (e.g. femoral) and concomitant decreases in mesenteric and renal vascular beds. Redistribution of blood flow parallels these changes so that an increase in cardiac output is accompanied by an increase in mesenteric and renal blood flow. In many instances the renal fraction of the total cardiac output has been found to increase. Increase in cardiac output produced by INTROPIN is not associated with substantial decreases in systemic vascular resistance as may occur with isoproterenol.

Hypotension – Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of INTROPIN, which have little effect on SVR. At high therapeutic doses, INTROPIN's alpha adrenergic activity becomes more prominent and thus may correct hypotension due to diminished SVR. As in the case of other circulatory decompensation states, prognosis is better in patients whose blood pressure and urine flow have not undergone profound deterioration. Therefore, it is suggested that the physician administer INTROPIN as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

CONTRAINDICATIONS: INTROPIN should not be used in patients with pheochromocytoma.

WARNINGS: INTROPIN should not be administered in the presence of uncorrected tachyarrhythmias or ventricular fibrillation.

Do **NOT** add INTROPIN to any alkaline diluent solution, since the drug is inactivated in alkaline solution.

Patients who have been treated with monamine oxidase (MAO) inhibitors prior to the administration of INTROPIN will require substantially reduced dosage. Dopamine is metabolized by MAO, and inhibition of this enzyme prolongs and potentiates the effect of INTROPIN. The starting dose in such patients should be reduced to at least one-tenth (1/10) of the usual dose.

Usage in Pregnancy – Animal studies have revealed no evidence of teratogenic effects from INTROPIN. In one study, administration of INTROPIN to pregnant rats resulted in a decreased survival rate of the newborn and a potential for cataract formation in the survivors. The drug may be used in pregnant women when, in the judgment of the physician, the expected benefits outweigh the potential risk to the fetus.

Usage in Children – The safety and efficacy of this drug in children has not been established. INTROPIN has been used in a limited number of pediatric patients, but such use has been inadequate to fully define proper dosage and limitations for use. Further studies are in progress.

PRECAUTIONS: Avoid Hypovolemia – Prior to treatment with INTROPIN, hypovolemia should be fully corrected, if possible, with either whole blood or plasma as indicated.

Decreased Pulse Pressure – If a disproportionate rise in the diastolic pressure (i.e. a marked decrease in the pulse pressure) is observed in patients receiving INTROPIN, the infusion rate should be decreased and the patient observed carefully for further evidence of predominant vasoconstrictor activity, unless such an effect is desired.

Extravasation – INTROPIN should be infused into a large vein whenever possible to prevent the possibility of extravasation into tissue adjacent to the infusion site. Extravasation may cause necrosis and sloughing of surrounding tissue. Large veins of the antecubital fossa are preferred to veins in the dorsum of the hand or ankle. Less suitable infusion sites should be used only if the patient's condition requires immediate attention. The physician should switch to more suitable sites as rapidly as possible. The infusion site should be continuously monitored for free flow.

Occlusive Vascular Disease – Patients with a history of occlusive vascular disease (for example, atherosclerosis, arterial embolism, Raynaud's disease, cold injury, diabetic endarteritis, and Buerger's disease) should be closely monitored for any changes in color or temperature of the skin in the extremities. If a change in skin color or temperature occurs and is thought to be the result of compromised circulation to the extremities, the benefits of continued INTROPIN infusion should be weighed against the risk of possible necrosis. This condition may be reversed by either decreasing or discontinuing the rate of infusion.

IMPORTANT – Antidote for Peripheral Ischemia: To prevent sloughing and necrosis in ischemic areas, the area should be infiltrated as soon as possible with 10 to 15 ml. of Saline solution containing from 5 to 10 mg. of Regitine® (brand of phentolamine), an adrenergic blocking agent. A syringe with a fine hypodermic needle should be used, and the solution liberally infiltrated throughout the ischemic area. Sympathetic blockade with phentolamine causes immediate and conspicuous local hyperemic changes if the area is infiltrated within 12 hours. Therefore, phentolamine should be given as soon as possible after the extravasation is noted.

Avoid Cyclopropane or Halogenated Hydrocarbon Anesthetics – Cyclopropane or halogenated hydrocarbon anesthetics increase cardiac autonomic irritability and therefore may sensitize the myocardium to the action of certain intravenously administered catecholamines. This interaction appears to be related both to pressor activity and to beta adrenergic stimulating properties of these catecholamines. Therefore, as with certain other catecholamines, and because of the theoretical arrhythmogenic potential, INTROPIN should be used with EXTREME CAUTION in patients inhaling cyclopropane or halogenated hydrocarbon anesthetics.

Careful Monitoring Required – Close monitoring of the following indices – urine flow, cardiac output and blood pressure – during INTROPIN infusion is necessary as in the case of any adrenergic agent.

ADVERSE REACTIONS: The most frequent adverse reactions observed in clinical evaluation of INTROPIN included ectopic beats, nausea, vomiting, tachycardia, anginal pain, palpitation, dyspnea, headache, hypotension, and vasoconstriction. Other adverse reactions which have been reported infrequently were aberrant conduction, bradycardia, piloerection, widened QRS complex, azotemia, and elevated blood pressure.

DOSAGE AND ADMINISTRATION:

WARNING: This is a potent drug: It must be diluted before administration to patient.

Suggested Dilution – Transfer contents of one ampul (5 ml. containing 200 mg. INTROPIN) by aseptic technique to either a 250 ml. or 500 ml. bottle of one of the following sterile intravenous solutions:

1) Sodium Chloride Injection, USP
2) Dextrose 5% Injection, USP
3) Dextrose (5%) and Sodium Chloride (0.9%) Injection, USP
4) 5% Dextrose in 0.45% Sodium Chloride Solution
5) Dextrose (5%) in Lactated Ringer's Solution
6) Sodium Lactate (1/6 Molar) Injection, USP
7) Lactated Ringer's Injection, USP

These dilutions will yield a final concentration for administration as follows:
250 ml. dilution contains 800 mcg./ml. of INTROPIN
500 ml. dilution contains 400 mcg./ml. of INTROPIN

INTROPIN has been found to be stable for a minimum of 24 hours after dilution in the sterile intravenous solutions listed above. However, as with all intravenous admixtures, dilution should be made just prior to administration.

Do **NOT** add INTROPIN Injection to 5% Sodium Bicarbonate or other alkaline intravenous solutions, since the drug is inactivated in alkaline solution.

Rate of Administration – INTROPIN, after dilution, is administered intravenously through a suitable intravenous catheter or needle. An i.v. drip chamber or other suitable metering device is essential for controlling the rate of flow in drops/minute. Each patient must be individually titrated to the desired hemodynamic and/or renal response with INTROPIN. In titrating to the desired increase in systolic blood pressure, the optimum dosage rate for renal response may be exceeded, thus necessitating a reduction in rate after the hemodynamic condition is stabilized.

Administration at rates greater than 50 mcg./kg./min. have safely been used in advanced circulatory decompensation states. If unnecessary fluid expansion is of concern, adjustment of drug concentration may be preferred over increasing the flow rate of a less concentrated dilution.

Suggested Regimen:

1. When appropriate, increase blood volume with whole blood or plasma until central venous pressure is 10 to 15 cm H_2O or pulmonary wedge pressure is 14-18 mm Hg.

2. Begin administration of diluted solution at doses of 2-5 mcg./kg./minute INTROPIN in patients who are likely to respond to modest increments of heart force and renal perfusion.

In more seriously ill patients, begin administration of diluted solution at doses of 5 mcg./kg./minute INTROPIN and increase gradually using 5 to 10 mcg./kg./minute increments up to 20 to 50 mcg./kg./minute as needed. If doses of INTROPIN in excess of 50 mcg./kg./minute are required, it is suggested that urine output be checked frequently. Should urine flow begin to decrease in the absence of hypotension, reduction of INTROPIN dosage should be considered. Multiclinic trials have shown that more than 50% of the patients were satisfactorily maintained on doses of INTROPIN less than 20 mcg./kg./minute. In patients who do not respond to these doses with adequate arterial pressures or urine flow, additional increments of INTROPIN may be employed in an effort to produce an appropriate arterial pressure and central perfusion.

3. Treatment of all patients requires constant evaluation of therapy in terms of the blood volume, augmentation of myocardial contractility, and distribution of peripheral perfusion. Dosage of INTROPIN should be adjusted according to the patient's response, with particular attention to diminution of established urine flow rate, increasing tachycardia or development of new dysrhythmias as indices for decreasing or temporarily suspending the dosage.

4. As with all potent intravenously administered drugs, care should be taken to control the rate of administration so as to avoid inadvertent administration of a bolus of drug.

OVERDOSAGE: In case of accidental overdosage, as evidenced by excessive blood pressure elevation, reduce rate of administration or temporarily discontinue INTROPIN until patient's condition stabilizes. Since INTROPIN's duration of action is quite short, no additional remedial measures are usually necessary. If these measures fail to stabilize the patient's condition, use of the short-acting alpha adrenergic blocking agent, phentolamine, should be considered.

RO 2-2985, a potent inotropic agent, produces prolonged increases in left ventricular pressure and coronary and renal blood flow in conscious dogs. To evaluate these effects, 18 dogs were chronically instrumented with aortic or left ventricular pressure catheters, or both, and coronary and renal pulsed Doppler flow probes; 14 to 25 days later, after control values were recorded, sufficient blood was removed from each dog to reduce mean aortic pressure to 40 to 50 mm Hg or left ventricular pressure to 50 to 65 mm Hg during a 15 minute period. This pressure was maintained by withdrawal or addition of blood as necessary for an additional 30 minutes. The animals were then separated into two groups; one group was given RO 2-2985, the other an equivalent amount of drug solvent. Measurements were then made for 75 minutes or until death occurred. Retransfusion was performed in those animals living at 75 minutes. All 10 animals that received RO 2-2985 lived. After the drug injection, blood pressure and coronary and renal blood flow increased. Only one of eight animals receiving the solvent alone lived. The remaining control animals showed progressive deterioration in pressure and flow until death. The data show that RO 2-2985 decreased mortality and increased blood flow in the coronary and renal beds during hemorrhage-induced hypotension.

RO 2-2985 (X537A) (Hoffman-LaRoche) is an antibiotic drug that was originally isolated from a species of Streptomyces.[1] Pressman et al.[2–6] found that this compound and several others can form a complex with cations including catecholamines and can transport them across lipid membranes. RO 2-2985 produces a marked and prolonged positive inotropic and coronary vasodilator effect in the anesthetized dog.[7–9] Recently we studied the effects of this drug on myocardial function and regional hemodynamics in conscious chronically instrumented dogs.[10] In these animals, RO 2-2985 produced an inotropic effect and a large increase in coronary, renal and iliac blood flow. Coronary vascular resistance was not measured, but renal and iliac resistance levels decreased after administration of the drug. Anesthetized animals studied during hypotension induced by hemorrhage showed increases in systemic arterial blood pressure and renal blood flow and no change in renal vascular resistance in response to the drug.

These hemodynamic changes suggested to us that RO 2-2985 might be therapeutically useful during acute states of hypotension that accompany blood loss. However, the influence of anesthesia and acute operative conditions cannot be assessed, nor can potential effects of the drug on mortality be evaluated in this preparation. In addition, Vatner[11] clearly demonstrated that the renal hemodynamic alterations that occur in conscious dogs subjected to hemorrhage may differ in both magnitude and direction from the alterations found in anesthetized dogs.

The present study was designed to define more clearly the hemodynamic effects of RO 2-2985 during hemorrhagic hypotension and to identify potential clinical applications of the drug. Hypotension was

induced in conscious chronically instrumented dogs and the effect of RO 2-2985 on mortality, systemic pressure and renal and coronary blood flow was evaluated.

Methods

With use of sterile technique and pentobarbital anesthesia (30 mg/kg body weight) a left thoracotomy and left flank and right groin incisions were performed in 18 mongrel dogs weighing 25 to 35 kg. The heart was exposed, Tygon tubing was inserted into the left ventricular cavity through an apical stab wound and was secured in place with a purse-string suture. A short section of the proximal left circumflex coronary artery was dissected free 1 to 2 cm distal to the bifurcation of the left main coronary, and a pulsed Doppler flow probe[12,13] was placed around it. The left renal artery was identified using blunt retroperitoneal dissection through the left flank incision; a pulsed Doppler probe was placed around it, care being taken to preserve renal innervation. Tygon tubing was then inserted into the right femoral artery through the groin incision and

was advanced in a retrograde manner to the level of the abdominal aorta and secured in place. All wires and tubing were then tunneled subcutaneously and exteriorized in the posterior cervical area. The incisions were closed, and during recovery (14 to 25 days) each animal was conditioned to the laboratory. Each animal was primarily cared for by the person who would later be responsible for its control during the actual experiment.

Protocol: On the day of the experiment the animal was positioned lying quietly on his right side. An intravenous catheter was inserted and advanced to a central location. The wires were connected to a multichannel pulsed Doppler flowmeter[12,13] for flow measurements, and the tubing was connected to Statham P23 Db transducers for pressure measurement. Data were recorded on an eight channel Brush recorder and stored on magnetic tape (Hewlett-Packard Corporation, model 3955). Mean values for flow and pressure were derived from the phasic signals electronically using resistance-capacitance filters with a 3 second time constant.

Control values were then recorded. Flow velocity contours were measured across the vessels and if either turbulence or poor signal to noise ratios were noted, data from the flow channel were discarded. Blood was then withdrawn rapidly from each animal in sufficient quantity over a 15 minute period to decrease mean aortic pressure to 40 to 50 mm Hg or (in animals in which only the left ventricular pressure catheter was functional) to a peak systolic pressure of 50 to 65 mm Hg. All 18 animals were maintained at this pressure for 30 minutes by the administration or withdrawal of blood as necessary.

Each animal was then randomly separated into one of two groups: (1) Group I (10 dogs) was given RO 2-2985 (1 mg/kg by intravenous injection), and (2) Group II (8 dogs) was given an equivalent amount of the drug solvent (a mixture of benzyl alcohol, propylene glycol and anhydrous alcohol) (0.2 cc/kg).

After the injection of either drug or solvent the intravenous tubing was clamped and the animals were studied for 75 minutes or until death. Those alive at 75 minutes underwent retransfusion with the withdrawn blood and were allowed to recover. During the shock period all animals showed signs of restlessness, pupillary dilatation and panting. Those that died progressed to an obtunded state before their death.

Blood flow measurements: When possible, blood flow was calibrated in vivo over a wide range of pressure and flow levels by cannulating the vessel distal to the flow probe and adjusting flow with use of a screw clamp. Flow was measured using a stopwatch and graduated cylinder. In experiments in which this was not possible flow levels were calibrated with use of a gravity drainage technique or from the Doppler equation. All three of these methods have been extensively tested and the results agree closely. During the 14 to 25 days after operation and before study the flow probes become encased in a fibrous capsule around the blood vessel. This development limits changes in geometric shape of that portion of the vessel directly under the probe.

Results

Post-hemorrhage period: The heart rate of the animals, measured at the beginning of each experiment, was 101 ± 5 beats/min (mean ± standard error of the mean). This increased to 159 ± 16 beats/min after hemorrhage and was not significantly changed thereafter by administration of RO 2-2985. The hemorrhage caused a decrease in mean aortic pressure, left ventricular systolic pressure, left circumflex coronary arterial blood flow and renal arterial blood flow. The values recorded before and after hemorrhage were: (1) mean aortic pressure 108 ± 4 to 46 ± 1 mm Hg, (2) left ventricular systolic pressure 118 ± 15 to 55 ± 2 mm Hg, (3) left circumflex coronary arterial blood flow 54 ± 2 to 28 ± 2 cc/min and (4) right renal arterial blood flow 152 + 5 to 54 ± 9 cc/min. All changes were highly significant ($P < 0.002$, paired Student's t test). Left circumflex coronary vascular resistance was 2.07 ± 0.20 mm Hg/min per cc^{-1} in the control state and 1.75 ± 0.94 after hemorrhage. The respective values for renal vascular resistance were 0.70 ± 0.01 mm Hg/ml blood flow per min and 1.01 ± 0.31. These values before and after hemorrhage were not significantly different ($P > 0.05$).

In the post-hemorrhagic period, immediately before injection of drug or solvent, the average values recorded from the animals that received RO 2-2985 were compared with those from the animals that received solvent. Mean aortic pressure, left ventricular systolic pressure, left circumflex coronary and renal blood flow and vascular resistance levels were not significantly different in the two groups.

Mortality after treatment: Mortality during the 75 minutes after the injection of drug or solvent differed greatly between the two groups. All 10 dogs treated with RO 2-2985 lived through the 75 minute post-injection period until retransfusion. Early in this investigation four of these animals were followed up for 2 weeks after retransfusion. All appeared to be in good health until they were killed. This follow-up period was not considered necessary in the remaining animals and if they appeared in good health, they were killed later in the day after retransfusion.

Seven of the eight dogs in the solvent-treated group died, five of these in the first 45 minutes after injection. This high early mortality rate left too few survivors late in the course of the experiments for meaningful statistical analysis of the data in this group. Thus the individual results of each dog in the solvent-treated group are listed in Table I, whereas the composite data for the drug-treated dogs are presented in Table II and Figures 1 and 2. The solvent has been used by us extensively in other experiments, has no sustained hemodynamic effects and has shown no evidence of toxicity.

Systemic pressure and blood flow measurements after treatment: With the exception of the one dog in the solvent-treated group that lived through 75 minutes, no dog in this group showed sustained improvement in either pressure or coronary or renal blood flow before death (Table I). In contrast, in the drug-treated group all these measurements were significantly increased over values in the post-hemorrhage period preceding drug injection (Table II, Fig. 1 to 3). The coronary and renal pressure-flow relations in the individual animals were such that, after the injection of the drug, both coronary and renal vascular resistance levels significantly decreased ($P < 0.05$ at 15 minutes).

Upon retransfusion, mean aortic pressure, left ventricular pressure and coronary blood flow increased over values during the original control state before hemorrhage ($P < 0.001$). Renal blood flow, already not signif-

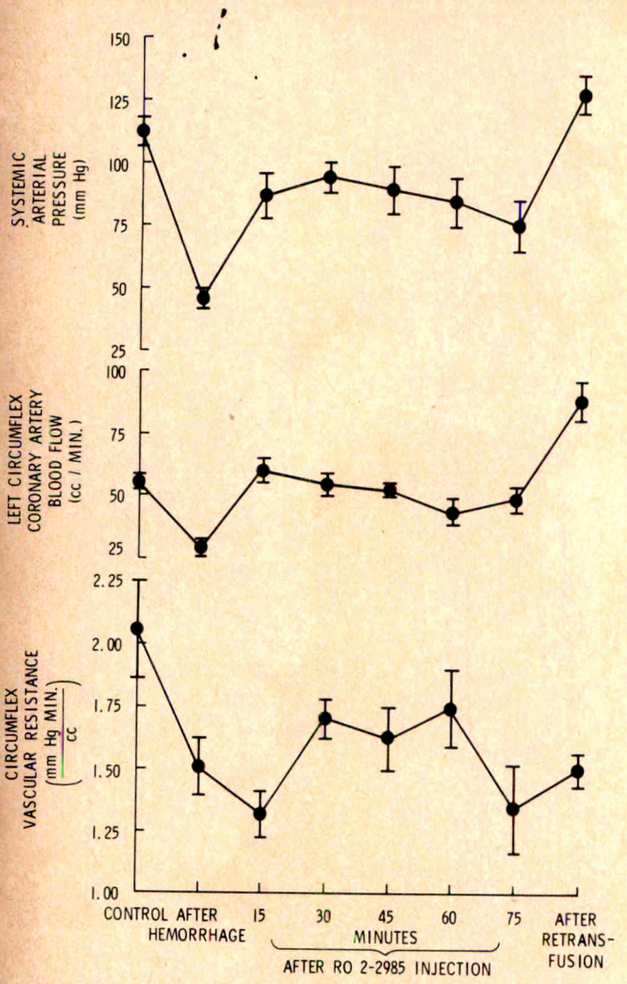

FIGURE 1. Effect of administration of RO2-2985 on systemic arterial pressure, circumflex coronary artery blood flow and circumflex vascular resistance after hemorrhagic hypotension was induced in conscious dogs. The bars in this and subsequent figures indicate standard error of the mean.

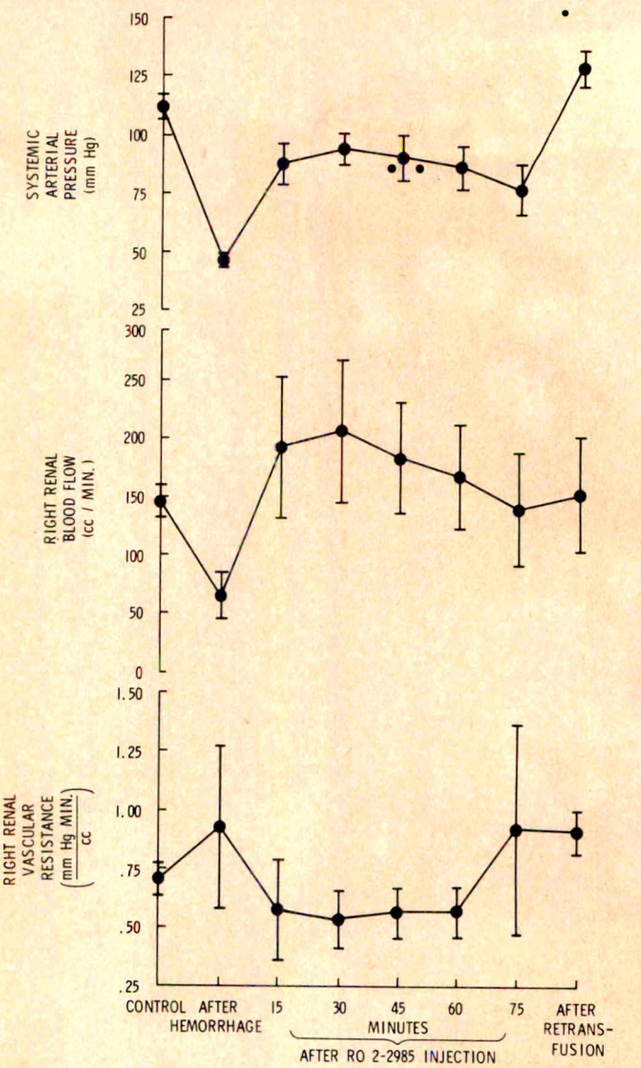

FIGURE 2. Effect of RO2-2985 administered during hemorrhagic hypotension on renal hemodynamics in 10 conscious dogs.

icantly different from values in the pre-hemorrhagic control state, did not change. After these initial retransfusion data were obtained, the hemodynamic measurements were discontinued.

Discussion

The data show that the ionophore RO 2-2985 significantly reduces mortality in a conscious canine model of hemorrhagic hypotension. The hemodynamic data are consistent with this finding because the drug produced marked improvement in arterial pressure and coronary and renal blood flow during the post-hemorrhagic state. These results were obtained in conscious unsedated chronically instrumented animals under conditions in which anesthesia and acute operative interventions could not be of influence.

The effects of the drug on arterial pressure and coronary and renal blood flow levels were directionally similar to the responses we reported for anesthetized animals with hemorrhagic hypotension,[10] but the renal vascular response differed. In the present study we found renal vasodilatation after administration of RO 2-2985 during hemorrhagic hypotension although we found no changes in renal vascular resistance in the study using anesthetized animals. Others[14,15] have also reported differences in renal vascular responses between awake and anesthetized preparations. The renal vascular bed has also been shown to respond differently to prostaglandin-inhibiting drugs when awake and anesthetized dogs were compared.[16] Both anesthesia and surgery are themselves major interventions, and differences in vascular responsiveness as a result of these procedures are to be expected.

Comparison with present studies: The findings of the present study require consideration in relation to other studies of hemorrhagic hypotension utilizing conscious dog models. Granata et al.[17] found an early increase, followed by a decrease in coronary vascular resistance, during progressive hemorrhage in conscious dogs. The hemorrhage produced in their study was over

a longer period of time (2 hours versus 15 minutes) and was slightly more severe (systemic arterial pressure of 35 to 45 mm Hg versus 40 to 55 mmHg) than in our study. This may explain the differences between their results and our own, in that we did not find a significant change in coronary vascular resistance with the shorter period of hemorrhage used in our study. The variable response of renal resistance found in our study is consistent with the results reported by Vatner.[11]

With the exception of the duration of drug effects, our data during hemorrhagic hypotension show directionally similar hemodynamic changes to those we found when the drug was administered to healthy conscious chronically instrumented dogs.[10] The total duration of vascular effects of the RO 2-2985 was not measured in the present experiments. However, the time to peak effect on both systemic arterial pressure (30 versus 60 minutes) and renal blood flow (30 versus 195 minutes) was shorter in the dogs with hemorrhagic hypotension than in healthy conscious dogs. The dogs treated with only the solvent illustrate the deteriorating hemodynamic state produced by this level of hemorrhagic hypotension. It is not surprising that the peak hemodynamic effects of a drug under such conditions would occur earlier than when the drug is given under conditions of circulatory stability.

Mechanism of hemodynamic effects: The mechanism by which RO 2-2985 produces these hemodynamic effects is not known. In healthy conscious chronically instrumented dogs the effects of the drug are clearly different from those found after injection of norepinephrine, epinephrine, isoproterenol or digitalis.[10] Furthermore, we have found that neither alpha adrenergic, muscarinic nor histaminergic receptor blockade totally blocks the effects of the drug[9,18] (and unpublished data). Pretreatment with reserpine blocks the inotropic, chronotropic and pressor effects of the drug; however, in dogs previously adrenalectomized and pretreated with 6-hydroxydopamine, RO 2-2985 exerted its usual hemodynamic effects[10] (and unpublished data).

A particularly intriguing action of the drug is its effect on the coronary vasculature.[18] Our previous studies[10,18] suggest that the increase in coronary blood flow produced by the drug is primary in nature and not merely a reflection of increased myocardial oxygen demand. It begins before the inotropic effect of the drug, peaks earlier and decreases while the pressure and the rate of rise of left ventricular pressure (dP/dt) are still increasing.[10] Pretreatment with reserpine does not block this effect of RO 2-2985 on coronary blood flow.[10]

This study has focused on the effects of the drug rather than on the mechanism by which they occur. Osborne et al.[19] recently demonstrated that this drug produces a translocation of large volumes of blood to the central circulation with a decrease in total body venous compliance. Some preliminary data obtained during our study support this finding. Two of the dogs studied, in addition to the instrumentation described, had ultrasonic segment length gauges implanted in the wall of the myocardium. These gauges measure regional myocardial dimensions. In these two dogs, after administration of RO 2-2985, end-diastolic length increased as measured by these crystals. Other inotropic agents have not been of particular value in the treatment of hemorrhagic hypotension and in some studies have had deleterious effects.[20] It may be that it is the combined effects of inotropic stimulation and increased central blood volume that are responsible for the results we have found.

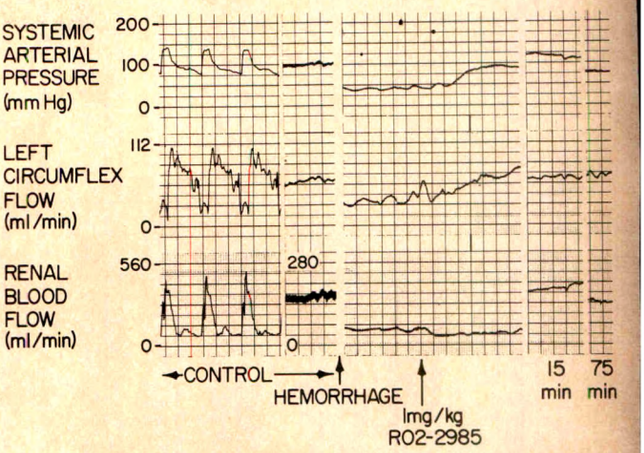

FIGURE 3. A typical recording of arterial pressure, circumflex coronary flow and renal blood flow (measured with the pulsed Doppler technique) in a conscious chronically instrumented dog before and after severe hemorrhage and after administration of RO2-2985. Note the change in scale in Panel 2.

Therapeutic implications: All animal models have limitations with regard to the simulation of clinical pathologic conditions, and data from animal studies should be extrapolated with extreme caution. Nevertheless, the striking decrease in mortality produced by RO 2-2985 in these studies, as well as the beneficial hemodynamic effects measured in two vital vascular beds critically comprised during severe hypotension, suggest that this type of chemical structure or a derivative of it may be clinically useful in combination with volume replacement in the therapy of acute hemorrhagic hypotension.

Bruce Treadmill Test in Children: Normal Values In a Clinic Population

GORDON R. CUMMING, MD, FRCP(C), FACC
DAYLE EVERATT, RN, RCT
LAVERNE HASTMAN, RT, RCT

Winnipeg, Manitoba, Canada

The Bruce treadmill protocol is suitable for children as young as age 4 years. Maximal endurance time may be used as the sole criterion of exercise capacity, and normal values were established with 327 children having an innocent heart murmur. Mean endurance time in boys increased from 10.4 minutes at age 4 to 5 years, to 14.1 minutes at age 13 to 15 years. Mean endurance time in girls increased from 9.5 minutes at age 4 to 5 years to 12.3 minutes at age 10 to 12 years. Mean maximal heart rate ranged from 193 to 206 beats/min. Age differences in mean maximal and submaximal heart rates were small. There were negative correlations between endurance time and the ratio of weight to height^3. There were negative correlations between heart rates at treadmill stages 1 to 3 and the endurance times. The correlation coefficient of endurance time with maximal oxygen uptake was 0.88, but for clinical purposes endurance time alone is a satisfactory indicator of exercise performance.

The Bruce treadmill test is a commonly used exercise test to assess exercise capacity and the electrocardiographic response to exercise stress in adults.[1] The test protocol calls for 3 minute stages of increasing belt speed and percent grade on a treadmill and is suitable for maximally stressing patients whose exercise capacity is as low as 5 mets* or as high as that of endurance-trained athletes. Extensive use of this test in a pediatric cardiology department has shown the test to be suitable for children aged 4 years and older. This report reviews some test results in normal children and youths aged 4 to 18 years.

Methods

Treadmill protocol: The treadmill was programmed for increases in grade and speed every 3 minutes as outlined by Bruce et al.[1] (Table I). Calibrations for grade and belt speed were checked at frequent intervals. The children were tested at the time of visiting a cardiac clinic. They had no prior experience with the treadmill and no opportunity for practice. Most were purposely tested in the absence of their parents. Each child was urged to continue to the point of severe fatigue and, with experience, the laboratory technicians and nurses became expert at persuading the small and sometimes reluctant young children, or the larger and sometimes apathetic adolescents, to perform maximal or at least very close to maximal exercise. The end point of the test was a refusal to do more work despite verbal encouragement. This was manifested by the child's hanging on to the guard rails and refusing to let go on his jumping off, pushing the emergency stop button or going limp in the arms of the supervisor. The test results of six children aged 4 and 5 years and three teenage girls have not been included because the supervisor believed that these nine children had not produced a near maximal effort.

Lead CM_5 of the electrocardiogram was recorded at the end of each exercise stage, at the end of maximal exercise and at 2 and 5 minutes of the recovery period. Heart rate was obtained by measuring the interval between five R waves.

* 1 met = resting metabolic rate = considered equal to an oxygen uptake of 3.5 ml/kg body weight per min.

TABLE I

Bruce Treadmill Test Protocol

Stage	Speed (miles/hour)	Grade (%)	Approximate Oxygen Cost (ml/kg per min)	Equivalent Ergometer Loads (kilopond-meters/min per kg body weight)
1	1.7	10	18	7
2	2.5	12	25	11
3	3.4	14	36	16
4	4.2	16	46	21
5	5.0	18	56	26
6	5.5	20	63	30
7	6.0	22	?70	34

No child was permitted to hold on to the guard rails for more than a few seconds to get his balance or for more than 5 seconds at the end of each exercise stage when the electrocardiogram was being recorded. Holding on materially reduces the metabolic cost of the work and adds considerably to the work time, even when only a few fingers are used. We did not use a harness for safety purposes because in the Bruce test the belt speed is low and an occasional fall has not been harmful. A technician was always available beside the child for support and to push an emergency stop button on the guard rail. All tests were performed in an air-conditioned laboratory at 19° C and 40 percent relative humidity. Reproducibility tests were carried out with 20 schoolchildren aged 7 to 13 years who repeated the test 3 to 10 days after the their first test.

Direct measurements of *maximal oxygen uptake* ($\dot{V}O_2$ max) were made in another group of 77 children by obtaining school volunteers and young athletes. Endurance times of these additional subjects were not included in the percentile calculations. In 38 of the schoolchildren oxygen uptake was measured during the last minute of each exercise stage and during the last few minutes of maximal exercise by collecting expired air in a Tissot spirometer and analyzing for oxygen and carbon dioxide with calibrated analyzers. There may be some controversy over the supervision of maximal exercise tests. In this laboratory all tests are carried out by trained technicians, usually in the absence of a physician. A physician is within 30 seconds call and reach of the laboratory for subjects with cardiovascular disease but not for normal children.

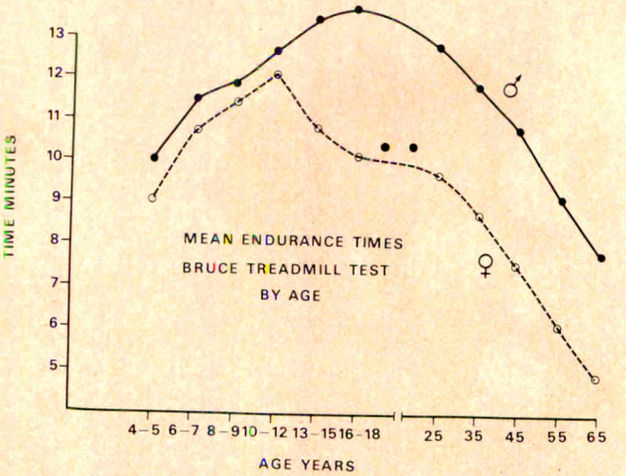

FIGURE 1. Mean endurance time by age for male and female subjects aged 4 to 65 years. For ages 4 to 18, values were taken from clinic patients with normal murmurs. For ages 25 to 65, male values were taken from volunteers in a normal male population. Each point is the mean of at least 60 subjects. For ages 25 to 65, female values were taken from the data of Bruce et al.[1]

Subjects: All 327 subjects tested had been referred to a cardiac clinic where a definite diagnosis of innocent murmur was made. This diagnosis was established on the basis of clinical findings, resting electrocardiograms in all subjects and chest roentgenograms in some.

Results

Endurance time: Percentile values for endurance times were established from a total number of 327 children divided into six age groups (Table II). The 50 percentile values increased in girls aged 4 to 7 years, leveled off for those aged 8 to 15 years then decreased in the older girls. For the boys the 50 percentile values

* R2 and R5 = recovery at 2 and 5 minutes sitting with feet elevated.

increased from age 4 and 5 years to age 8 and 9 years, then increased more gradually thereafter to reach peak values at age 13 to 15 years. The 10 and 25 percentile values were disproportionately lower for children in the younger and older age groups, possibly because some of these subjects could not be motivated to work maximally.

Mean average endurance times for ages 4 to 65 years are shown in Figure 1. Values for adult men were taken from an ongoing survey of a normal population being studied in this laboratory[2] and are similar to values reported by Bruce et al.[1] for Seattle men. Values for adult women were taken from the report of Bruce et al.[1] For male subjects the mean endurance time at age 8 years was the same as that at age 35; at age 6 it was equal to that at age 40 and at age 4 to 5 was equal to that at age 50. For female subjects the mean endurance time in 4 and 5 year olds was better than that recorded after age 35, and the mean time at age 6 and 7 was better than that recorded for female subjects aged 13 years and older. The mean values for girls were similar to those of boys up to age 12 years, differing by only 30 to 45 seconds; after age 12 the gap widened. The mean endurance time at age 16 to 18 years was 35 percent longer in the male subjects, and at age 55 the difference was 55 percent. In the children the endurance time represents the maximal time they would work with the technicians, who usually were able to encourage them to continue a few minutes after they wanted to stop; middle-aged adults were not encouraged to the same degree. Because of the selection methods, the values in Figure 1 are not reliable norms for the population at large but are shown for comparative purposes.

Heart rate: Table III and Figures 2 and 3 show the mean heart rates of the various age groups at rest, at each exercise stage and during recovery. The mean heart rates were similar in most age groups. For both boys and girls the resting and exercise rates were fastest in the youngest age group. The mean maximal heart rate of the various age groups ranged from 193 to 206 beats/min. For stages 1 to 3 the 13 to 15 year old boys had the lowest heart rate. The 16 to 18 year old boys had the highest recovery rates and there were only slight differences in the mean rates for the other age groups. If fitness for submaximal exercise is judged on the basis of the lowest heart rate for submaximal work, then boys were most fit at age 13 to 15. Some children, particularly girls, had a heart rate of up to 190 beats/min during stage 2 of the test and yet were capable of completing stages 3 and 4 and had a final maximal heart rate of 200 to 220 beats/min. The lowest maximal heart rate by age group ranged from 180 to 193 beats/min, and the highest from 203 to 220.

Correlation of heart rate and endurance time: There were significant negative correlations between the heart rates for stages 2 and 3 of the Bruce test and the endurance times. Not unexpectedly, subjects with a slower heart rate during the submaximal portions of the test had a longer endurance time. The correlation coefficients for the various age groups and sexes ranged from 0.20 to 0.77 (Table IV). These correlations would

TABLE IV

Correlation Coefficients of Endurance Time versus Heart Rate for Stage 2 of Bruce Test

† $P < 0.01$.

allow the prediction of maximal performance from submaximal heart rate as is done with bicycle ergometer work.[3]

Oxygen uptake: Age differences in the oxygen uptake ($\dot{V}O_2$) during the 3rd minute of stages 1 to 3 of the Bruce test are present as indicated in Table V. The lowest age group tested, the 7 year olds, had the highest $\dot{V}O_2$ values (6 to 20 percent above adult values); by age 11 to 12 years the values for children were only 1 to 6 percent higher than those reported for adults by Bruce et al.[1] The oxygen costs of stages 4 and 5 have not been listed because only a few subjects went on to complete

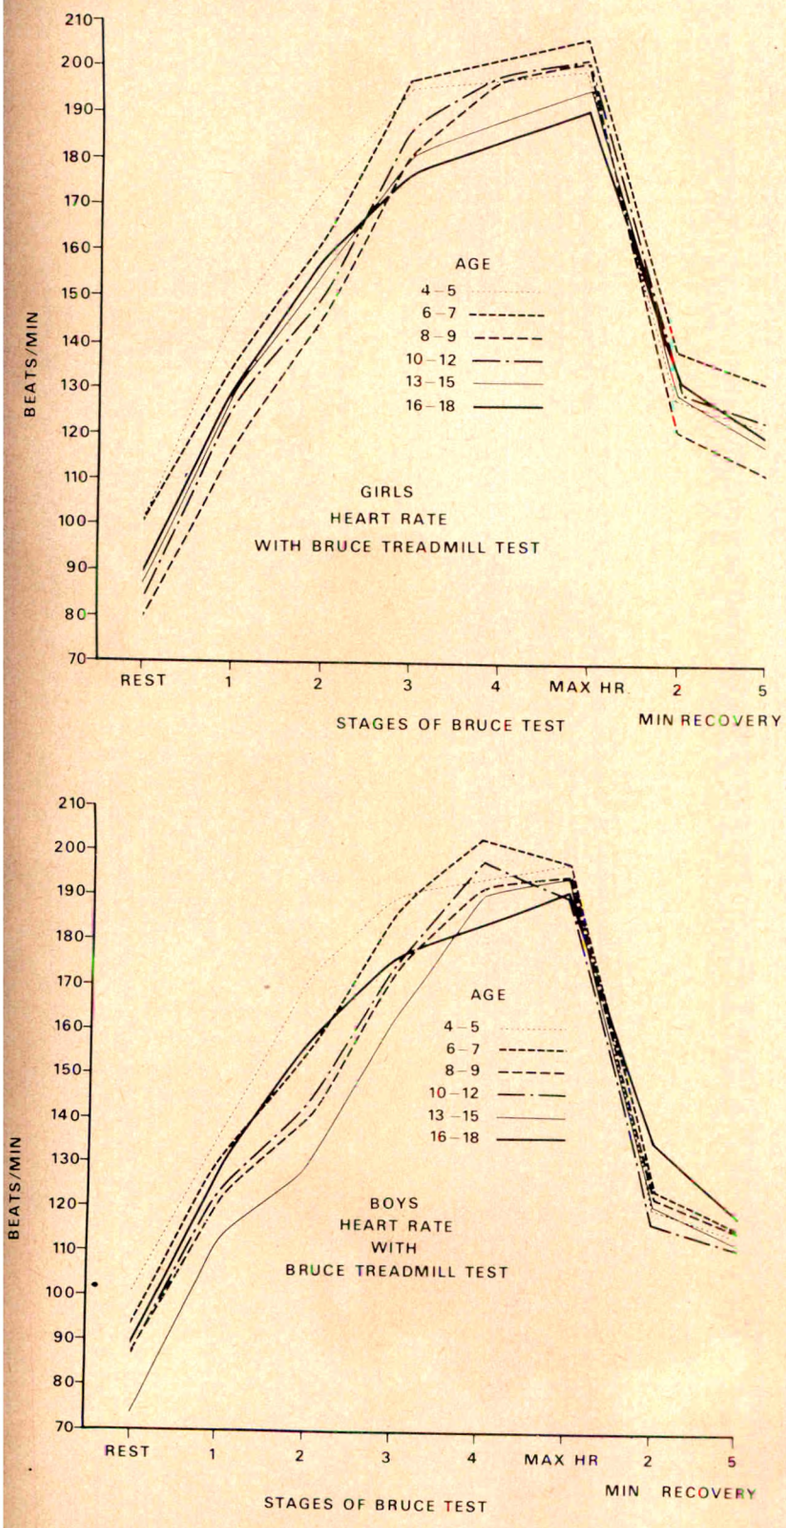

FIGURE 2. Mean heart rate during and after the Bruce treadmill test. **A,** in girls with a normal murmur. **B,** in boys with a normal murmur. MAX HR = maximal heart rate; MIN = minutes.

at least 2 minutes of the next load, a minimal requirement to ensure that the cost of the stage in question was not greater than the person's maximal $\dot{V}O_2$. In 36 athletes aged 13 to 20 years we found the oxygen uptake during the 3rd minute of stage 4 to be 46.9 ± 2.7 ml/kg per min (mean ± standard deviation), and of stage 5 to be 56.5 ± 3.1 ml/kg per min.

The ratio of weight to height[3] was used as an index of heaviness. Linear regression studies showed that in each age group there was a negative correlation between endurance time and this ratio, the correlation coefficients ranging from 0.20 to 0.47. These correlations were of low order but were statistically significant ($P < 0.05$).

Data on maximal oxygen uptake and endurance time were collected from an additional 53 girls and 24 boys (not included in the percentiles for endurance time). There was a close correlation between maximal $\dot{V}O_2$ and endurance time. The values for the girls are shown in Figure 3. For boys the correlation coefficient between endurance time and maximal $\dot{V}O_2$ was 0.85.

Comparison with bicycle ergometer: Many reports of exercise capacity in children have utilized the bicycle ergometer as the test device. Average boys reach stage 5 of the Bruce test; to achieve the equivalent metabolic load on the ergometer the 25 kg child must work at 640 kilopond-meters/min, and the 50 kg child at 1,300 kilopond-meters/min, or about 25 kilopond-meters/min per kg, a very difficult load to sustain. The equivalent bicycle loads in kilopond-meters/min per kg for the various stages of the Bruce test are given in Table I.

Reproducibility tests: Twenty normal schoolchildren aged 7 to 13 years performed the Bruce test on two occasions 3 to 10 days apart, neither they nor the examiner being aware of the time achieved on the first test. Endurance time ranged from 10.4 to 17.5 minutes; the mean times were 13.9 ± 2.1 for trial 1 and 13.7 ± 1.9 minutes for trial 2, and the linear regression of time 1 on time 2 gave a correlation coefficient of 0.94. The test was highly reproducible in this limited subsample of children.

Discussion

No magic formula was used in the design of the Bruce protocol; comfortable combinations of grades and belt speeds were chosen to provide light, moderate and maximal exercise stresses. Other suggested protocols[4–6] may be equally satisfactory. However, a modified Balke test[4] using 2 or 2.5 miles/hour and grade increments of 1 percent starting at 7 percent grade was tried in our laboratory in 150 children aged 4 to 6 years; the test was not as suitable as the Bruce test for fit cooperative children because it lasted too long, boredom became a factor, and the grade became too steep before exhaustion occurred. The method of Taylor et al.[7] of performing a maximal oxygen uptake test has been used in our laboratory for children aged 11 to 16 years, but this protocol requiring running at 6.5 miles/hour was not suitable for younger children. Because of the wide acceptance and popularity of the Bruce test for adults, it was decided to use this test as a start toward standardization of all clinical stress testing in our laboratory.

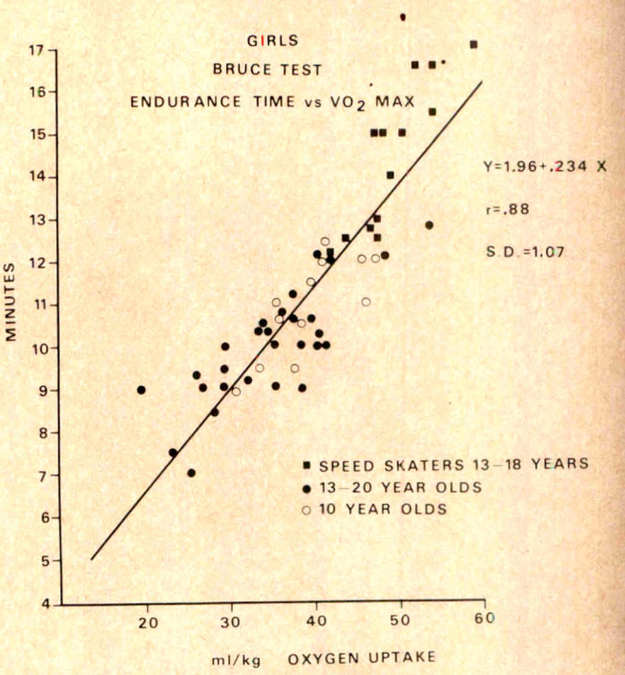

FIGURE 3. Endurance time on the Bruce treadmill test versus maximal oxygen uptake ($\dot{V}O_2$ max) obtained during the same test in three groups of subjects: 12 girl volunteers, aged 10 years, from a grade 5 school class; 13 girls, aged 13 to 18 years, training for competitive speed skating; 28 girls, aged 13 to 20 years, attending normal school classes or working in a hospital.

Determinants of exercise endurance time: The

* Data from Bruce et al.[1]

endurance time achieved is a result of many factors. It is obviously dependent on the motivation of the child to work to near exhaustion and on the skill of the technicians in the handling of young children. Physiologic factors that allow longer endurance times include aerobic and anaerobic power. The anaerobic component of a progressive test of 10 to 20 minutes' duration is mainly dependent on the ability of the working muscles to form lactate from glycogen during the last few minutes of exercise. This power may be less in prepubertal children because of a lower muscle glycogen content and a lower concentration of the enzyme phosphofructokinase.[8] The anaerobic system may be totally depleted of energy sources after 1 minute of supermaximal work,[9] so that differences in anaerobic power would not account for major differences in endurance times with the Bruce test, which lasted 9 to 18 minutes.

Aerobic power is dependent on the pumping capacity of the heart, the normal function of the lungs, the oxygen carrying capacity of the blood and the perfusion and oxidative metabolism in the working muscles. The efficiency of treadmill walking and running is said to be roughly equal in different subjects, but Table II indicates that there is a coefficient of variation of about 10 percent in the oxygen cost of submaximal exercise. Some of this variation is due to measurement error; some is due to interindividual differences in efficiency. There also were age differences in efficiency, and children at age 7 were up to 15 percent less efficient than older children. Two children of the same age and size may have differing abilities to walk and run on the treadmill because of unknown factors ("treadmill and running know-how"), and these differences may not be associated with measurable differences in energy metabolism. We have been impressed that children who are lean and wiry and tall for their age have a longer endurance time than soft or pudgy children, but the correlation studies using the crude measure of weight/height^3 as an indication of body build showed that build differences explained only about 16 percent of the interindividual variation in endurance time.

Correlation of endurance time and maximal oxygen uptake: Because of the many factors other than the aerobic system that contribute to the endurance time, we prefer to leave the measurement as a time rather than using it to predict maximal $\dot{V}O_2$. The correlation studies shown in the results not unexpectedly indicate a high correlation between endurance time and $\dot{V}O_2$ max, but the standard error of predicting $\dot{V}O_2$ max is at least 10 percent of the mean, and nothing is gained by this extrapolation of the data.

Oxygen uptake could have been measured in every child, but our unpublished experiences with children indicate that such measurements would have reduced the endurance time in many of the younger children and lost the cooperation of several to the degree that a maximal effort would not have been made. This problem could possibly be overcome by repeated tests, but the extra time involved places direct $\dot{V}O_2$ measurements in the research laboratory and not for routine clinical use, unless it can be shown that the additional information is of clinical value.

Reproducibility tests indicated that children did not perform better on a second test. Because the test was to be used as a screening test for exercise capacity, it was desirable that no practice be necessary to perform well. The first two stages of the test were usually sufficient to eliminate any element of fear and to allow the subject to gain confidence.

Selection of normal test subjects: Lavallee et al.[10] recently reported that in a group of 700 schoolchildren followed up for 5 years, growth and $\dot{V}O_2$ max (directly measured during bicycle exercise) were the same in the 20 percent recorded to have innocent murmurs as in the 80 percent without a recorded murmur. Although this evidence supports the view that children with innocent murmurs can be considered normal subjects in stress testing, the clinic patients in our study were a special subsample of a large population of children with murmurs who happened to be referred to a specialty clinic.

Going into the schools for normative data in children permits one to collect a large sample in a short time and to use random selection methods. However, utilizing volunteers in a school environment is different from testing an often reluctant child persuaded by the parent to come to an unfamiliar hospital clinic. Both "normal" and abnormal subjects in a clinic are tested in random order as they come. The same technicians test normal subjects and patients on the same apparatus in the same environment over the same time period. When a new technician enters the system, data for normal subjects continue to be obtained. Technicians have tended to obtain a longer endurance time in the normal children as they gained experience and provided the children with greater goals. This emphasizes the need for all exercise laboratories to continue monitoring normal subjects concomitantly with test patients. Although it is possible that higher values for maximal performance may be obtained with volunteers from the school system, it is debatable whether the latter are an ideal population against which to compare clinic patients.

Advantages of method for clinical testing: The Bruce test proved to be highly suitable for the clinical exercise testing of children aged 4 years and older. The same protocol is used for all ages, the response to submaximal exercise loads may be documented, the heart rate responses are similar for children of all ages, maximal oxygen uptake can be roughly estimated, a maximal exercise capacity measurement is obtained based on what the subject actually did and not on a prediction made by extrapolation, longitudinal data on growing children can be obtained using exactly the same exercise protocol and in contrast to the bicycle ergometer, there are no calibration problems with the exercise apparatus and no need to have a large number of work loads based on body weight. No prior experience or practice by the patient is necessary and, because the belt speed is slow, injury and fear of performing on the treadmill are minor issues.

Surgical Significance of the Coronary Arterial Anatomy in Truncus Arteriosus Communis

KENNETH R. ANDERSON, MBChB, FRCPA*
DWIGHT C. McGOON, MD, FACC
J. T. LIE, MD, FACC

Rochester, Minnesota

In truncus arteriosus communis, as in other anomalies of conotruncal development, the coronary arterial anatomy not only differs from that found in the normal heart but also is subject to unpredictable variations. A consistently distinctive pattern was found in roughly two thirds of 31 cases, a frequency approximating that with which a distinctive coronary arterial pattern occurs in complete transposition of the great vessels. Surgical injury to a major coronary artery was identified in 2 of the 30 hearts from patients with truncus arteriosus communis who died in the early postoperative period. Of particular significance are large branches of the right coronary artery crossing the upper anterior surface of the right ventricle to supply the anterobasal surface of both ventricles and the upper part of the interventricular septum. These arteries are at special risk in surgical procedures utilizing a conduit anastomosed to a right ventriculotomy.

Truncus arteriosus communis is a congenital cardiac malformation in which a single arterial trunk arises from the heart and receives the outflow from both ventricles. There may be some inequality of positioning of the trunk so that it favors either the left or the right ventricle, and an interventricular communication is present directly beneath the single semilunar valve of the truncus. The coronary arteries arise from the truncus proximally and the pulmonary arteries arise more distally. Truncus arteriosus communis is classified by the nature of the pulmonary arterial origin from the truncus.[1,2]

This study reviews the anatomy of the coronary arteries in 31 hearts with truncus arteriosus communis and documents instances of surgical injuries to major coronary arteries that had occurred in the hearts of 30 patients who died in the early postoperative period.

Materials and Methods

Thirty-four hearts with classic truncus arteriosus communis were available for study. All the hearts were from the tissue registry of the Department of Pathology and Anatomy at the Mayo Clinic and were from autopsies performed during the 8 year period from 1968 to 1976, inclusive. The age of the patients at autopsy ranged from 18 days to 14 years. The surgical experience from this institution has previously been reported.[3] A detailed examination was made to confirm the diagnosis anatomically. The coronary ostia were examined and their position in relation to the cusps of the truncal valve was recorded. The procedure included measurements to ascertain the height of the ostia above the truncal valve ring. In three hearts, truncal valve replacement had been carried out and it was not possible to document the position of the ostia in relation to the cusps of the truncal valve. These three hearts were excluded from the component of the study dealing with the coronary arterial anatomy although they were included in the study to identify surgical injury to the more distal vessels. Careful dissection of the coronary arteries was performed and the coronary anatomy documented. A note was made of the approximate relative size of the vessels. Particular attention was paid to any areas where arteries were in close proximity to suture lines or hematoma and the lumen of the vessel in such areas was carefully examined for the presence of any occlusive lesion.

Results

Truncal valve: To be able to document the sites of origin of the coronary arteries one must first document and establish a nomenclature for the cusps and commissures of the truncal valve. In the absence of a second semilunar valve other reference planes such as the ventricular septum and the position of origin of the pulmonary arteries must be used. It was found that if the valve was tricuspid (24 hearts [78 percent]) one commissure was pointed either anteriorly or in a right anterior oblique direction. Although there was variable rotation between these extremes, and there was often minor variation in the relative size of the individual cusps, one cusp was predominantly posterior in position. This cusp can be designated posterior and the other cusps right anterior and left anterior. If the valve is bicuspid (four hearts [13 percent]) or quadricuspid (three hearts [9 percent]), there is considerable variation in the inclination of the commissures and the position of the cusps.

Ostia and proximal coronary arteries: Thirty-one hearts were used in this component of the study. The positions of the ostia and the proximal arteries are summarized diagrammatically in Figures 1 to 3. In 19 of the 31 hearts (61 percent), regardless of whether the truncal valve was bicuspid, tricuspid or quadricuspid, the left coronary artery arose from the left posterior aspect of the truncus and the right coronary artery arose from the right anterior aspect. Thus, in 61 percent of the hearts a consistent pattern of origin of the coronary arteries was observed. A total of 4 of the 31 hearts (13 percent) had either a single ostium or very closely associated ostia.

When the truncal valve was tricuspid, the most frequent pattern (observed in 15 hearts [48 percent]) was origin of the right coronary artery from the sinus of Valsalva above the right anterior cusp so that the vessel gained very direct access to the right atrioventricular (A-V) groove. The left coronary artery arose from the sinus of Valsalva above the posterior cusp, coursed around the left side of the truncus and divided anterior to the truncus so that the mainstem of the left coronary artery was long. The left circumflex branch gained access to the left A-V sulcus but the left anterior descending branch originated well to the left. In a further four hearts (13 percent), the right coronary artery originated posteriorly and the left coronary artery from the left anterior sinus of Valsalva. This minor variation could be the result of differences in rotation of the truncus.

In five hearts the truncal valve was tricuspid but the coronary arterial anatomy was atypical (Fig. 2, A and B). In two of these hearts there were two coronary ostia, and in three hearts both arteries arose from a single ostium. In the hearts with two ostia, it was not possible to attribute the variation to differing rotation of the truncus.

In seven hearts, the truncal valve was either bicuspid (four hearts) or quadricuspid (three hearts). In the four hearts with a bicuspid valve (Fig. 3) the coronary arterial pattern and the position of the ostia approximately conformed to the positions most frequently seen with a tricuspid valve. The three hearts with a quadricuspid valve had an atypical coronary pattern, and one of these hearts had a single coronary ostium.

TABLE I
Summary of Surgical Procedures in 30 Cases of Truncus Arteriosus Communis

Procedure	Cases (no.)
Total correction utilizing a conduit	
Aortic homograft	16
Hancock conduit prosthesis	11
Palliative procedures	
Blalock-Hanlon	1
Pulmonary arterial banding	1
Exploration only	1
Total	30

Anterior surface of the right ventricle: This area is of considerable importance because it is here that ventriculotomy incisions are made and conduit prostheses are anastomosed during reparative surgical procedures. As previously mentioned, in the most frequently observed coronary arterial pattern the left coronary artery bifurcated well to the left of the truncus. Thus, at its origin it was displaced to the left of the interventricular sulcus. It then coursed downward on the surface of the left ventricle, not reaching the interventricular sulcus until a point approximately halfway down the anterior surface of the heart. This pattern was previously described by Bharati et al.[4] Furthermore, the vessel was usually smaller in caliber than one expects the left anterior descending coronary artery to be. The small size and the leftward displacement of this vessel appear to result in a greatly reduced contribution to the blood supply of the right ventricle and the interventricular septum. Large diagonal branches of the right coronary artery, which run a course parallel to the conus artery but are situated farther down on the anterior surface of the right ventricle, are almost invariably present in truncus arteriosus communis (Fig. 4). The conus artery and these other diagonal branches of the right coronary artery supply almost all the anterior surface of the right ventricle, often the upper interventricular septum and occasionally part of the anterior surface of the left ventricle.

Surgical injury to the coronary arteries: In the 34 cases available, 30 patients had recent surgical procedures (Table I). In the majority (27 cases), the procedure utilized a conduit, either an aortic homograft or a Hancock valved conduit prosthesis. The operative procedure involved patch closure of the right ventricular outflow tract to the truncus, detachment of the pulmonary vessel or vessels from the truncus and placement of the conduit between the right ventriculotomy and detached pulmonary arteries.[5]

Injury to a major coronary artery was identified in two cases. In one, the injury involved the main right coronary artery, which had been drawn up from its position

in the right A-V sulcus and obliterated by sutures closing the right atriotomy wound in the appendage (Fig. 5). In the other, a large diagonal branch of the right coronary artery on the anterior surface of the right ventricle above the ventriculotomy was tied after inadvertent injury. As previously mentioned, large diagonal branches of the right coronary artery traversing to the left on the anterior surface of the right ventricle are frequently present in truncus arteriosus communis. In two further cases, similar arteries of moderate size were obliterated by sutures attaching the conduit to the right ventriculotomy, and in all cases some much smaller vessels were by necessity compromised. In none of the hearts in which vessels were occluded was a localized area of myocardial infarction distinguishable macroscopically or microscopically from the generalized pathologic changes usually present in patients who die in the immediate period after open heart surgery.

Discussion

In congenital anomalies of conotruncal development coronary arterial anatomy differs from that found in the normal heart and is subject to a greater likelihood of unpredictable variations. This has been well established

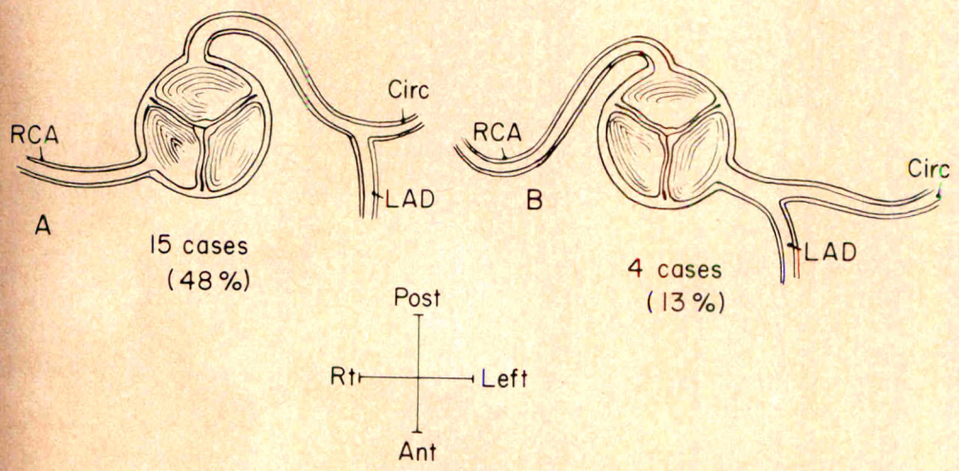

FIGURE 1. The most commonly encountered positions of the coronary arterial ostia in truncus arteriosus communis in our series. The lesser variation (**B**), present in four cases, can be explained on the basis of a variable degree of rotation of the trunk. Ant = anterior; Circ = left circumflex coronary artery; LAD = left anterior descending coronary artery; Post = posterior; RCA = right coronary artery; Rt = right.

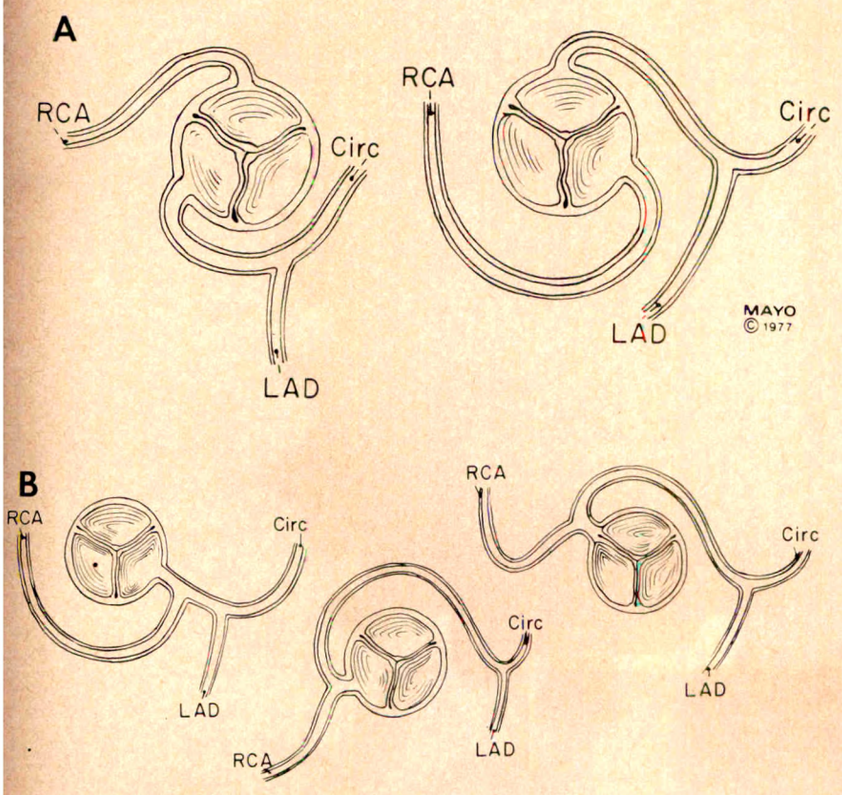

FIGURE 2. The position of the coronary ostia in five hearts with a tricuspid truncal valve but atypical coronary arterial anatomy. **A,** the two hearts with two coronary ostia; **B,** the three hearts with a single coronary ostium. Orientation and abbreviations as in Figure 1.

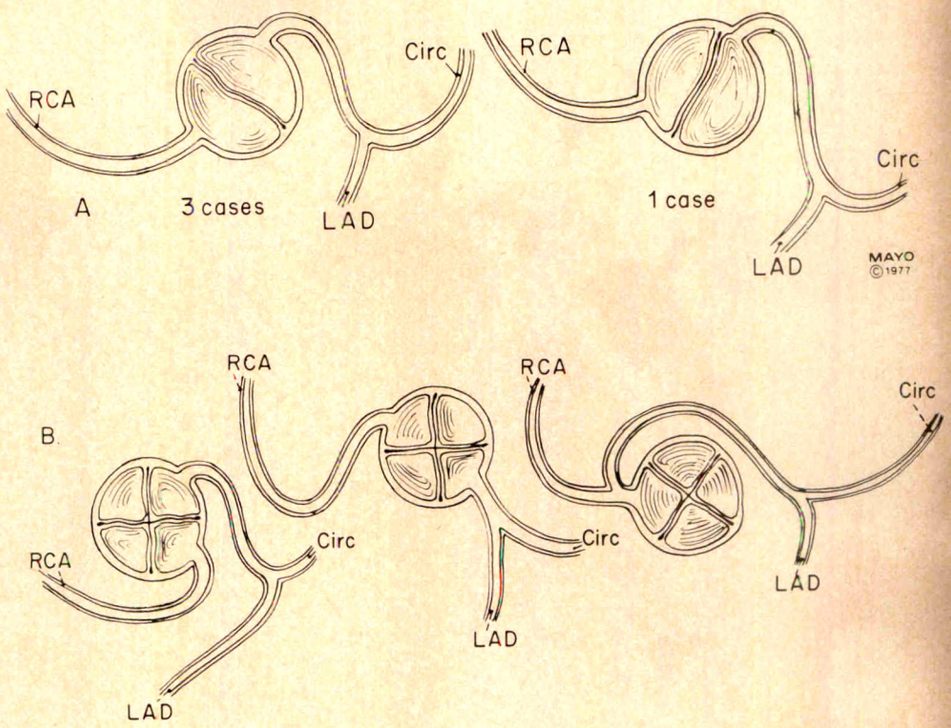

FIGURE 3. The position of the coronary ostia in seven hearts with a bicuspid or quadricuspid truncal valve. **A,** the four hearts with a bicuspid valve; **B,** the three hearts with a quadricuspid valve. Orientation and abbreviations as in Figure 1.

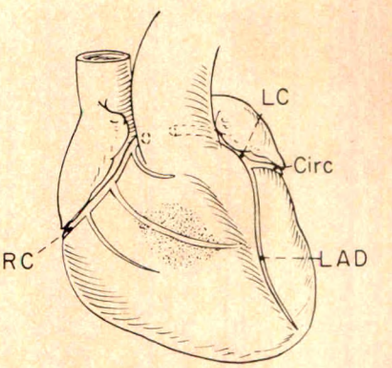

FIGURE 4. Diagrammatic illustration of the anterior surface of a heart with truncus arteriosus communis showing the coronary arterial anatomy often encountered. The anterior descending branch (LAD) of the left coronary artery (LC) is displaced to the left in its proximal course and does not reach the anterior interventricular sulcus till a point approximately halfway down the anterior surface of the ventricles. Large diagonal branches of the right coronary artery (RC) running parallel to the conus artery but situated farther down on the surface of the right ventricle are usually present. These arteries are in danger of being injured by a ventriculotomy incision or when a conduit is anastomosed to the right ventricle (**stippled area**). Circ = circumflex branch of the left coronary artery.

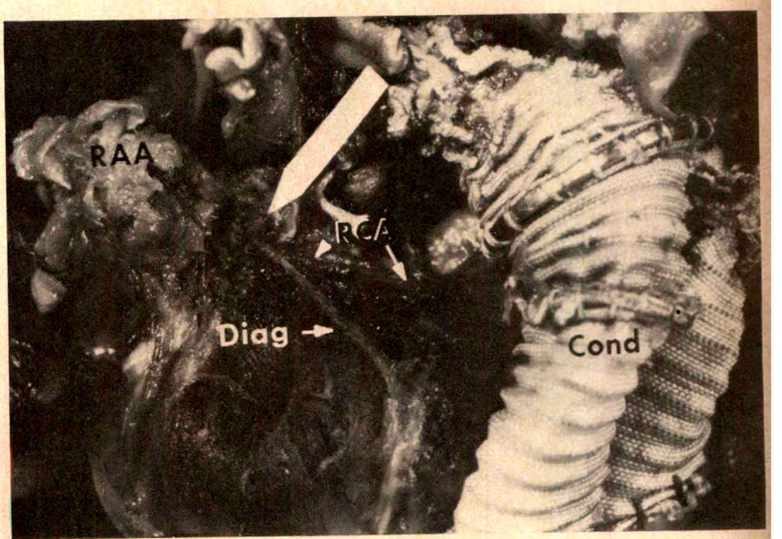

FIGURE 5. Surgical injury to the right coronary artery (RCA), which has been drawn up from its position in the right A-V groove (**arrow**) and incorporated in sutures securing the atriotomy wound in the right atrial appendage (RAA). Cond = conduit prosthesis (right ventricle to pulmonary artery); Diag = diagonal branch of the right coronary artery.

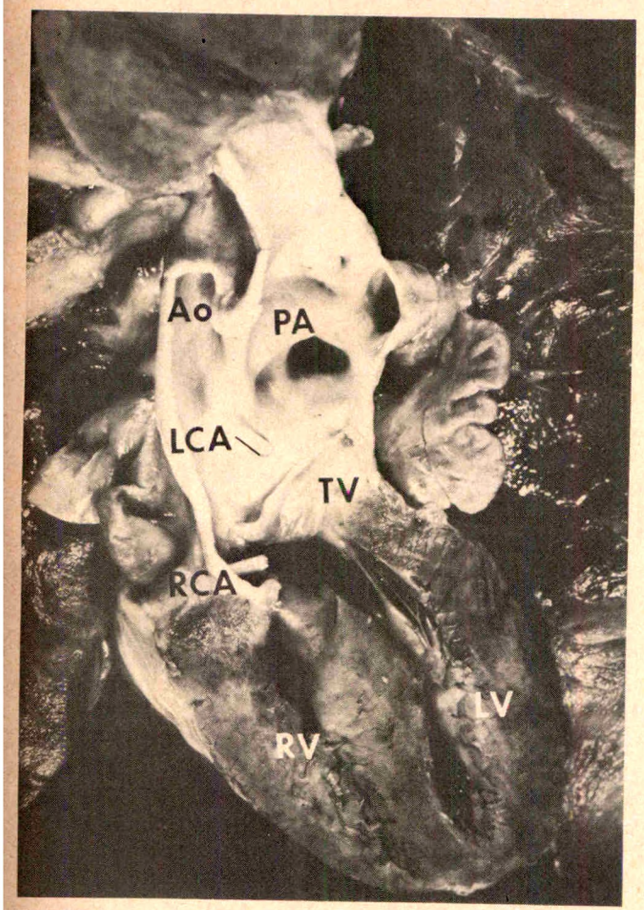

FIGURE 6. Heart at autopsy showing the truncus and truncal valve (TV) opened to expose the coronary ostia. The left coronary arterial ostium is anomalously high above the sinus of Valsalva and in close proximity to the origin of the pulmonary artery. Ao = aorta; LCA = left coronary artery; LV = left ventricle; PA = pulmonary artery; RCA = right coronary artery; RV = right ventricle; TV = truncal valve.

in complete transposition of the great vessels,[6–8] and appears to apply also to truncus arteriosus communis.[9] In explaining the embryologic basis of transposition, the abnormal positions of the coronary ostia are part of the evidence favoring a hypothesis involving disordered conotruncal rotation rather than deficient spiraling of the aorticopulmonary, truncal and conal septa. Truncus arteriosus communis is generally believed to be the result of failure of growth of these septa but it seems probable that a rotational anomaly of the truncus must also occur to explain the displacement of the ostia.

Previous mention has been made of the abnormally high position of the coronary ostia in truncus arteriosus communis.[4,10] In some of our cases an ostium was noted to arise at or slightly above the junction of the sinus of Valsalva to the ascending truncus, but we did not consider this a significant anomaly when measurements from the aortic valve ring were considered. The junction of the sinus to the ascending truncus is often variable and difficult to define. Although not in this series, we have observed a very high anomalous left ostium situated just below the origin of the pulmonary trunk (Fig. 6). Such an artery would have been in danger when the pulmonary trunk was divided from the truncus during a total correction procedure, but we believe that anomalously high ostia of this degree are uncommon in truncus arteriosus communis.

Surgical implications: The two patients whose major coronary arteries were ligated and the two whose smaller anterior diagonal branches were injured died in the immediate postoperative period. Low output failure and arrhythmias were the cause of death. There appeared to be no features to distinguish the low output failure in these cases from low output failure of other causes occurring after cardiac surgery. Although it is only speculative that these injuries were responsible for the postoperative heart failure and arrhythmias, it is likely that they contributed significantly. In two cases injuries were to major vessels: in one case to the main right coronary and in the other to an anterior diagonal branch of the right coronary artery, which was similar in caliber to the left anterior descending artery. Patients in the pediatric age group usually do not have coronary artery disease and therefore would not be expected to have significant collateral vessels. Thus, occlusion of a major coronary artery would be expected to lead inevitably to infarction. Infarction at this time when cardiac function is already compromised as a result of surgery might well be expected to have disastrous consequences. Myocardial infarction was not identified, either macroscopically or with routine light microscopy, in the two hearts in which major coronary arteries were occluded. This is not surprising because the patients in both cases died in the early postoperative period after cardiopulmonary bypass, and the changes in the myocardium attributable to open heart surgery and subsequent resuscitation efforts would obscure the subtle pathologic changes of very recent myocardial infarction.

Anterior diagonal branches of the right coronary artery are almost invariably present in truncus arteriosus communis. Their course approximately parallels that of the conus artery except that they are situated lower down on the anterior wall of the ventricle. The importance of these vessels is enhanced because the left anterior descending coronary artery is often small and tends to be displaced well to the left in its proximal course. Thus, these branches of the right coronary artery supply the anterior surface of the right ventricle and may supply a significant proportion of the upper anterior wall of the left ventricle. It is also probable that they give rise in some cases to the perforating branches to the upper interventricular septum.

Clinical implications: We have demonstrated that anterior diagonal branches of the right coronary may be divided by a ventriculotomy incision or may be obliterated by sutures securing a conduit anastomosed to the ventriculotomy. This risk is greatly accentuated when the coronary arteries cannot be visualized at surgery because of pericardial fibrosis resulting from previous operative procedures. Special care and preoperative documentation of the coronary arteries, particularly the right coronary artery, with selective coronary angiography may be indicated in these cases.

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Number pages in sequence after last page of references.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals; Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

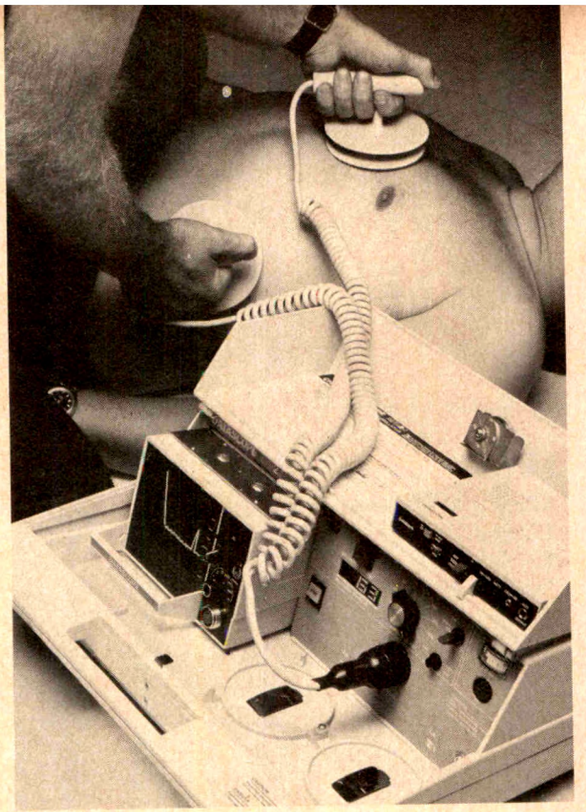
For 7 out of 10 patients, your present defibrillator may be powerful enough.

But more important, for 3 out of 10 it may not be.



Recent studies of defibrillation have disclosed some disquieting facts: "the success rate for defibrillation of human adults is only about 5% with defibrillators which deliver 300 watt-seconds of energy."* And "the probability of defibrillating a subject who weighs over 220 pounds is extremely low."* These studies have produced the following finding: "virtually all defibrillators now in use have inadequate output to defibrillate many human adults..."*

Because of this, we developed the Datascope M/D2J. A portable defibrillator capable of delivering not 300, or the widely available 320, but 460 watt-seconds of energy. Fully 1/3 more energy than most any other portable defibrillator made today.

Which means,very simply, that you have more capability when you need it.

But the Datascope M/D2J doesn't just deliver more energy than other defibrillators. It tells you more about what it's delivering.

It is the only defibrillator in the world that reads the current delivered to the subject during defibrillation. (Energy produces current. But current is what produces defibrillation. Which is why current is the truly meaningful measure.) It also reads selected delivered energy. And delivered energy into a built-in test load. And instead of test lights, or ready lights, all readings are precisely shown on a bright digital display.

To this point, we've been discussing the M/D2J as if it were merely a defibrillator. Of course, it's a monitor/defibrillator. The defibrillator is an impressive part. But the other parts are equally impressive. The M/D2J offers the finest non-fade monitor of any monitor/defibrillator in emergency medicine.

And it offers the new Databank. The first cassette recording system in emergency medicine. An instrument that does away with the bulk of paper recording while allowing you to record not merely ECG, but also to record the detailed management of the patient verbally onto the tape.

Which means that in addition to offering more energy, our system offers more capability than any monitor/defibrillator in the world.

For more information on the new M/D2J, write: Datascope Corp., 580 Winters Avenue Paramus, N.J. 07652

The new M/D2J with Databank.

THE PRACTITIONERS' DERMATOLOGY

. . .is a commonsense dermatology text written specially for the busy practitioner. This comprehensive, tightly written book is generously filled with over 600 illustrations, many of them classics and all neatly integrated into the text.

"Practical medicine, while it differs from academic and investigative, is eminently worthy" (Preface, The Practitioners' Dermatology)—this orientation pervades every discussion of structure, function, etiology and treatment in the book.

Here's what reviewers are saying:

"A notable contribution to dermatology"

"The first text in years that uses simple words and no circumlocutions and gives straightforward opinions and advice"

"Ideal for practitioners"

"Will be well received by not only practitioners and medical students but by dermatologists as well"

Drs. Sutton and Waisman have divided the text into 22 chapters; the first 6 present clear, understandable discussions of the structure, physiology, etiology, diagnosis and treatment of the skin and its general diseases; the last 16 chapters present the specific dermatoses, abnormalities and diseases organized by causative factors. An excellent index provides easy, accurate referencing.

Let us send you a copy to look over for 30 days without cost. If it's not what you want, send it back and owe nothing. Fill out the trial copy coupon today.

Peritrate® SA
Sustained Action
(pentaerythritol tetranitrate) **80 mg**
Peritrate®
(pentaerythritol tetranitrate) **40 mg**
Peritrate®
(pentaerythritol tetranitrate) **20 mg**
Peritrate®
(pentaerythritol tetranitrate) **10 mg**

CAUTION: Federal law prohibits dispensing without prescription.
Description: Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Each tablet of Peritrate 40 mg contains pentaerythritol tetranitrate 40 mg. Each tablet of Peritrate 20 mg contains pentaerythritol tetranitrate 20 mg. Each tablet of Peritrate 10 mg contains pentaerythritol tetranitrate 10 mg. Peritrate (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg and Peritrate (pentaerythritol tetranitrate) are contraindicated in patients who have a history of sensitivity to the drug.
Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.
Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe, persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:
(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate (pentaerythritol tetranitrate) may be administered in individualized doses up to 160 mg a day. Dosage can be initiated at one 10 mg or 20 mg tablet q.i.d. and titrated upward to 40 mg (two 20 mg tablets or one 40 mg tablet) q.i.d. one-half hour before or one hour after meals and at bedtime. Alternatively, Peritrate Sustained Action 80 mg can be administered on a convenient b.i.d. dosage schedule.
Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg—double-layer, biconvex, dark green/light green tablets in bottles of 100 (N 0047-0004-51) and 1000 (N 0047-0004-60). Also unit dose, package of 10 x 10 strips (N 0047-0004-11).

Peritrate (pentaerythritol tetranitrate) 40 mg—pink scored tablets in bottles of 100 (N 0047-0008-51).

Peritrate (pentaerythritol tetranitrate) 20 mg—light green, scored tablets in bottles of 100 (N 0047-0001-51) and 1000 (N 0047-0001-60). Also unit dose, package of 10 x 10 strips (N 0047-0001-11).

Peritrate (pentaerythritol tetranitrate) 10 mg—light green, unscored tablets in bottles of 100 (N 0047-0007-51) and 1000 (N 0047-0007-60).
STORE BETWEEN 59° and 86° F (15° and 30° C).
Animal Pharmacology: In a series of carefully designed studies in pigs, Peritrate (pentaerythritol tetranitrate) was administered for 48 hours before an artifically induced occlusion of a major coronary artery and for seven days thereafter. The pigs were sacrificed at various intervals for periods up to six weeks. The result showed a significantly larger number of survivors in the drug-treated group. Damage to myocardial tissue in the drug-treated survivors was less extensive than in the untreated group. Studies in dogs subjected to oligemic shock through progressive bleeding have demonstrated that Peritrate (pentaerythritol tetranitrate) is vasoactive at the postarteriolar level, producing increased blood flow and better tissue perfusion. These animal experiments cannot be translated to the drug's actions in humans.
Full information is available on request.

Only CPI offers four warranty options.

A choice in lithium that lets you match pacemaker to patient condition...with confidence.

If all patient conditions were the same, you'd only need one pacemaker. An optimum situation but medically unrealistic. The variety of patient needs demands a variety of implant options. Size, price and warranty life are all considerations when matching pacemaker to patient. The most critical of these factors however, is warranty life.

CPI's limited warranties are based on clinical data accumulated since 1972 and theoretical calculated longevity which has been determined for each unit. As such, the warranties are statements of CPI's product confidence and reliability. Confidence and reliability that only lithium offers.

The expanded line and warranties include:
• MAXILITH-10 • MINILITH-8 • MINILITH-5 • MINILITH-3.
Numerical designation indicates warranty life.
CPI pacemakers are available in asynchronous and demand models. All units are offered in unipolar and bipolar configurations.

No other pacemaker company can offer you this range of options in models and warranty life... all in lithium. For your needs, and for your patients.

Four warranty options. Only from CPI.

* **Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: Possibly effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, hypotension, increased intracranial pressure and idiosyncrasy to this drug.

Warnings: For ORAL, not sublingual use. Capsules must be swallowed whole. NITRO-BID® 2.5 and 6.5 Capsules are not intended for immediate relief of anginal attacks.

Precautions: Use the smallest dose which proves effective because continued administration of larger doses may lead to tolerance. Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. If blurring of vision or dryness of mouth occurs, drug should be discontinued.

Adverse Reactions: Occasionally transient headaches may occur. Overdoses may cause flushing, headaches, tachycardia, dizziness.

Dosage and Administration: One capsule two or three times daily at 8 to 12 hour intervals.

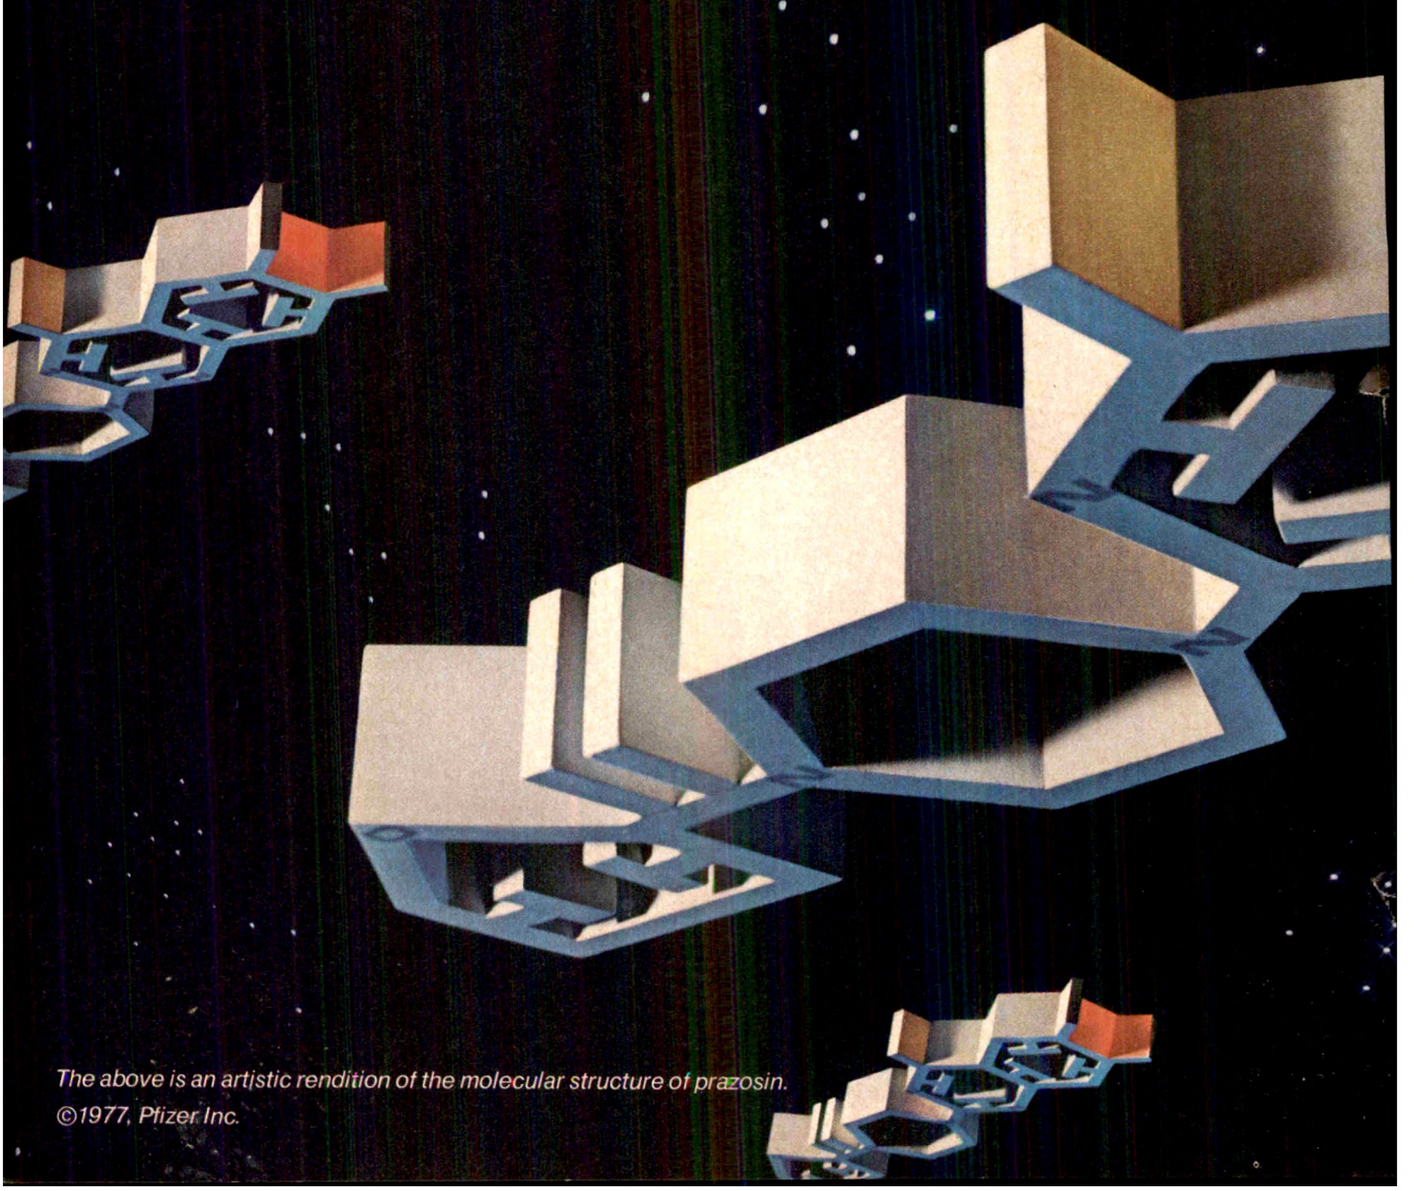
FROM PFIZER...

MINIPRESS® Capsules 1mg, 2mg, 5mg (prazosin HCl)

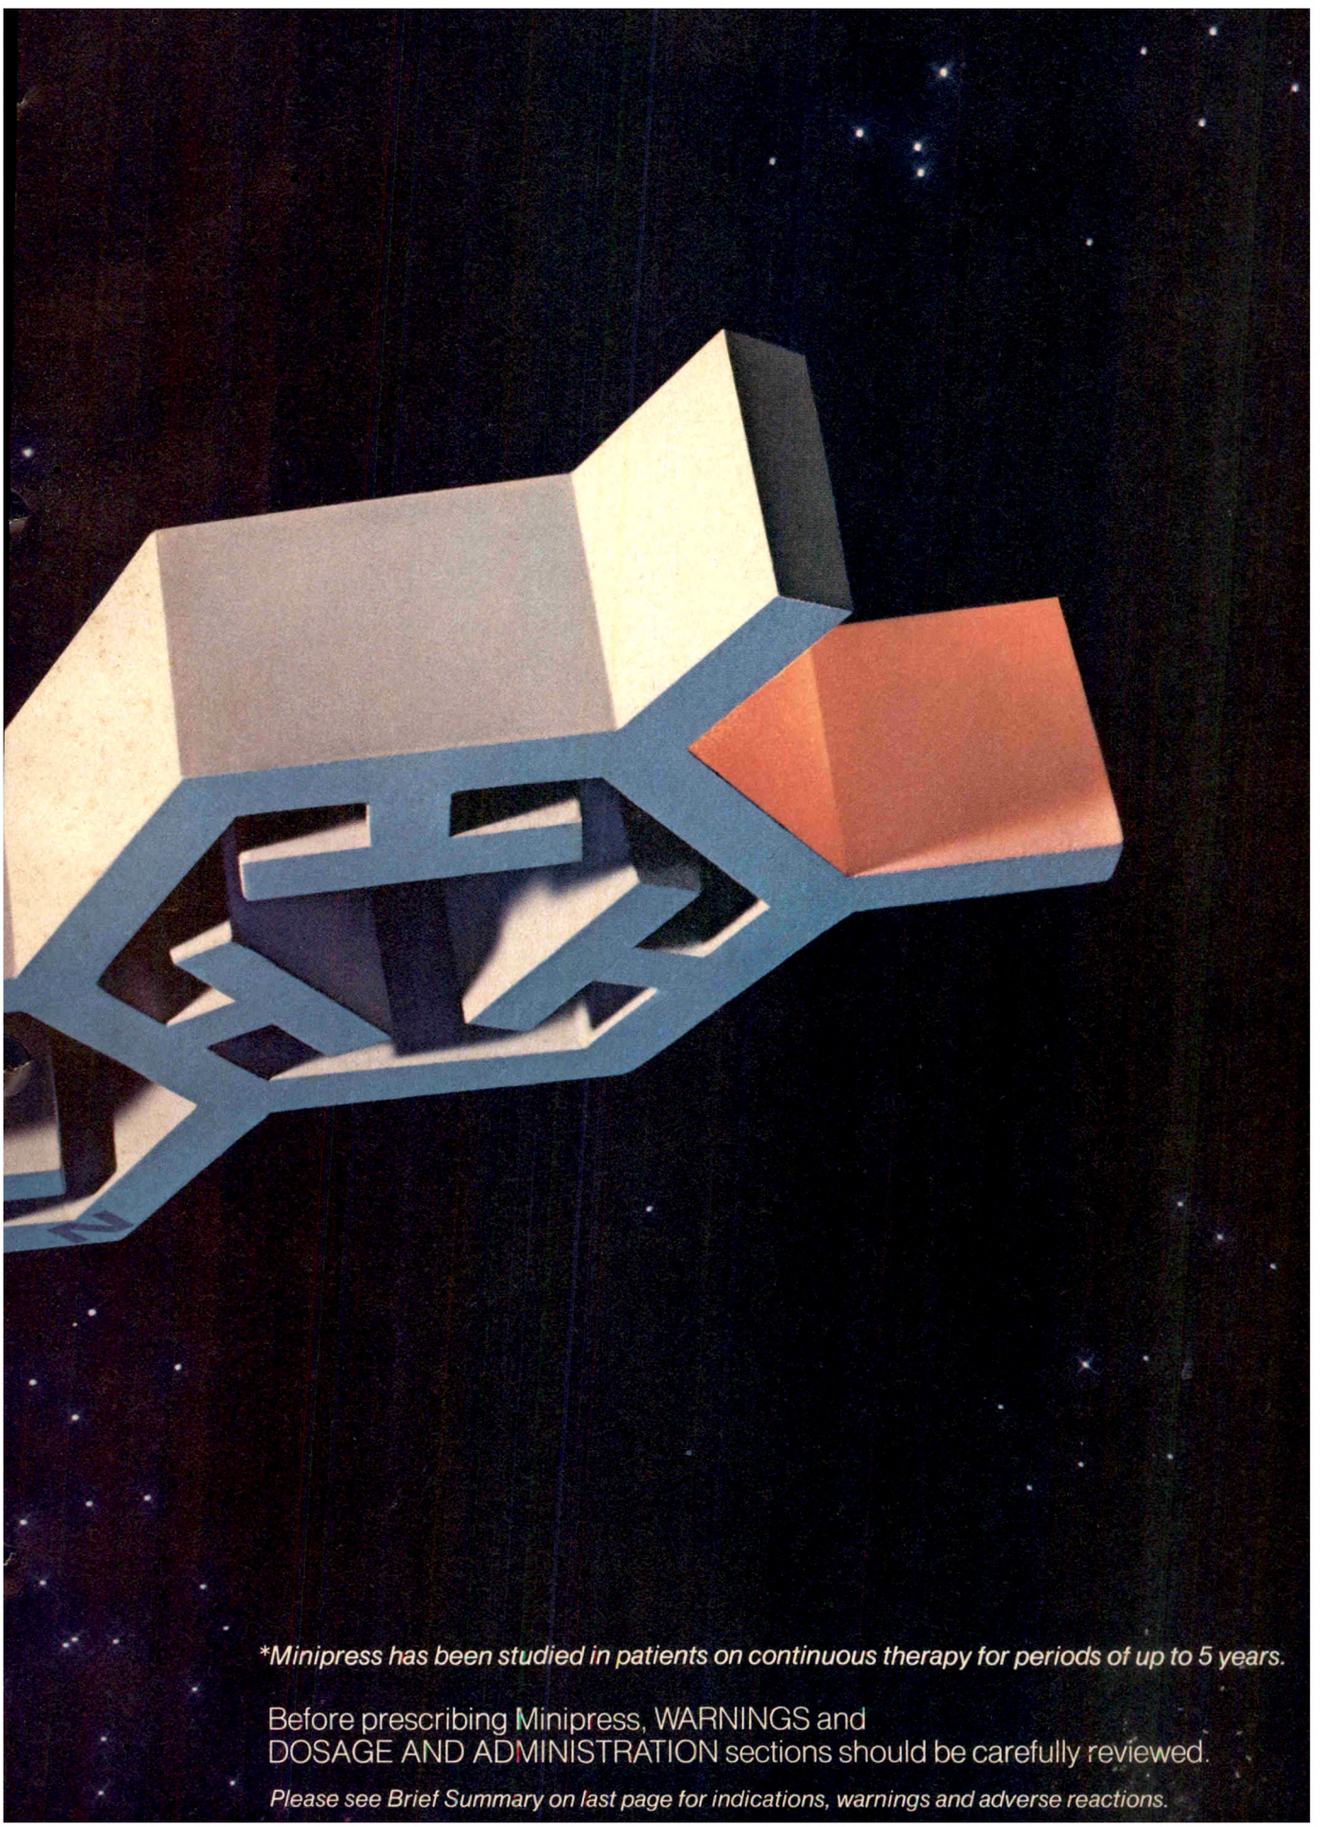
A FLEXIBLE ANTIHYPERTENSIVE— ALONE OR IN COMBINATION

- chemically and pharmacologically unique vasodilator
- mild to moderate in activity
- effective in all grades of hypertension
- well suited for long-term therapy*
- no tolerance observed in long-term therapy*



The above is an artistic rendition of the molecular structure of prazosin.

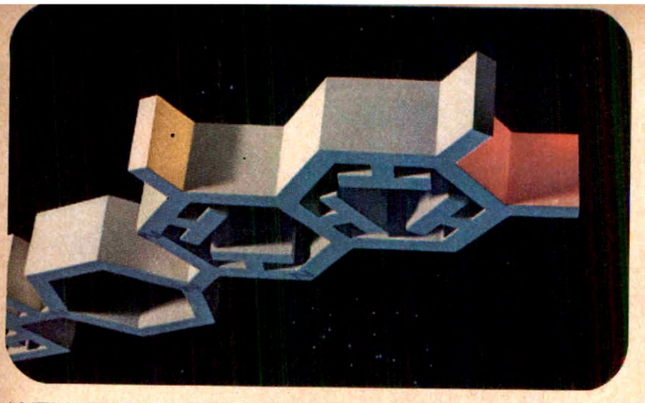
©1977, Pfizer Inc.



**Minipress has been studied in patients on continuous therapy for periods of up to 5 years.*

Before prescribing Minipress, WARNINGS and DOSAGE AND ADMINISTRATION sections should be carefully reviewed.

Please see Brief Summary on last page for indications, warnings and adverse reactions.



WELL SUITED FOR LONG-TERM THERAPY...

MINIPRESS® Capsules 1mg, 2mg, 5mg (prazosin HCl)

- Chemically and pharmacologically unique vasodilator.
- Mild to moderate in activity.
- Effective in all grades of hypertension, either alone or in combination with a diuretic and/or other antihypertensive agent.
- Direct action on the arterioles without clinically significant effects on cardiac output, renal blood flow or glomerular filtration rate. Reflex tachycardia frequently associated with other vasodilators is much less common with Minipress.
- No tolerance observed in long-term therapy in patients on continuous therapy for periods of up to 5 years.
- Studies in patients on continuous therapy for periods of up to 5 years indicate that Minipress is well suited for long-term therapy.
- Side effects most frequently experienced with Minipress in a series of 934 patients were: dizziness (10.3%), headache (7.8%), drowsiness (7.6%), lack of energy (6.9%), weakness (6.5%), palpitations (5.3%), and nausea (4.9%). A small percentage of patients have experienced orthostatic hypotension (3.4%) and syncope (1.3%). (For a more detailed description of orthostatic hypotension and syncope, see Warnings in Brief Summary before initiating therapy with Minipress.)
- Starting dosage: 1 mg t.i.d.
- Usual maximum recommended dosage: 20 mg daily, given in divided doses.
- Some patients can be maintained adequately on a b.i.d. dosage regimen.
- Available in 1-mg, 2-mg, and 5-mg capsules.

BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) Capsules *For Oral Use*

INDICATIONS. MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS. MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS. The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION. The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. Higher doses usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED. MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437), and 5 mg (blue and white #438) capsules in bottles of 250, and unit dose packages of 100 (10 x 10's).

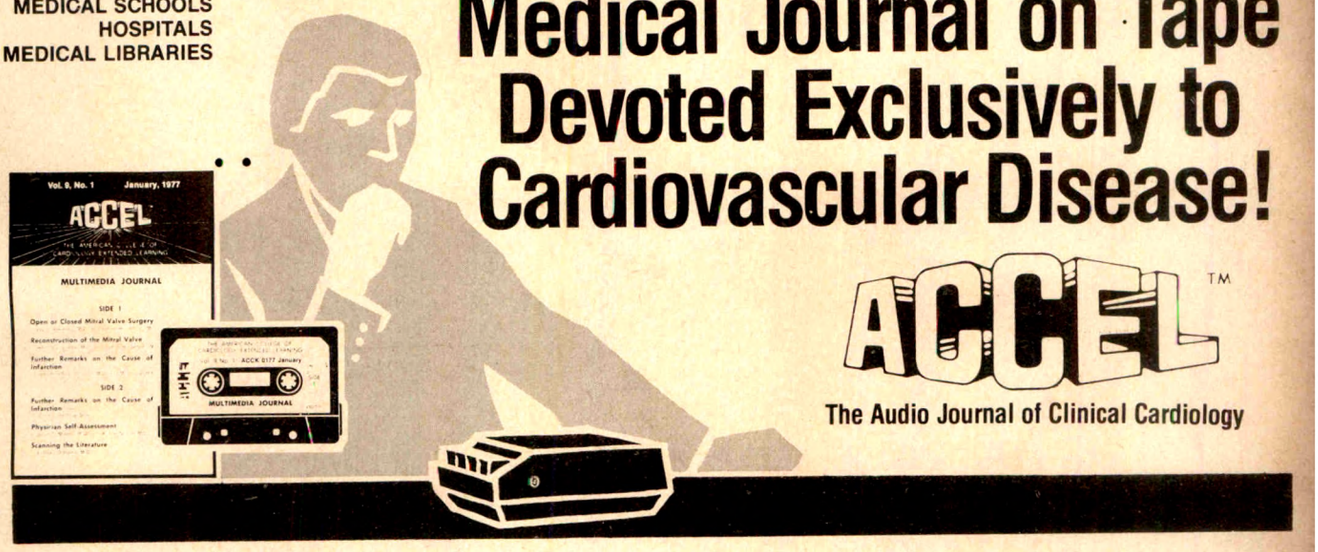
The American College of Cardiology brings you the

Medical Journal on Tape Devoted Exclusively to Cardiovascular Disease!



ACCEL™

The Audio Journal of Clinical Cardiology

Every month, each subscriber to ACCEL receives a packet including a 60-minute audio-cassette tape and accompanying booklet.

Covering one or more subjects of vital concern to cardiologists and other physicians and medical personnel treating cardiac patients, the material is also an important reference for medical schools and libraries as well as hospitals.

Recorded, for the most part, by leading cardiologists, researchers and practicing physicians discussing developments in their own words and voices, the tapes cover theory, diagnosis, treatment, research, case histories and more.

Cardiological seminars and conferences are also covered . . . in effect bringing highlights of these meetings to subscribers who could not attend.

The accompanying booklets offer additional information, self-assessment quizzes, reviews of audio-cassettes, video-cassettes and other informational material of interest in the field of cardiology.

Clear, comprehensive and authoritative, these 60-minute audio tapes will become an important part of your professional library, available for review for yourself, your nurse, or anyone on your staff.

In your car, listen to world-renowned cardiologists explain their latest theories and experiments . . . in their own words and voices.

In your office, attend seminars and conferences, listen to the papers, the summaries, the news in the making.

In your den, on the beach, in a plane, train or boat, hear topflight authorities discussing cardiac symptoms, diagnoses, treatments, and results.

Effects of Long-Term Oral Administration of Isosorbide Dinitrate On the Antianginal Response to Nitroglycerin

Absence of Nitrate Cross-Tolerance and Self-Tolerance Shown by Exercise Testing

GARRETT LEE, MD
DEAN T. MASON, MD, FACC
ANTHONY N. De MARIA, MD, FACC*

Davis and Sacramento, California

Controversy exists regarding the ability of sustained-release orally administered nitrates to induce cross-tolerance to sublingual doses of nitroglycerin. Therefore this study compared the effects of isosorbide dinitrate and placebo on nitroglycerin-induced improvement in exercise testing in 28 patients with coronary artery disease. Maximal exercise tests were performed in all patients before and 10 minutes after sublingual administration of 0.6 mg of nitroglycerin both before and after 1 month of administration of either placebo or isosorbide. During the control period, nitroglycerin produced improvement in mean duration of exercise (placebo from 302 to 390 seconds and isosorbide from 302 to 391 seconds; both $P < 0.001$) and a derived index of maximal oxygen consumption (placebo from 21.1 to 24.5 and isosorbide from 21.1 to 24.8 cc/kg per min; both $P < 0.001$); maximal heart rate-blood pressure product remained unchanged (placebo from 23.3 to 23.7 $\times$ 10^3 and isosorbide from 19.2 to 20.2 $\times$ 10^3; both $P > 0.05$). During the posttreatment period nitroglycerin again resulted in increases in exercise duration (placebo from 306 to 368 seconds and isosorbide from 373 to 411 seconds; both $P < 0.01$) and a derived index of oxygen consumption (placebo from 21.3 to 23.7 and 23.9 to 25.4 cc/kg per min; both $P < 0.01$) whereas maximal heart rate-blood pressure product was without change with placebo ($P > 0.05$) but minimally higher after administration of isosorbide (20.7 to 22.8 $\times$ 10^3; $P < 0.01$). An identical level of S-T segment improvement was achieved at maximal exertion after nitroglycerin in both groups. Thus the demonstration in this study of the ability to achieve equivalent improvements in exercise performance before and 1 month after isosorbide dinitrate therapy indicates that long-term oral administration of large doses of this long-acting nitrate does not result in cross-tolerance to the antianginal action of sublingually administered nitroglycerin. In addition, the long-acting nitrate achieved therapeutic efficiency without evidence of self-tolerance.

Although nitroglycerin given sublingually has long been demonstrated to be an effective antianginal agent, considerable controversy has existed regarding the value of sustained-release orally administered nitrate preparations in the treatment of angina pectoris.[1–4] Indeed, initial experimental studies[5] regarding the absorption and metabolism of ingested nitroglycerin indicated that the agent underwent complete biotransformation by the liver to inactive metabolites and thus could not be administered by the oral route. Recently, however, numerous studies[6–8] have demonstrated the ability of orally administered isosorbide dinitrate, when administered in large doses, to induce beneficial effects in patients with coronary artery disease. Thus, alleviation of symptoms,[6,9] enhanced exercise tolerance,[7,8,10,11] reduced electrocardiographic manifestations of myocardial ischemia[6–8] and favorable alterations in cardiocirculatory

hemodynamics[4,12–14] have all been documented to occur after the oral administration of isosorbide dinitrate. Accordingly, the sustained-release orally administered preparation of this organic nitrate is being widely applied in the prophylactic treatment of angina pectoris.

Although considerable data are available regarding the antianginal effects of isosorbide dinitrate, the ability of this agent to induce cross-tolerance to sublingually administered nitroglycerin remains unresolved. Thus, some investigators[15,16] have reported attenuation of the acute nitroglycerin-induced changes in heart rate, blood pressure and venous tone after long-term treatment with long-acting nitrates, but such findings have not been universal.[17] Further, no data are available regarding the relation of such decreases in circulatory responsiveness and the clinical antianginal action of sublingual doses of nitroglycerin. Exercise stress testing provides a method of objectively assessing the clinical effect of sublingually administered nitroglycerin on angina pectoris. In this study we utilized such testing to evaluate whether prolonged oral administration of sustained-release isosorbide dinitrate would induce cross-tolerance to the antianginal effect of sublingual doses of nitroglycerin.

Methods

Patients: Twenty-eight patients (20 men and 8 women, mean age 56 years) with atherosclerotic heart disease and stable angina pectoris were studied. The presence of coronary artery disease was documented with coronary arteriography in all 23 patients who underwent this procedure; the additional five patients manifested classic symptoms of angina pectoris or had electrocardiographic evidence of a previous myocardial infarction. No patient had demonstrated evidence of acute myocardial infarction for at least 3 months before this study, had signs or symptoms of heart valve disease or congestive heart failure or was taking digitalis, beta adrenergic blocking agents or any other coronary vasodilator other than sublingually administered nitroglycerin. All patients had previously manifested 1 mm or greater S-T segment depression on electrocardiography during treadmill exercise testing and had responded to sublingual administration of nitroglycerin with increased duration of treadmill exercise.

Exercise testing: The stress protocol utilized consisted of multistage treadmill exercise according to the method of Bruce et al.[18] Exercise was performed on a motorized treadmill (model 18-49C, Quinton Instruments, Seattle, Washington) while the electrocardiogram was obtained on a multichannel recorder (model 3500, Marquette Medical Instruments, Milwaukee, Wisconsin or model 7712, Hewlett-Packard Instruments, Palo Alto, California). Electrocardiographic leads I, aVF and V_5 were monitored continuously throughout the exercise test; a recording of these leads was obtained at 3 minute intervals and for 6 minutes after the termination of exercise. Systemic blood pressure was also measured at 3 minute intervals and at the termination of exercise by means of a cuff sphygmomanometer. All patients had prior exposure to this form of exercise testing to negate the effect of habituation on the reproducibility of exertional performance. Informed consent was obtained in every case.

Protocol (Fig. 1): At the initiation of the study, each patient underwent an exercise test performed to maximal exertion limited by the symptoms of angina, fatigue or marked dyspnea. After a 45 minute period of rest, 0.6 mg of nitroglycerin was given sublingually. After a further 10 minute period designed to ensure optimal nitroglycerin effect, the exercise test was repeated. All patients then received in double blind fashion capsules of similar appearance containing either placebo or isosorbide dinitrate, 40 mg,* each taken orally every 8 hours for 1 month. Six hours after ingestion of the last capsule, exercise tolerance before and after sublingual administration of nitroglycerin was reevaluated. Thus, the study was designed to determine whether the improvement in exercise performance induced by nitroglycerin was attenuated by the subsequent administration of the long-acting antianginal agent isosorbide dinitrate.

The following measurements were obtained in both placebo and isosorbide dinitrate–treated patients: maximal duration of exercise in seconds, a derived index of maximal total body oxygen consumption obtained from a regression equation derived by Bruce et al.[18] relating oxygen consumption to duration of exertion, heart rate-blood pressure product (which permits estimation of myocardial oxygen consumption calculated as the product of maximal heart rate and peak systolic blood pressure) and S-T segment depression in the electrocardiogram. Results were subjected to statistical analysis according to Student's *t* test for paired data.

Prenitroglycerin control (C) and postnitroglycerin (NTG) exercise tests were performed at each period. NS = not significant; p = probability.

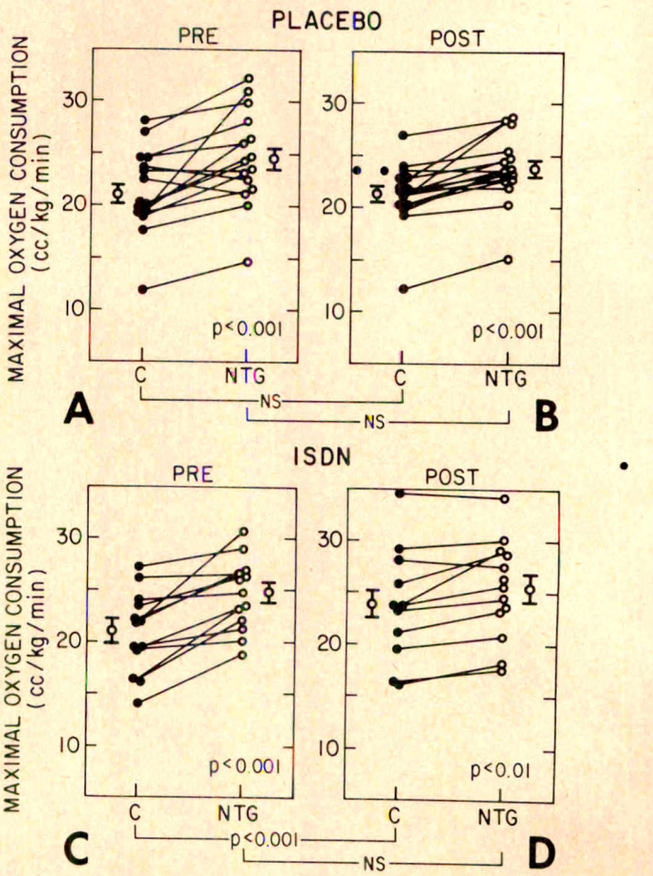

FIGURE 4. Group data for a derived index of oxygen consumption ($\dot{V}O_2$). Data presentations and abbreviations as in Figure 3.

Results

All patients manifested at least 1 mm of S-T segment depression for 60 msec on exercise electrocardiography. Figure 2 represents the electrocardiographic record from a representative patient who received isosorbide dinitrate. No significant alterations were observed in the symptoms that resulted in the termination of exercise after administration of either placebo or isosorbide dinitrate.

Duration of exercise: Individual and mean data on the duration of exercise are shown in Figure 3. During the control period in patients who received placebo (Fig. 3A), the sublingual administration of nitroglycerin prolonged the duration of exercise from 302 ± 24 to 390 ± 27 seconds (mean ± standard error of the mean) (P <0.001). One month after placebo therapy this group manifested an almost identical (P >0.05) increase in exercise duration from 306 ± 18 to 368 ± 20 seconds (P <0.001) (Fig. 3B). Thus, no significant difference was observed in the increased duration of treadmill exercise after sublingually administered nitroglycerin in the patients who received placebo. Premedication exercise tests in the patients who received isosorbide dinitrate also demonstrated an increased duration of exercise after nitroglycerin from 302 ± 30 to 391 ± 27 seconds (P <0.001) (Fig. 3C). After 1 month of isosorbide dinitrate therapy, prenitroglycerin exercise test duration in this group increased to 373 ± 36 seconds (P <0.001) (Fig. 3D), a value significantly higher than that of the prenitroglycerin exercise duration before isosorbide dinitrate therapy. Importantly, after nitroglycerin the maximal achievable duration of exertion in the group given isosorbide dinitrate was increased even further than before the sublingual administration of this agent, to 411 ± 34 seconds (P <0.001) (Fig. 3D). In addition, the maximal period of exertion after the administration of nitroglycerin was similar (P >0.05) before and after the 1 month period of isosorbide dinitrate therapy.

Maximal oxygen consumption index: Data regarding the derived index of maximal oxygen consumption are given in Figure 4. Maximal oxygen consumption improved from 21.1 ± 0.9 (prenitroglycerin) to 24.5 ± 1.0 (postnitroglycerin) (P <0.001) (Fig. 4A) and from 21.3 ± 0.7 (prenitroglycerin) to 23.7 ± 0.8 (postnitroglycerin) cc/kg per min (P <0.001) (Fig. 4B) before and after, respectively, 1 month of placebo administration. In patients who received isosorbide dinitrate the increase in derived oxygen consumption after administration of nitroglycerin was similar to that of the patients who received placebo, from 21.1 ± 1.2 to 24.8 ± 1.0 (P <0.001) (Fig. 4C) and 23.9 ± 1.4 to 25.4 ± 1.3 cc/kg per min (P <0.01) (Fig. 4D) before and after, re-

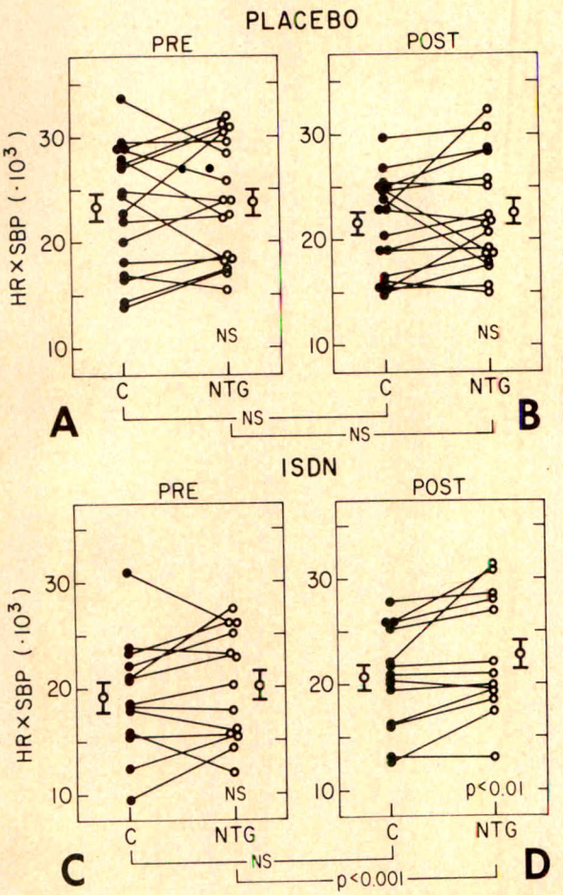

FIGURE 5. Group data for heart rate-systolic blood pressure (HR × SBP) (× 10^3). Presentation of data and abbreviations as in Figure 3.

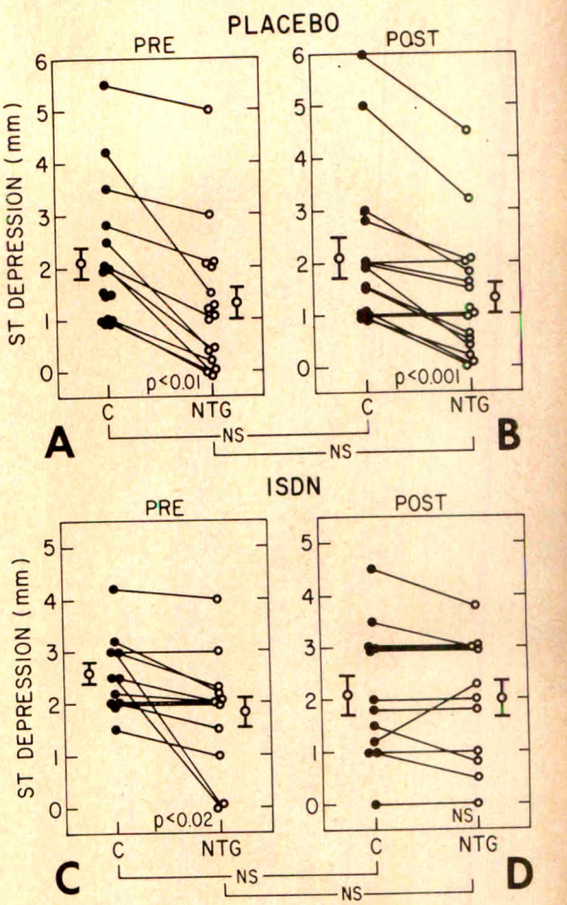

FIGURE 6. Group data for electrocardiographic S-T depression (mm). Presentation of data and abbreviations as in Figure 3.

spectively, 1 month of isosorbide dinitrate therapy. Thus, maximal achievable derived oxygen consumption was identical ($P < 0.05$) after the administration of nitroglycerin in the periods before and after isosorbide dinitrate therapy. Consistent with the increase in exercise duration, derived maximal oxygen consumption during exercise before nitroglycerin was greater ($P < 0.001$) after 1 month of isosorbide dinitrate therapy.

Heart rate-blood pressure product: Data regarding heart rate-blood pressure product are depicted in Figure 5. Maximal heart rate-blood pressure product, expressed to 10^3, was unchanged before and after the administration of nitroglycerin, from 23.3 ± 1.4 to 23.7 ± 1.3 ($P > 0.05$) (Fig. 5A) and from 21.6 ± 1.1 to 22.6 ± 1.2 ($P > 0.05$) (Fig. 5B) before and after, respectively, the administration of placebo capsules. Similarly, heart rate-blood pressure product at maximal exertion was not statistically different in the preisosorbide dinitrate period before and after the sublingual administration of nitroglycerin: from 19.2 ± 1.5 to 20.2 ± 1.5 ($P > 0.05$) (Fig. 5C). After isosorbide therapy, a minimal increase in the maximal level of this variable reaching statistical significance was observed after the sublingual administration of nitroglycerin: 22.8 ± 1.6 compared with the prenitroglycerin value of 20.7 ± 1.4 ($P < 0.01$) (Fig. 5D).

S-T segment depression: Regarding the quantity of S-T segment depression observed at maximal exertion (Fig. 6), nitroglycerin produced a significant reduction in this electrocardiographic abnormality, from 2.1 ± 0.3 to 1.3 ± 0.3 mm ($P < 0.01$) (Fig. 6A) before and after, respectively, ($P < 0.001$) (Fig. 6B) 1 month of placebo. S-T segment depression at maximal exertion in the group given isosorbide dinitrate was similarly reduced after nitroglycerin in the premedication period, from 2.6 ± 0.2 to 1.8 ± 0.3 ($P < 0.02$) (Fig. 6C). However, the extent of S-T segment depression manifested in the prenitroglycerin exercise electrocardiogram after administration of isosorbide was substantially less than that observed in the control period before its administration. Thus, although the S-T segment depression at maximal exertion observed after nitroglycerin was identical before and after oral administration of isosorbide dinitrate, the maximal degree of S-T segment depression after isosorbide was similar before and after nitroglycerin: from 2.1 ± 0.4 mm prenitroglycerin to 2.0 ± 0.3 mm postnitroglycerin ($P > 0.05$) (Fig. 6D). Thus, the ability of sublingually administered nitroglycerin to augment exercise duration and maximal oxygen consumption without a concomitant increase in electrocardiographic evidence of myocardial ischemia was maintained after long-term administration of isosorbide dinitrate.

Percent alteration in exercise variables: Subsequently, we analyzed the percent change from control values induced by sublingual administration of nitroglycerin in the periods before and after the administration of placebo and isosorbide dinitrate. No change in the percent increase in duration of exercise and the derived index of oxygen consumption or the decrease in S-T segment depression induced by nitroglycerin was observed from the pre- to postplacebo periods: from 37 to 25 percent, from 17 to 12 percent and from 40 to 40 percent, respectively (all $P > 0.05$). After administration of isosorbide, a significant augmentation of exercise duration and derived oxygen consumption and a substantial decrease in S-T segment depression were observed even before the administration of nitroglycerin. Consequently, reductions in the percent increase in exercise duration induced by nitroglycerin (from 38 to 13 percent), derived oxygen consumption (from 19 to 7 percent) and decrease in S-T segment depression (from 29 to 3 percent) (all $P < 0.05$) were calculated after therapy with isosorbide even though the further alterations in these variables effected by nitroglycerin resulted in values identical to those achieved in the pre-isosorbide period after nitroglycerin.

Discussion

The recent demonstration of the value of orally administered sustained-release isosorbide dinitrate in the prophylactic therapy of angina pectoris has led to the increased application of this agent in patients with ischemic heart disease.[3,4,6–13] In addition, isosorbide has also been utilized as a ventricular unloading agent in the treatment of chronic congestive heart failure.[14] Thus, the question whether isosorbide dinitrate administered orally in large doses induces the development of tolerance, especially in regard to cross-tolerance to sublingually administered nitroglycerin, has assumed greater importance.

Cross-tolerance to nitroglycerin after long-acting isosorbide dinitrate: Although the propensity for long-acting organic nitrates to induce cross-tolerance to nitroglycerin has been suspected for many years, clinical investigations of this tendency have been few and have yielded conflicting data. Thus, Schelling and Lasagna[15] noted a slight attenuation in the decrease in systemic blood pressure and reflex tachycardia produced by sublingually administered nitroglycerin after 4 weeks of pentaerythol tetranitrate. Additionally, Zelis and Mason,[16] utilizing plethysmography, observed a reduction in venodilation but not arteriolar dilation in response to sublingually administered nitroglycerin after the oral administration of isosorbide dinitrate for 6 weeks. In contrast, Goldstein et al.[17] observed no alteration in the response of physiologic measurements or exercise tolerance to sublingually administered isosorbide dinitrate after long-term administration; and Aronow and Chesluk[19] observed the identical antianginal effect of sublingually administered nitroglycerin before and after prolonged use of isosorbide dinitrate. However, in the two latter studies, the dose of oral nitrate utilized was not as large as that required for effective prophylactic therapy of angina pectoris.

Our investigation indicates that cross-tolerance to the antianginal effect of sublingually administered nitroglycerin is not induced by the long-term oral administration of isosorbide dinitrate in large doses. Thus, maximal duration of exercise, derived index of oxygen consumption, heart rate-blood pressure product and S-T segment depression after nitroglycerin was identical before and after long-term administration of the long-acting nitrate preparation (Fig. 3 to 6). In addition, because exertional capacity, oxygen consumption and S-T segment depression were improved in the control period after 1 month of isosorbide therapy, but not after placebo, no major tolerance to isosorbide dinitrate itself was evident. However, our study was not specifically designed to evaluate tolerance to isosorbide itself, and it is possible that minor degrees of tolerance could have been overlooked.

Effect of long-term isosorbide therapy on clinical antianginal effect of nitroglycerin: Previous studies[15,16] indicating that long-term administration of long-acting organic nitrates induces cross-tolerance to nitroglycerin dealt with isolated measures of cardiocirculatory function such as systemic blood pressure and forearm venous tone. Accordingly, no inferences could be drawn from these reports regarding the influence of long-term nitrate administration upon the clinical antianginal effect of nitroglycerin. In our investigation, exercise stress testing provided an objective method for evaluating the influence of long-term isosorbide dinitrate therapy on the clinical antianginal effects of nitroglycerin. Previous studies[20] have indicated that maximal exercise capacity during treadmill walking is readily reproducible in patients with coronary artery disease after an initial educational experience. That peak exertion is indeed constant was well demonstrated by the identical values recorded for both exercise duration and derived index of maximal oxygen consumption before and after placebo therapy (Fig. 3 and 4). Thus, the finding that nitroglycerin induced the same duration of exercise and derived maximal oxygen consumption with equivalent S-T segment depression after and before long-acting isosorbide dinitrate therapy constitutes strong objective evidence that the latter does not induce cross-tolerance to the clinical antianginal effects of nitroglycerin.

Our data were also analyzed in regard to percent improvement in those measurements manifesting a response to sublingually administered nitroglycerin. No differences were noted in any of the exercise functions assessed after as compared with before placebo. Conversely, reductions in the percent increase in exercise duration and the derived index of oxygen consumption and decrease of S-T segment depression induced by nitroglycerin were observed after administration of isosorbide dinitrate. However, this diminution in the percent change in response to nitroglycerin was referable entirely to alterations in these values produced by the sustained action of isosorbide dinitrate in the control period. Thus, significant increases in exercise duration and derived oxygen consumption and a substantial decrease in S-T segment depression occurred before the administration of nitroglycerin after 1 month

of isosorbide therapy. Nevertheless, nitroglycerin was still able to augment further these beneficial effects to levels identical with those produced before isosorbide administration (Fig. 6). Thus, patients continued to achieve the same maximal duration of exercise and derived oxygen consumption in response to nitroglycerin without additional S-T segment depression after isosorbide dinitrate therapy as before administration of this agent.

Although heart rate-blood pressure product does not account for all the determinants of myocardial oxygen demand, it has been demonstrated to represent a relatively accurate index of this function.[21] Thus, interventions that enable greater duration of exercise and maximal oxygen demand by virtue of increasing myocardial oxygen supply (such as coronary artery bypass surgery) are associated with increases in heart rate-blood pressure product.[22] The observation that the rate-pressure product was unchanged at maximal exertion after nitroglycerin in our study supports the concept that the increase in exercise capacity produced by this agent is referable to a decrease in myocardial oxygen demand. Although the maximal rate-pressure product increased slightly after nitroglycerin during exercise testing after isosorbide dinitrate therapy, the change was considered too small to be of substantial physiologic significance.

In our study, isosorbide dinitrate was administered in large doses for 1 month. That this period is sufficiently long to induce cross-tolerance to nitroglycerin is indicated by the finding in two previous studies[15,16] that circulatory responsiveness to nitroglycerin was reduced in a similar period of time. In addition, headaches precipitated by nitrates have characteristically been observed to disappear within a few weeks.[23,24] Finally, evidence of cross-tolerance to the vasodilator effects of nitroglycerin has been recorded after only 3 days of long-term nitrate administration in rats.[25]

In conclusion, our data indicate that cross-tolerance to the antianginal effect of sublingually administered nitroglycerin is not induced by long-term oral administration of isosorbide dinitrate. Although previous studies have reported evidence suggesting the development of cross-tolerance to nitroglycerin induced by long-acting nitrates, such small changes in circulatory function apparently do not impair the clinical antianginal effect of this agent.

The effect of digitalis glycosides on vascular resistance varies from one vascular bed to another and is also related to the hemodynamic state of the patient. To determine whether the rate of infusion is also a determinant of the vasoactive response the effect of various infusion rates of ouabain on the coronary and systemic beds was examined and the associated changes in myocardial oxygen consumption in patients without heart failure were quantitated. A 10 second and 2 minute infusion of ouabain (15 μg/kg body weight) produced 18.1 ± 5.6 percent and 7.5 ± 1.7 percent increases in mean arterial pressure and 23.7 ± 9.8 percent and 17.6 ± 7.5 percent increases in systemic vascular resistance, respectively ($P < 0.05$ for each). A 15 minute infusion produced no statistically significant change in either variable. Coronary vascular resistance increased 13.4 ± 5.2 percent ($P < 0.05$) after a 10 second infusion but did not change during or after a 15 minute infusion. The 10 second infusion was also associated with transient deterioration of myocardial lactate metabolism. Thirty minutes after ouabain administration mean arterial pressure had returned to control levels, but myocardial oxygen consumption remained increased by 12.5 ± 3.9 percent ($P < 0.025$), indicating that ouabain produces a net increase in myocardial oxygen demand in patients without heart failure.

Rapid intravenous administration of ouabain produces systemic and coronary arteriolar constriction that may lead to clinical deterioration. These effects can be avoided by slower delivery of the drug. Even in patients without heart failure, the increase in myocardial oxygen consumption with full digitalization is small.

Digitalis glycosides are usually administered clinically for their inotropic or electrophysiologic effects. However, they also alter vascular tone, and this effect may significantly influence the outcome of therapy. The effect of digitalis on vascular tone depends on several factors. The extent and direction of changes in vascular tone depend on whether or not heart failure is present.[1] In the experimental animal the magnitude and direction of the effect varies from one vascular bed to another.[2] In addition, if ischemia were to be produced by digitalis-induced vasoconstriction, the response might be modified by local metabolic factors. Although many studies have demonstrated the vasoconstrictive ability of digitalis in man, several studies[3,4] have shown little or no effect when the drug is given slowly rather than as a bolus injection. Thus, the rate of infusion of digitalis may also be an important determinant of changes in vascular resistance. Indeed, the vasoconstrictive ability of digitalis in the coronary circulation of man remains to be demonstrated. The lone previous study[5] showed no effect and its results conflict with the data accumulated in experimental animals.

In this study of patients without heart failure we determined the time course of changes in coronary and systemic vascular resistance with various rates of infusion of ouabain, quantitated the increase in myocardial oxygen consumption produced and related these changes to changes observed in myocardial metabolism.

Material and Methods

Patients: A total of 36 patients were studied, 22 to evaluate the effects of ouabain on the systemic circulation and 14 to evaluate its effects on the coronary circulation. The patients had a mean age of 59 years (range 33 to 81 years). No patient manifested clinical evidence of congestive heart failure. The mean right atrial pressure was 4 mm Hg or less in each patient. The pulmonary arterial wedge pressure or left ventricular end-diastolic pressure was less than 12 mm Hg in each of the 17 patients in whom it was measured. No patient manifested cardiomegaly in the chest roentgenogram. Two patients had previously received digitalis glycosides, but neither had received these agents within the 3 weeks preceding the study. The dose of ouabain in this study was 15 μg/kg body weight. Informed consent was obtained from each patient before study.

Systemic circulation: Thirteen of 22 patients whose systemic circulation was evaluated had coronary artery disease as judged from a classical history of angina pectoris or myocardial infarction. In 4 of these 13 the diagnosis was confirmed with angiography. The remaining nine patients were studied during the course of evaluation for conduction system abnormalities.

Brachial arterial and right atrial pressures were monitored using fluid-filled catheter systems. Cardiac output was measured with the indicator-dilution technique using either indocyanine green or cold saline solution. Eight patients were given a 15 minute infusion of ouabain, seven patients a 2 minute infusion and seven patients a 10 second infusion. Cardiac output measurements were made at 2, 4, 6, 8, 12, 15 and 30 minutes in the 10 second and 2 minute infusion groups and at 4, 8, 12, 15, 30 and 45 minutes in the 15 minute infusion group. Systemic vascular resistance was calculated as the quotient of the decrease in pressure from the brachial artery to the right atrium and the cardiac output.

Coronary circulation: Of the 14 patients whose coronary circulation was studied, 7 were being evaluated for coronary artery disease that was confirmed with coronary angiography. Of seven other patients who were being studied for conduction system abnormalities three had classical angina pectoris. Thus 10 of the 14 patients had coronary artery disease. Mean arterial pressure was measured continuously using a brachial arterial catheter. Coronary sinus flow was measured using the thermodilution technique of Ganz et al.[6] at 2, 4, 6, 8, 12, 15 and 30 minutes after initiation of the infusion of ouabain. Coronary vascular resistance was calculated as the quotient of the decrease in pressure from the brachial artery to the coronary sinus and the coronary sinus flow.

Myocardial oxygen supply and demand: Blood samples were obtained from the coronary sinus and from the brachial artery before and 6 to 8, 15 and 30 minutes after initiation of the infusion of ouabain. Oxygen content was calculated from the partial pressure of oxygen, pH and hemoglobin concentration using a Severinghaus nomogram.[7] Myocardial oxygen consumption was calculated as the product of the arterial coronary venous oxygen difference and coronary sinus flow. Lactate concentration was determined with use of a technique described previously.[8]

Statistical analysis: The percent change from control value was determined for each variable at each time period and the significance of changes from the control value determined using a paired t test.

Results

Systemic circulation: Mean arterial pressure increased at each of the three rates of infusion of ouabain (15 minutes, 2 minutes and 10 seconds). The extent of increase in mean arterial pressure decreased progressively as the rate of infusion was prolonged, and statistically significant changes from control values were observed only in the 10 second and 2 minute infusion groups (Table I). The increases in arterial pressure in the 10 second and 2 minute infusion groups were accompanied by decreases in cardiac output, whereas a slight increase in arterial pressure in the 15 minute infusion group was accompanied by a small increase in cardiac output. Only the reduction in cardiac output in the 2 minute infusion group was statistically significant.

Systemic vascular resistance increased abruptly in the 10 second infusion group, reaching a peak within 6

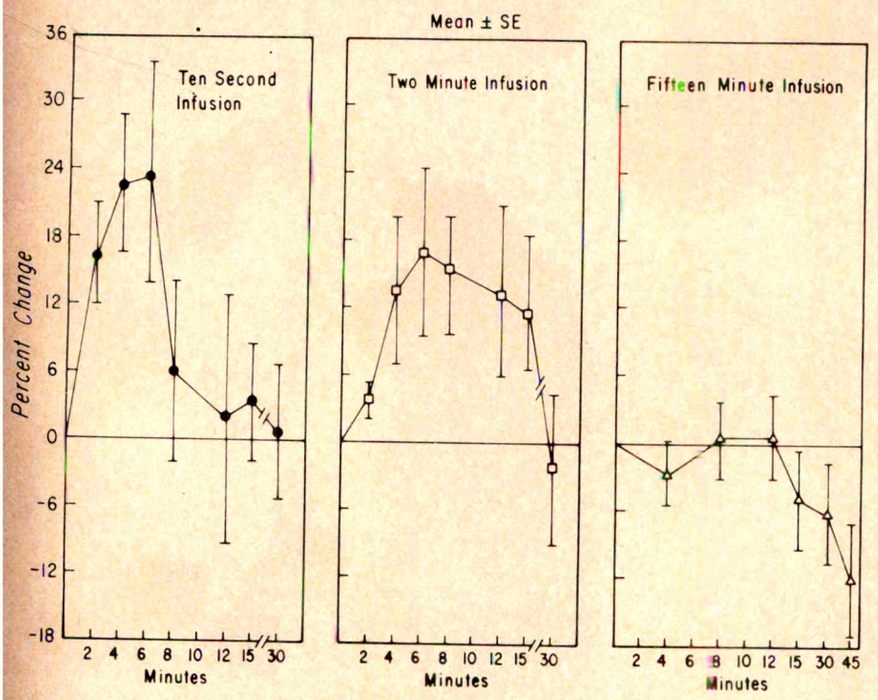

FIGURE 1. Effect of ouabain on systemic vascular resistance shown as percent change from control for three rates of infusion. SE = standard error of the mean.

minutes of infusion (Fig. 1). Maximal increases ranged from 12 to 66 percent (mean 31.7 percent). Lesser changes occurred in the 2 minute infusion group in which increases ranged from 7 to 52 percent (mean 24 percent). The time of peak changes occurred at either 2 or 4 minutes in the 10 second infusion group and either 6 or 8 minutes in the 2 minute infusion group. No significant changes in systemic vascular resistance occurred at any time in the 15 minute infusion group.

Coronary circulation: The changes in mean arterial pressure induced by ouabain in this group of 14 patients (Table II) were similar to those found at at the corresponding infusion rates in the first portion of the study (systemic circulation, see preceding). No change occurred in right atrial pressure. Coronary blood flow decreased in five of seven patients given a 10 second infusion of ouabain. The mean change was a reduction of 8.0 ± 7.4 percent ($P > 0.05$) at 2 minutes. Subsequently coronary blood flow remained near control levels. No significant change occurred at any time in the group of patients given a 15 minute infusion. Coronary vascular resistance increased abruptly in the 10 second infusion group but decreased to near preinfusion levels by the end of the period of observation (Fig. 2). No significant change in coronary vascular resistance occurred at any time in the 15 minute infusion group.

Myocardial oxygen supply and demand: Myocardial oxygen consumption increased in both the 10 second and 15 minute infusion groups. In the 10 second infusion group the increase was 15.6 ± 5.2 percent, 14.0 ± 5.6 percent and 13.7 ± 4.1 percent at 8, 15 and 30 minutes. At the corresponding times the increases in the

* $P < 0.05$.

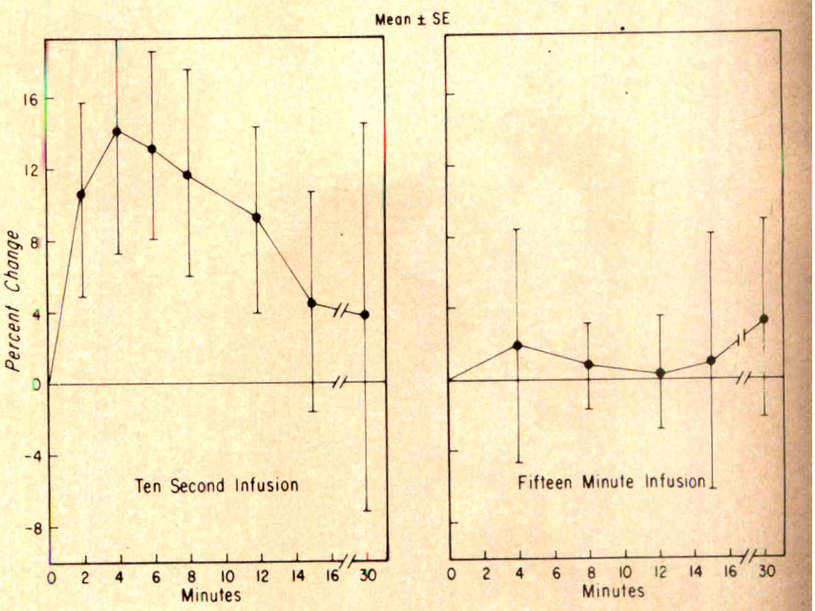

FIGURE 2. Effect of ouabain on coronary vascular resistance shown as percent change from control values after 10 second and 15 minute infusions. SE = standard error of the mean.

15 minute infusion group were 10.3 ± 5.8 percent, 11.1 ± 10.4 percent and 12.1 ± 5.8 percent. The difference between the two groups was not significant. At the end of 30 minutes when vascular resistance had returned to near control levels in both groups myocardial oxygen consumption had increased 12.5 percent from 13.5 ± 0.94 to 15.1 ± 1.09 ml O_2/min (P <0.025), indicating that ouabain increases myocardial oxygen consumption in patients who do not have heart failure (Fig. 3).

Lactate extraction decreased at 6 minutes in all patients given a 10 second infusion. In two patients lactate extraction reverted to lactate production and in one patient with resting lactate production lactate metabolism deteriorated further. The mean decrease in the percent of lactate extraction was 7.7 ± 1.2 percent at 8 minutes (P <0.05). However, as coronary vascular resistance decreased, lactate extraction improved to 0.5 ± 2.6 percent (P >0.05) and 12.7 ± 2.3 percent (P <0.05) at 15 and 30 minutes, respectively. In the group with the slow infusion rate lactate extraction increased in all but one patient who had a transient decrease. The increase in extraction was 12.4 ± 4.8, 15.7 ± 5.1 and 7.3 ± 3.7 percent at 8, 15 and 30 minutes, respectively (P <0.05 at 8 minutes). One of the two patients in this group with resting lactate production manifested lactate extraction, and the other produced less lactate. Thirty minutes after initiation of the infusion the two groups were similar (Fig. 4).

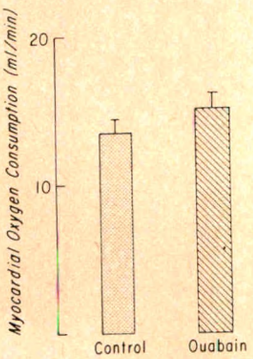

FIGURE 3. Increase in myocardial oxygen consumption induced by ouabain in patients without heart failure (P <0.025 by paired t test). Although the increase is small, it is statistically significant because values in each patient changed in the same direction.

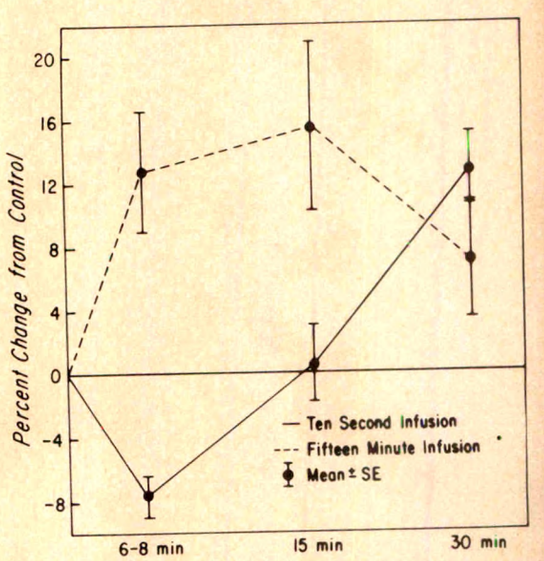

FIGURE 4. The mean absolute percent change from control values in myocardial lactate extraction or production shown for patients receiving 10 second and 15 minute infusions of ouabain. SE = standard error of the mean.

Discussion

Systemic circulation: Digitalis glycosides are able to produce arteriolar constriction in every vascular bed that has been tested.[1,2,9–12] The effect of glycosides was shown to vary in intensity from one vascular bed to another and was even biphasic in the mesenteric vascular bed of conscious animals.[2] In that study simultaneously recorded changes in the iliac vascular bed were approximately twice those found in the mesenteric and renal vascular beds. The effect of glycosides on vascular tone also varies with the underlying hemodynamic state of the patient; that is, with heart failure vasodilation occurs after digitalis administration and without heart failure vasoconstriction occurs.[1] Our study demonstrates that systemic vasoconstriction resulting from digitalis administration is also a function of the rate of infusion of ouabain and does not occur if the rate of infusion is prolonged to 15 minutes. Because this period of time is far short of the 22 hour serum half-life of ouabain, drug excretion does not explain our findings.[13]

Most of the clinical effects of peripheral vasoconstriction are deleterious, although part of the efficacy of digitalis in converting atrial tachyarrhythmias may reside in its ability to increase arterial pressure when given rapidly. However, after rapid infusion of digoxin, a hypertensive crisis resulting in a stroke occurred in one patient[14] and induction of pulmonary edema in another.[15] Numerous cases of nonocclusive splanchnic infarction have occurred, usually in the setting of chronic digitalis administration.[16,17] However, preexisting circulatory failure and widespread atherosclerosis are commonly found in patients with splanchnic infarction, and the contribution of digitalis is difficult to assess.

These observations are also relevant to the patient with cardiogenic shock[15] in whom it has been postulated that the circulatory state may deteriorate because the peak afterload effect of digitalis precedes the peak inotropic effect.[11,18] This association is also difficult to assess because patients with cardiogenic shock are frequently not in a stable clinical state and are prone to clinical deterioration even without intervention. However, it would be unwise to administer digitalis rapidly to a patient with cardiogenic shock when vasoconstriction may be avoided by slower infusion.

Coronary circulation: A previous study[5] examining the effect of strophanthus on coronary vascular resistance showed no effect 22 minutes after administration. However, the nitrous oxide technique employed in that study is not suitable for rapid measurement of coronary blood flow, and the effect of strophanthus was determined only once after its administration. Our data suggest that the effect of the drug had dissipated at the time of the postinfusion measurement in that study. Digitalis is able to produce an increase in coronary vascular resistance, but the effect is not of long duration and can be avoided completely by slow administration of the drug.

Digitalis exerts its effects by acting directly on arteriolar smooth muscle and by a neurogenic mechanism activated by alpha adrenergic receptors,[19] probably located in the central nervous system.[20] Digitalis also alters sympathetic tone indirectly by increasing baroreceptor sensitivity. Therefore the changes in vascular resistance produced by digitalis in patients with increased sympathetic tone such as those with congestive heart failure may be different from the changes observed in our study.

Myocardial oxygen supply and demand: The potential for deleterious effects in the ischemic myocardium resulting from arterial vasoconstriction is of special importance. The effect of digitalis on myocardial oxygen consumption (MVO_2) is complex. We have previously shown that ventricular end-diastolic volume decreases even in patients who do not have congestive heart failure.[8] However, MVO_2 increases in these patients because the cost of the enhanced contractile state exceeds the decrease in MVO_2 associated with a reduction in end-diastolic volume and wall tension. An increase in afterload such as we have demonstrated after rapid administration of ouabain would tend to increase MVO_2 further. However, coronary vasoconstriction does not allow an increase in coronary blood flow despite the increased perfusion pressure. As a result, lactate metabolism deteriorated (Fig. 4). In contrast, when a slow infusion of ouabain was given the hypertensive and coronary vasoconstrictive responses did not occur and changes in lactate extraction were favorable (Fig. 4). Thus, the rate of infusion may be a crucial variable to consider when evaluating the effects of digitalis on augmentation or decrease in infarct size in man or in experimental myocardial infarction.

Our study also demonstrates that whether digitalis is given rapidly or slowly, MVO_2 increases in patients who do not have heart failure, confirming observations that we have made previously.[8]

Myocardial oxygen consumption, calculated as the product of coronary sinus flow and arterial coronary venous difference, may not be identical to myocardial oxygen needs if myocardial ischemia results. The disparity in lactate metabolism between the groups with the rapid and slow infusion rates suggests a difference in the ratio of oxygen supply to oxygen need. Thus, a real difference in oxygen needs of the myocardium may have been present even though the difference in myocardial oxygen consumption between the two groups was not statistically significant.

Implications: The balance between myocardial oxygen supply and demand is critical in patients with coronary artery disease. Changes in myocardial oxygen consumption after administration of digitalis are least favorable in patients without heart failure, but even in these patients the cost appears relatively small. Our study suggests that possible deleterious effects of glycosides in experimental myocardial infarction[21] and in patients with myocardial infarction[22] may be more closely related to the vasoconstrictive properties of digitalis than to changes in myocardial oxygen consumption. Moreover, the vasoconstrictive changes may be avoided by slow administration of the drug.

Termination of Ventricular Tachycardia With Bursts of Rapid Ventricular Pacing

JOHN D. FISHER, MD, FACC
RAHUL MEHRA, PhD
SEYMOUR FURMAN, MD, FACC

Bronx, New York

Bursts of rapid ventricular pacing used during 573 episodes of ventricular tachycardia in 23 patients terminated 512 episodes (89 percent), with burst rates averaging 56 beats/min above the ventricular tachycardia rate, for 5 to 10 captures. Tachycardia was accelerated by pacing bursts to rates below 300 beats/min in 16 episodes (3 percent); 10 of these terminated spontaneously or responded to further bursts. Acceleration of heart rate to more than 300 beats/min or ventricular fibrillation occurred six times (1 percent), each episode requiring direct current cardioversion. Pacing bursts had no effect in 38 instances (7 percent), mostly in patients with terminal cardiogenic shock. Implantable pacemakers delivering bursts of rapid ventricular pacing were placed in two patients who have used these units at home. No deaths were associated with bursts of rapid ventricular pacing, which is an effective, rapid, pleasant alternative to repeated direct current cardioversion and a useful tool during electrophysiologic testing in patients with recurrent ventricular tachycardia.

Ventricular tachycardia has been terminated by pacing at rates just in excess of the ventricular rate and then slowly decreasing the rate.[1] Random[2] or programmed extrasystoles[3–7] may terminate ventricular tachycardia. These techniques for pacemaker cardioversion of ventricular tachycardia are difficult to apply rapidly and require skilled adjustments by the operator of the pacemaker. An exception is the use of a magnet to convert an inhibited pacemaker to asynchronous (competitive) pacing during ventricular tachycardia. Although the magnet can be applied quickly, considerable time may elapse before a stimulus occurs that is precisely timed to terminate the ventricular tachycardia; further, the technique is not useful when two or more stimuli are required for termination of ventricular tachycardia.

Termination of ventricular tachycardia by bursts of rapid ventricular pacing at rates of 190 to 300 beats/min often for several seconds' duration has been reported in small series of one to four cases,[8–11] and we have presented preliminary data on a larger number of cases.[12] Most investigators have remarked on the apparent benignity and effectiveness of this method of cardioversion. We used such pacing in 573 episodes of ventricular tachycardia in 23 patients, gaining an appreciation of the benefits, limitations and complications of bursts of rapid ventricular pacing. Our purpose is to document the effectiveness of this technique in the management of ventricular tachycardia and to compare this method with other pacing techniques. General principles of management of ventricular tachycardia will not be reviewed.

Materials and Methods

Patients

Twenty-three patients received bursts of rapid ventricular pacing during ventricular tachycardia. Group I included 15 patients whose ventricular

tachycardia recurred in spite of drug therapy (Table I) and who underwent serial electrophysiologic-pharmacologic studies, performed as previously described,[13,14] to achieve detailed characterization and control of their arrhythmias. The description and results of electrophysiologic testing to be outlined are limited to pacemaker induction and termination of ventricular tachycardia. Responses to bursts of ventricular pacing were established in the catheterization laboratory, and bursts were often used repeatedly when the patient returned to the cardiac care unit. Informed consent was obtained from all patients.

Group II included eight patients who received bursts of rapid ventricular pacing on an emergency basis at the bedside to terminate recurrent ventricular tachycardia. These were acutely ill patients for whom frequent direct current cardioversion was the alternative and in whom strenuous electrophysiologic testing did not seem appropriate (Table II). Efforts to prevent ventricular tachycardia with drug therapy continued (Table I) but had been unsuccessful before the use of pacing bursts. The patient's clinical status and urgent need for treatment precluded informed consent in three cases, and treatment proceeded in accordance with the hospital's guidelines for such emergencies.

The electrocardiographic diagnosis of ventricular tachycardia was confirmed by evidence in intracardiac electrograms for atrioventricular (A-V) dissociation with fusion beats, retrograde block or similar findings and in Group I patients by the absence of a His bundle potential before the ventricular complex or the presence of a retrograde His bundle potential after the ventricular complex. Atrial and ventricular stimulation studies in Group I patients showed no evidence of anomalous A-V pathways.

Electrophysiologic Studies

Group I, 15 patients: In 10 subjects three multipolar leads were inserted for pacing and recording from the high right atrium, right ventricular apex and the His bundle, low right atrium and right ventricle. Recordings were made using an Electronics for Medicine DR 12 recorder at a paper speed of 100 or 200 mm/sec or a Mingograf 803 recorder. During normal sinus rhythm or ventricular pacing at rates of less than 100 beats/min, programmed extrastimuli were introduced with a Devices type 4279 modular pacing system into the atrium and ventricle to initiate tachycardia. If ventricular tachycardia was not induced, ventricular programmed extrastimuli were given in the ventricular outflow tract and, if necessary, the inflow tract. Techniques including programmed extrasystoles with more rapid pacing rates, exercise or isoproterenol, or both, or repetitive bursts of rapid ventricular pacing at 180 to 300 beats/min for 3 to 6 seconds were used if other methods failed to produce ventricular tachycardia.

TABLE II

Clinical Profile of Patients Receiving Bursts of Rapid Ventricular Pacing

	Group I (15 patients)	Group II (8 patients)
Coronary artery disease	9	8
Without acute infarct	9	1*
Acute myocardial infarction	0	6*
Post cardiac surgery	0	1
Cardiomyopathy	1	0
Other disease	2†	0
Unknown disease	3	0

Age range (mean)	13–86 (51)	46–75 (66)

* With digitalis toxicity.

† One patient had a prolonged Q-T syndrome; one had Chagas disease.

Five patients arrived in the catheterization laboratory with ventricular tachycardia. Although in hemodynamically stable condition, they were investigated using a single tripolar or bipolar catheter to minimize the time before termination of the tachycardia. No additional leads were inserted in these patients because the electrocardiographic and His bundle recordings confirmed ventricular tachycardia in each and because it was possible with the single catheter to reinduce ventricular tachycardia after its cessation.

Programmed extrastimuli were used in 12 patients during ventricular tachycardia in an attempt to define a window or zone within the cycle when programmed extrastimuli would terminate the arrhythmia. In 10 patients, attempts were made to overdrive the ventricular tachycardia by pacing at rates of 30 or less beats/min in excess of the ventricular rate and then gradually reducing the rate or stopping abruptly.

Treatment with bursts of rapid ventricular pacing for 1 to 3 seconds was used for ventricular tachycardia that did not end spontaneously or after the preceding maneuvers or that was not tolerated by the patient. In the first three subjects, the pacing burst rate was 300 beats/min. Subsequently, initial bursts were at rates of 40 to 50 beats/min faster than the rate of ventricular tachycardia for five to seven captures. If ventricular tachycardia persisted, stimuli resulting in 10 to 12 captures were given at the same pacing burst rate; then if necessary the rate was increased by 25 beats/min reverting to five to seven captures. These steps were repeated until termination or acceleration of ventricular tachycardia occurred. Patients with sustained acceleration of ventricular tachycardia to rates of less than 300 beats/min were treated with further bursts of rapid ventricular pacing. Direct current cardioversion was used if required. Two patients with ventricular rates of more than 300 beats/min were treated with bursts of rapid ventricular pacing. Thereafter, because of rapid hemodynamic decompensation direct current cardioversion was used for all such patients.

Bursts of rapid ventricular pacing were asynchronous*, that is, not based on sensing of the ventricular tachycardia, in all but three patients in whom an orthorhythmic pacer† was used for noncompetitive bursts.

Permanent pacers for termination of ventricular tachycardia by bursts of rapid ventricular pacing were implanted in two Group I patients after serial electrophysiologic-pharmacologic testing.

Group II patients: Eight acutely ill patients with ventricular tachycardia for whom the only alternative treatment was frequent direct current cardioversion were treated with bursts of rapid ventricular pacing at the bedside without formal electrophysiologic studies. Six had acute myocardial infarction with recurrent ventricular tachycardia not prevented by conventional pharmacologic and pacing therapy, one was in the immediate postoperative state after cardiac surgery and one had digitalis toxicity. In six cases the special pacemaker was first set at a low rate in the demand mode (General Electric or orthorhythmic units) to obviate stimulation during the vulnerable period. The rate was then increased until capture was obtained at a rate of 30 or less beats/min in excess of the ventricular tachycardia. After capture was achieved, the rate was decreased or the pacing was stopped abruptly. If ventricular tachycardia persisted, bursts of rapid ventricular pacing were used as described for Group I. In two critical cases, pacing bursts were the initial method used to terminate tachycardia. Programmed extrastimuli were not used in Group II patients because of the much longer time required to establish the termination window.

Patients in Groups I and II were placed in the coronary care unit with a pacemaker capable of delivering bursts of rapid ventricular pacing. House staff members and the nurses were taught to deliver pacing bursts in the event of ventricular tachycardia, while preparations for electrical and pharmacologic cardioversion proceeded concurrently.

Optimal rate for bursts of rapid ventricular pacing: The relation between the rate of tachycardia and the minimal pacing rate for its termination or acceleration was analyzed. The data were not weighted by numbers of episodes; that is, multiple similar episodes of tachycardia in one patient treated with the same pacing burst rate were counted as a single episode, equal to a single episode in another patient. Ventricular tachycardia–bursts of rapid ventricular pacing pairs were used in these calculations only when 1:1 capture occurred.

To derive a clinically useful formula for optimal burst rate, the data described were analyzed by computer (PDP8e, Digital Equipment Corporation, Maynard, Massachusetts) using a curve-fit program and fitted to six curves, representing linear, exponential, power and three hyperbolic functions.

Results

Clinical responses: Bursts of rapid ventricular pacing terminated 512 of 573 episodes (89 percent) of ventricular tachycardia (Tables III and IV). No deaths were related to the use of bursts and no morbidity was associated with insertion of the catheter electrodes. Ventricular tachycardia induced during electrophysiologic studies was identical in rate and configuration to the patient's spontaneous tachycardia.

Five types of responses to bursts of rapid ventricular pacing occurred (Table III): (1) Termination of ventricular tachycardia immediately or after one or more ventricular premature beats after cessation of the burst (see Fig. 1 and 4). (2) Acceleration of ventricular tachycardia to a rate of less than 300 beats/min, often then stopping spontaneously or with further bursts (Table III) (Fig. 2 and 3). (3) Acceleration of ventricular tachycardia to a rate greater than 300 beats/min, or ventricular fibrillation requiring direct current cardioversion. (4) Deceleration of ventricular tachycardia. (5) No effect on the ventricular tachycardia, with or without capture of the ventricle. Bursts of rapid ventricular pacing were more effective than other pacing techniques for termination of ventricular tachycardia (Fig. 1, Table V).

Responses differed greatly among patients but were generally consistent and predictable for each person. No relation existed between administration of digitalis or antiarrhythmic medications and response to bursts of rapid ventricular pacing. Except in the presence of shock, seen only in patients with coronary artery disease, the response to bursts of rapid ventricular pacing did not appear to vary with the underlying disease, although there were too few patients without coronary artery disease to permit a definitive statement. Bursts

* The pacemakers used were: Devices model 4279 (Devices Implants Ltd., Welwyn Garden City, United Kingdom); General Electric model A2071AC; General Electric Co., Milwaukee, Wisconsin; Medtronic model 5320, Medtronic, Inc., Minneapolis, Minnesota; and a pacemaker built by Bioengineering Laboratory, Montefiore Hospital and Medical Center, Bronx, New York.

† Savita Type CSO-RL, distributed by Edwards Pacemaker Systems, Irvine, California. This unit has a sensing circuit that allows programmed extrasystoles or bursts to be given either at a selected interval (in milliseconds) after the last sensed beat, or at an interval that is a selected percentage of the cycle length ("orthorhythmic" mode).

TABLE III

Summary of Responses to Bursts of Rapid Ventricular Pacing

Ventricular Tachycardia	Group I (540 episodes VT)	Group II (33 episodes VT)	Total (573 episodes VT)
Terminated	498(92%)	14(42%)*	512(89%)
Accelerated to a rate of less than 300 beats/min†	14(3%)	2(6%)	16(3%)
Accelerated to a rate greater than 300 beats/min or ventricular fibrillation	6(1%)	0	6(1%)
Decelerated	1(<1%)	0	1(<1%)
Unchanged	24(4%)	17(52%)	38(7%)

* In patients without shock with ventricular tachycardia at a rate of less than 250 beats/min, 11 of 16 episodes (69 percent) were terminated.
† When accelerated, ventricular tachycardia was terminated by further bursts of rapid ventricular pacing (6 episodes), spontaneously (4 episodes) or by direct current cardioversion (6 episodes plus all with a rate greater than 300 beats/min or ventricular fibrillation).

TABLE IV

Responses to Bursts of Rapid Ventricular Pacing: Further Data

	Group I (15 patients)	Group II (8 patients)	Total (23 patients)
Patients (no.) with 1 or more episodes of VT terminated by BRVP	13(87%)	7(88%)	20(87%)
Patients (no.) with 1 or more episodes of VT accelerated by BRVP	8(53%)	2(25%)	10(43%)
Patients (no.) in above group in whom altering BRVP rate and duration prevented acceleration of VT	4(50%)	2(100%)	6(60%)
Patients (no.) in whom BRVP never had effect	1(7%)	1(13%)	2(7%)
Times (no.) BRVP used	712	71	783
Ratio between times BRVP used and termination of VT	1.43	5.07	1.53
Patients (no.) in whom BRVP used for			
1–5 episodes	2	5	7
6–10 episodes	6	3	9
10–20 episodes	4	0	4
90–200 episodes	3	0	3
Patients (no.) receiving digitalis	9(60%)	3(38%)	12(52%)
Patients (no.) in latter group in whom			
VT was terminated once or more	8(89%)	3(100%)	11(92%)

Patients (no.) in latter group in whom			
VT was terminated once or more	8(89%)	4(80%)	12(86%)
VT was accelerated once or more	4(44%)	1(20%)	5(36%)
Patients (no.) in whom BRVP was used during acute infarction	0	6(75%)	6(26%)
Patients (no.) in latter group in whom			
VT was terminated once or more	...	4(67%)	4(67%)
VT was accelerated once or more	...	2(33%)	2(33%)
Patients (no.) without acute infarction	15(100%)	2(25%)	17(74%)
Patients in latter group in whom			
VT was terminated once or more	13(87%)	2(100%)	15(88%)
VT was accelerated once or more	8(53%)	0(0%)	8(47%)

* The total of 9 patients receiving digitalis and 9 not receiving digitalis in Group I exceeds the total of 15 patients in this group because data are separated for 3 patients who received digitalis during part of the time they received bursts of rapid ventricular pacing. In terms of episodes of ventricular tachycardia, 225 occurred in patients receiving digitalis; 202 (90 percent) were terminated and 8 (4 percent) were accelerated by bursts of rapid ventricular pacing. For patients not receiving digitalis, 310 of 348 episodes (89 percent) were terminated and 14 (4 percent) were accelerated.
BRVP = bursts of rapid ventricular pacing; VT = ventricular tachycardia.

TABLE V

Termination of Ventricular Tachycardia: Comparative Effectiveness of Bursts of Rapid Ventricular Pacing and Other Techniques

	Group I	Group II	Total
Patients in whom ventricular tachycardia (VT) was terminated by			
Bursts of rapid ventricular pacing (BRVP)*	13 of 15 (87%)	7 of 8 (88%)	20 of 23 (87%)
Programmed extrastimuli (PES)†	6 of 12 (50%)	NA	6 of 12 (50%)
BRVP but PES failed	5 of 6 (83%)	NA	5 of 6 (83%)
Overdrive pacing at 30 or less beats/min above rate of VT‡	2 of 10 (20%)	0 of 6	2 of 16 (13%)
BRVP but overdrive failed	8 of 8 (100%)	5 of 6 (83%)	13 of 14 (93%)
PES or overdrive (in patients with both)	5 of 10 (50%)	NA	5 of 10 (50%)
BRVP; both PES and overdrive failed	4 of 5 (80%)	NA	4 of 5 (80%)
PES or overdrive but BRVP failed	0	0	0

* All 23 patients received bursts of rapid ventricular pacing. Of these, 12 received programmed extrasystoles, 16 received overdrive pacing at 30 or less beats/min above the rate of ventricular tachycardia, 10 received both and 5 received neither.
† Six patients received only one programmed extrastimulus in any diastolic interval, three received one and two extrastimuli and three received one, two and three extrastimuli.
‡ Duration of overdrive ranged from a few seconds to 7 minutes.
NA = not attempted.

TABLE VI

Rates (beats/min) of Ventricular Tachycardia (VT) and Bursts of Rapid Ventricular Pacing (BRVP) Resulting in Termination or Acceleration of Ventricular Tachycardia

	VT Rate			BRVP Rate		
	With BRVP Induced Termination of VT	With BRVP Induced Acceleration of VT	P^* <	Resulting in Termination of VT	Resulting in Acceleration of VT	P <
VT rate <200	161 ± 19(15)†	160 ± 11(10)	NS	226 ± 30	267 ± 54	0.025
VT rate ⩾200	234 ± 37(9)	QNS	...	273 ± 42	QNS	...
Overall	188 ± 45(24)	178 ± 32(14)	NS	244 ± 41	270 ± 48	NS 0.10

*P = significance by Student's t test.
†Mean ± standard deviation (number of rate-pacing pairs. See text for derivations of numbers).
NS = not significant; QNS = quantity not sufficient (four instances, as defined in text).

of rapid ventricular pacing terminated ventricular tachycardia in 93 percent of episodes (505 of 544) when the rate of tachycardia was less than 250 beats/min and when the patient's condition was stable. Bursts of rapid ventricular pacing terminated ventricular tachycardia in only 17 percent (5 of 29) when the patient had shock before the onset of ventricular tachycardia, when shock developed or when the rate of the ventricular tachycardia exceeded 250 beats/min.

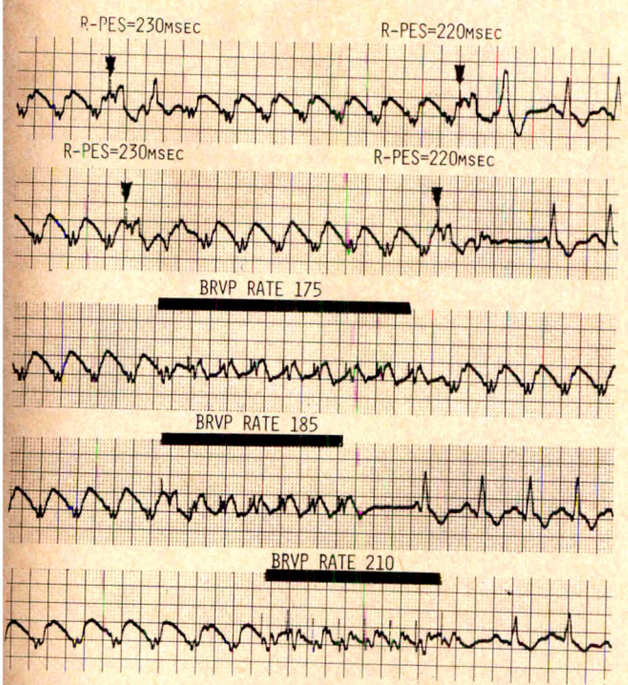

FIGURE 1. Effects of programmed extrastimuli (PES) and bursts of rapid ventricular pacing (BRVP) during ventricular tachycardia. The **top two panels** show ventricular tachycardia at a rate of 150 beats/min reproducibly terminated by programmed extrastimuli 220 (but not 230) msec after the preceding QRS complex **(arrows).** Because the refractory period was 215 msec, the zone during which single extrasystoles were effective was small. In the **third panel,** bursts of rapid ventricular pacing at 175 beats/min **(dark lines)** capture the ventricle, but ventricular tachycardia persists. In the **fourth and fifth panels,** bursts of rapid ventricular pacing at rates of 185 to 210 beats/min for seven to eight captures uniformly terminated the ventricular tachycardia (higher rates were not used in this case). R = R wave.

Cardiac care unit personnel became adept at manual operation of rapid pacemakers. They terminated ventricular tachycardia in 95 percent of more than 100 episodes in patients refractory to medical treatment, usually well before direct current countershock could have been applied. More than 200 episodes of ventricular tachycardia were treated automatically in the cardiac care unit with the orthorhythmic pacer.

Acceleration of ventricular tachycardia by bursts of rapid ventricular pacing: This occurred in 22 of 573 episodes (4 percent) and at least once in 10 of 23 patients (43 percent), including 8 of 15 (53 percent) in Group I and 2 of 8 (25 percent) in Group II. The incidence of acceleration was similar with noncompetitive and asynchronous pacing.

In 6 of 10 patients, recurrent acceleration of ventricular tachycardia by bursts of rapid ventricular pacing could be prevented by altering the rate or duration of the burst. For example, a 33 year old man with cardiomyopathy had ventricular tachycardia at a rate of 180 beats/min that was accelerated by pacing at 280 beats/min or by pacing at 230 beats/min for more than 2.5 seconds; however, bursts at 230 beats/min for 1.5 to 2.0 seconds consistently terminated the tachycardia. In this patient pacing at 10 to 30 beats/min above the rate of ventricular tachycardia captured the ventricle, but the original tachycardia reemerged as the rate was gradually reduced.

In four patients in Group I, each taking different antiarrhythmic medications, acceleration of ventricular tachycardia followed bursts of rapid ventricular pacing, but after a change in medications, there was no acceleration of ventricular tachycardia in response to bursts.

Optimal rate for bursts of rapid ventricular pacing: Analysis in 24 cases using unweighted data revealed that a pacing burst rate of 244 ± 41 (standard deviation) terminated tachycardia at 185 ± 45 beats/min. Overall rates of tachycardia and pacing bursts resulting in acceleration were similar to rates that resulted in termination of tachycardia, but when

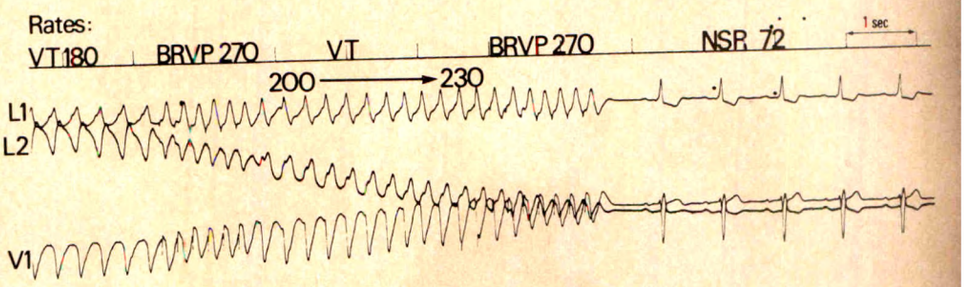

FIGURE 2. Acceleration of ventricular tachycardia (VI) from a rate of 180 to 230 beats/min by bursts of rapid ventricular pacing (BRVP) at 270 beats/min for six captures. The accelerated tachycardia was terminated by further bursts of rapid ventricular pacing. 1 second time lines at top. L1, L2 and V1 = electrocardiographic leads I, II and V_1, respectively; NSR = normal sinus rhythm.

tachycardia rates of less than 200 beats/min were considered separately, faster bursts were significantly more likely to cause acceleration (Table VI).

This analysis provided data on relations between the mean rates of tachycardia and pacing bursts. A formula for optimal burst pacing rate for any given rate of tachycardia was obtained using the curve-fitting program. Best fit was obtained with the linear equation Y = BX + A, with an index of determination of 0.80, where Y is the ventricular tachycardia (VT) rate; B and A are derived constants and X is the burst of rapid ventricular pacing (BRVP) rate. Solving for X will give the pacing burst rate likely to be effective for a given tachycardia rate.* Thus,

$$Y = BX + A$$

$$\text{or VT rate} = B\,(\text{BRVP rate}) + A$$

$$\text{BRVP rate} = \frac{\text{VT rate} - A}{B}$$

For all VT rates,

$$\text{BRVP rate} = \frac{\text{VT rate} + 47}{0.969} \qquad (r = 0.892)$$

For VT rate <200 beats/min,

$$\text{BRVP rate} = \frac{\text{VT rate} - 39}{0.539} \qquad (r = 0.892)$$

For VT rate ≥200 beats/min,

$$\text{BRVP rate} = \frac{\text{VT rate} - 7.3}{0.831} \qquad (r = 0.938)$$

Pacing rates too rapid for 1:1 capture were not included in the preceding calculations but were used for termination of ventricular tachycardia in two patients. One episode ended

* These formulas are useful as general guidelines, but occasionally very different pacing rates may be required. One patient treated after these data were compiled consistently required pacing at 240 beats/min for 12 to 15 captures to terminate a tachycardia at a rate of 140 beats/min. Pacing just in excess of the rate of tachycardia for up to 40 minutes and one to three programmed extrastimuli were ineffective.

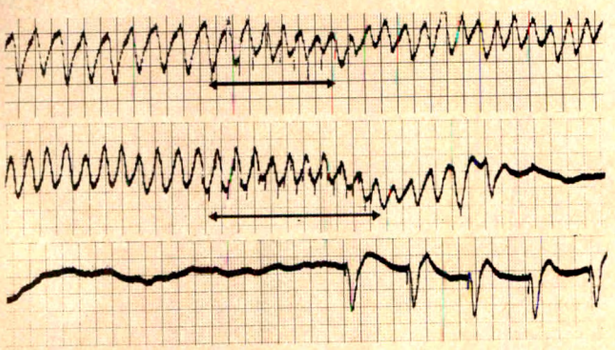

FIGURE 3. Ventricular tachycardia at a rate of 207 beats/min accelerated to 255 beats/min by bursts of rapid ventricular pacing at 350 beats/min **(arrows)** in a patient with terminal cardiogenic shock. In the **middle panel,** after bursts of rapid ventricular pacing at lower rates proved ineffectual, bursts at 780 beats/min resulted in 3:1 ventricular capture and the ventricular tachycardia was replaced by asystole, whereupon pacing at 78 beats/min was instituted. It is possible that this ventricular tachycardia ended spontaneously or that further efforts at lower burst rates would have succeeded, but ventricular capture was not obtained until there was a burst rate of 780 beats/min.

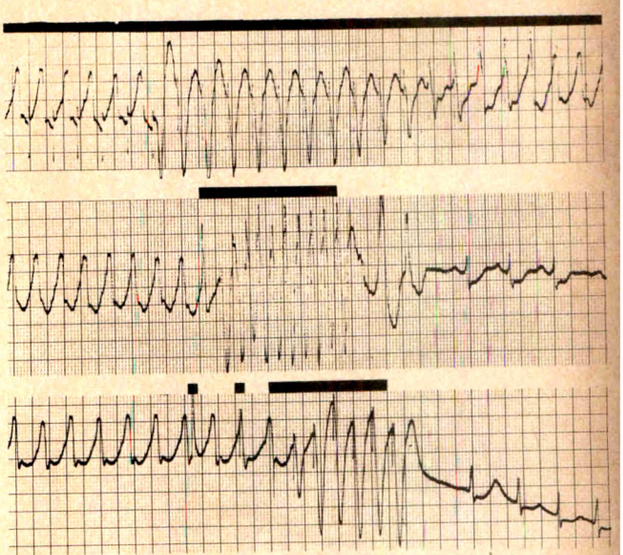

FIGURE 4. Ventricular tachycardia in a patient who later received an implanted pacemaker for bursts of rapid ventricular pacing (see text). **Top panel,** lead II. A ventricular pacemaker is on at 202 beats/min during ventricular tachycardia at 207 beats/min. Capture is obtained but the ventricular tachycardia soon emerges. **Middle panel,** bursts of rapid ventricular pacing at 400 beats/min terminated the episode, but two spontaneous extrasystoles followed. **Bottom panel,** bursts of rapid ventricular pacing at 260 beats/min **(long black bar)** terminated ventricular tachycardia without subsequent extrasystoles. The two pacemaker impulses at a slower rate **(two black squares)** occurred as the General Electric pacemaker was switched from once to twice the indicated rate.

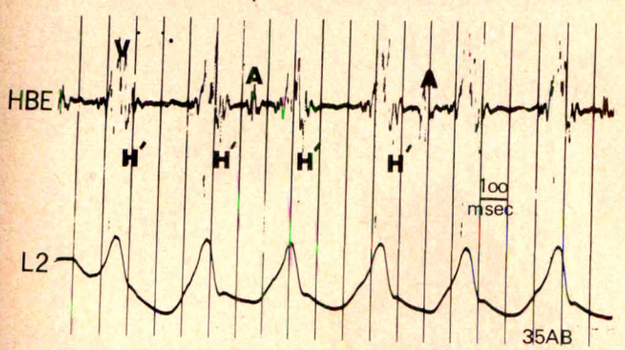

FIGURE 5. Same patient as in Figure 4. Tracing of His bundle electrogram (HBE) during ventricular tachycardia revealing 2:1 ventriculoatrial conduction with retrograde His bundle potentials (H') confirming the diagnosis of ventricular tachycardia.

after pacing at 780 beats/min with 3:1 capture (Fig. 3), lower rates having failed. Rates up to 1,200 beats/min were used in two patients without acceleration of the tachycardia.

Duration of bursts of rapid ventricular pacing: Acceleration of tachycardia could be prevented in some cases by reducing the number of captures. Because asynchronous bursts often begin with stimuli falling ineffectively in the refractory period, the number of captures was analyzed. Determination of the minimal number of captures required to terminate tachycardia was difficult because the number of stimuli or captures could not be precisely controlled with all pacemakers used. Pacing bursts for 4 to 6 captures were often effective and for 7 to 10 captures were usually effective; more than 10 captures were rarely required.

Implantable pacemakers for bursts of rapid ventricular pacing: Permanent pacemakers for termination of ventricular tachycardia by bursts of rapid ventricular pacing were implanted in two patients in Group I after serial electrophysiologic-pharmacologic testing[13–15] failed to establish a fully protective pharmacologic regimen. A 61 year old woman[10] had had for 6 years episodes of ventricular tachycardia at a rate of 200 beats/min that occurred in clusters at approximately 2 week intervals, frequently causing syncope within 10 to 15 seconds. The cause of these episodes was not explained by chemical tests, echocardiography or cardiac catheterization, which yielded normal findings including normalcy of the coronary arteries. The electrocardiogram was normal except for a modest Q-T interval prolongation (QTc interval 0.43 to 0.48). Bursts of rapid ventricular pacing ended 150 episodes (Fig. 4 and 5). An implantable unipolar pacemaker (Cordis Corporation, Miami, Florida) with a ventricular inhibited rate of 81 beats/min was specially constructed. When a magnet was placed over the unit, it emitted a burst of impulses at a rate of 295 beats/min, 8.6 milliamperes with a pulse duration of 1.42 msec, for 2.5 seconds (12 stimuli) and then reverted to pacing at a rate of 81 beats/min. If the ventricular tachycardia was not terminated, the magnet had to be removed and reapplied for another burst. In the 28 months since implantation the patient herself has terminated six episodes that were subjectively identical to her ventricular tachycardia, in each case after a single application of the magnet she keeps.

The second patient, a 33 year old man with congestive cardiomyopathy and ventricular tachycardia at a rate of 180 beats/min, underwent implantation of a Cordis ventricular inhibited pacemaker with an escape rate of 70 beats/min and a magnetically induced rate of 227 beats/min for eight stimuli. He used the unit many times at home and in the hospital, but it was removed after 1 month because ventricular tachycardia occurred more frequently after pacemaker implantation, even after the endocardial lead was repositioned.

Discussion

Advantages of method: For many patients, bursts of rapid ventricular pacing have the advantages of easy application, predictable effectiveness and apparent benignity. Other techniques have important drawbacks. Although one, two or three programmed extrasystoles can terminate tachycardias, they may be less effective, less predictable (Table V) and more time-consuming and require extensive instrumentation and thus may not be suitable for emergency use in a patient in unstable condition. Single random extrasystoles from an asynchronous pacemaker can also terminate ventricular tachycardia, but they take considerably longer than bursts of rapid ventricular pacing to be effective and share with bursts the possibility of stimulation in the vulnerable period. Ventricular tachycardia may sometimes be terminated by gradually increasing the rate of a ventricular inhibited pacer until it exceeds that of the tachycardia, achieving capture and then reducing the rate or turning the pacer off. This does not always work (13 percent success rate in our series) even when a burst of rapid pacing does (Table V).

The peril of myocardial damage induced by repeated direct current countershock may not be great if given through large paddles at intervals exceeding 3 minutes,[16] but such restraint is not always possible when treating recurrent ventricular tachycardia, and there remains the physical and psychologic discomfort to the patient. A burst of rapid ventricular pacing provides quick and painless cardioversion with minimal electrical current.

Mechanism of action of burst pacing: The basis of the effect of bursts of rapid ventricular pacing is not known. It is likely that in reentry arrhythmias the reentry pathway is interrupted just as multiple extrasystoles have been postulated to "peel back" the refractory periods and block reentry.[17,18] This presumption is strengthened because in many patients both programmed extrasystoles and bursts of rapid pacing were successful in terminating the same tachycardia. Bursts of pacing may also terminate ectopic automatic rhythms provided the ectopic focus does not reappear after overdrive suppression.[19,20]

Potential problems and dangers: A problem associated with bursts of rapid ventricular pacing is the possibility of acceleration of the tachycardia. In some patients there was a critical rate and duration "envelope" for success; bursts too slow or too short were ineffective, whereas those that were too rapid or too prolonged caused acceleration. Similar overdrive excitation of ventricular pacemakers by prolonged rapid pacing

has been studied in dogs.[21] Acceleration of ventricular tachycardia without a change in the QRS configuration may result from enhanced automaticity, as observed in the slow response tissue of simian mitral valves[22] or digitalis-poisoned Purkinje fibers,[23] or from an alteration in a microreentry circuit confined to a small volume of myocardium. Acceleration with altered QRS configuration could derive either from altered efferent conduction from an accelerated focus or from a change in the circus pathway.

The risk of ventricular fibrillation caused by bursts of rapid ventricular pacing is of concern just as it is during asynchronous ventricular pacing for ventricular tachycardia.[2] In our series very rapid ventricular tachycardia degenerating into ventricular fibrillation occurred in fewer than 1 percent of episodes (Table III). Nevertheless, if the technique is used cautiously, its benefits outweigh its risks. Laboratory and clinical experience shows that stimulation in the vulnerable period is less likely to cause ventricular fibrillation when unipolar cathodal stimulation is used at low levels of current output[24,25] and in a metabolically and hemodynamically compensated nonischemic ventricle.[26] We have usually used bipolar pacing for bursts of rapid ventricular pacing with temporary leads, but the implanted units were unipolar. Use of unipolar cathodal pacing with temporary electrodes and timing of the first stimulus of the bursts of rapid ventricular pacing to avoid the vulnerable period may further decrease the risks of ventricular fibrillation. Experimental observations indicate that rapid heart rates after acute myocardial infarction can be arrhythmogenic, perhaps as a result of increased nonuniformity of refractory periods.[27,28] Myocardial irritability is enhanced at rapid rates during ouabain toxicity.[29] Added caution is thus wise when bursts of pacing are used during states of acute myocardial infarction and digitalis toxicity, although we have used the technique successfully in both situations without an increased incidence of acceleration or ventricular fibrillation (Table IV).

Clinical applications: An implantable unipolar low output pacemaker delivering bursts of rapid ventricular pacing is appropriate when persistently recurring ventricular tachycardia responds best or only to pacing, without acceleration during many episodes over an extended period of time. The patient or family is thus provided with a mechanism for emergency conversion of ventricular tachycardia outside the hospital. When possible, however, the patient should go to the hospital before activating the pacemaker in case acceleration should occur. The family should be instructed in cardiopulmonary resuscitation.

Bursts of rapid ventricular pacing are useful in three clinical settings: (1) Acutely, if recurrent ventricular tachycardia has not been controlled by other means, bursts of pacing can minimize the need for direct current cardioversion. (2) During electrophysiologic studies in patients in more stable condition with recurrent ventricular tachycardia, bursts of pacing can immediately terminate an induced tachycardia, allowing serial testing of antiarrhythmic agents until a combination is found that protects the patient against ventricular tachycardia.[13–15] (3) In the rare patient whose tachycardia is not otherwise controlled, an implantable pacemaker is a useful option.

Treatment of 573 episodes of ventricular tachycardia with bursts of pacing has led to an appreciation of the benefits and risks of this technique. Bursts of rapid ventricular pacing represent a powerful addition to the therapies for recurrent ventricular tachycardia.

EDWARD R. DORNEY, MD
B. WOODFIN COBBS, MD
CHARLES R. HATCHER, Jr., MD, FACC

Atlanta, Georgia

Four cases are presented of aortic root dissection after aortocoronary bypass surgery in which the origin of the intimal tear was at or very near the aortic site of saphenous vein anastomosis. Two cases were documented at autopsy. In one of two cases diagnosed with aortography, the patient underwent surgical correction and survived. All patients had long-standing severe hypertensive cardiovascular disease or severe generalized atherosclerotic disease, or both. Clinical awareness of aortic dissection after coronary bypass surgery in this group of patients should make early diagnosis with successful surgical correction feasible.

Aortocoronary bypass surgery is an accepted surgical procedure for relief of angina pectoris refractory to medical treatment.[1,2] Recent reports[3,4] have also suggested prolonged survival with surgical management of left main coronary artery disease. Previously recognized complications of coronary bypass surgery[5,6] include postoperative infection, pulmonary embolism, pericarditis, pericardial tamponade[7] and myocardial infarction. Except for two cases recently reported,[8] dissecting aortic aneurysm initiated at the site of vein implant has not been recorded.

We report four well documented cases of aortic root dissection in which the intimal tear was at or very near the site of vein anastomosis. Three of our cases were recognized during the early postoperative course and one case several months later during follow-up study. One patient underwent aortographic confirmation and successful surgical correction of the dissection. All four patients had long-standing hypertensive cardiovascular disease or severe generalized atherosclerotic disease, or both. Awareness of this complication in this group of patients in the early postoperative period should encourage accurate diagnosis and prompt surgical correction of this potentially fatal complication.

Case Reports

Case 1

A 67 year old white man was admitted with progressive angina pectoris. He had had severe hypertensive cardiovascular disease for 22 years (diastolic blood pressure 90 to 140 mm Hg), with an episode of malignant hypertension in 1966. For 10 years he had had severe angina pectoris that required radioactive iodine ablation of thyroid function in 1966. Medications included propranolol (320 mg/day), isosorbide dinitrite, hydralazine, furosemide, digoxin and thyroxine. Physical examination revealed clinical myxedema. Blood pressure was 200/110 mm Hg, and a fourth heart sound was heard. Systolic bruits were present over the abdominal aorta and both femoral arteries; popliteal and pedal pulses were absent. Chest roentgenography revealed mild left ventricular enlargement. Electrocardiography disclosed normal sinus rhythm, old inferior infarction and left ventricular hypertrophy. The patient underwent cardiac catheterization and surgery. Cardiac catheterization disclosed severe triple vessel coronary artery disease with subtotal stenosis of the left main artery. A bypass graft to the left anterior descending artery was performed at Emory University Hospital.

During the first postoperative day because of markedly fluctuating hypertension (diastolic pressure 135 mm Hg) the patient was treated with diazoxide,

propranolol (20 to 40 mg every 6 hours) and hydralazine. On the fifth postoperative day he complained of precordial pain radiating to the posterior cervical area. On the eighth postoperative day the pain recurred, blood pressure was 200/120 mm Hg and the patient became pale and diaphoretic. The neck veins were distended, and a grade 2/6 murmur of aortic regurgitation was noted. Pericardiocentesis of 200 cc of bloody fluid provided temporary relief, but the patient subsequently had a cardiac arrest and died.

Autopsy revealed a 1.5 cm tear in the aortic root near the site of vein graft anastomosis (Fig. 1) with aortic dissection and rupture into the pericardium. There was severe generalized atherosclerosis and right renal arterial stenosis. Histologic examination of the aorta revealed no cystic medial necrosis but severe intimal atheroma.

Comment: This patient had long-standing hypertension and severe peripheral atherosclerosis. The postoperative course was complicated by widely fluctuating hypertension. Aortic dissection with the tear near the site of the vein implant occurred with severe chest pain, aortic regurgitation, cardiac tamponade and death. Severe generalized atherosclerosis and no medial disease of the aorta were documented at autopsy.

Case 2

A 51 year old white man with angina pectoris refractory to medical treatment was admitted for cardiac catheterization. The patient had a 10 year history of hypertension (diastolic blood pressure 90 to 130 mm Hg). Angina pectoris of 5 years' duration had worsened significantly in the previous 3 months despite treatment with propranolol (160 mg/day) and isosorbide dinitrite. Physical examination revealed a blood pressure of 210/120 mm Hg, an apex impulse displaced 1 cm lateral to the mid-clavicular line, abnormal S_3 and S_4 heart sounds and a 2/6 holosystolic murmur at the apex. The electrocardiogram revealed left ventricular hypertrophy, and the chest roentgenogram disclosed mild left ventricular enlargement. An exercise tolerance test revealed 4 mm S-T depression at 1 1/2 minutes of stage I of the standard Bruce protocol; cardiac catheterization disclosed severe triple vessel coronary artery disease. The patient underwent double aortocoronary bypass graft surgery at the Emory University Hospital.

On the first postoperative day the patient had marked hypertension (245/140 mm Hg) that responded initially to diazoxide. On the second postoperative day widely fluctuating hypertension was treated with propranolol (40 mg every 6 hours), hydralazine and methyldopa. On the eighth postoperative day the patient had a sudden onset of severe precordial pain and diaphoresis and became pulseless; attempts at resuscitation were unsuccessful.

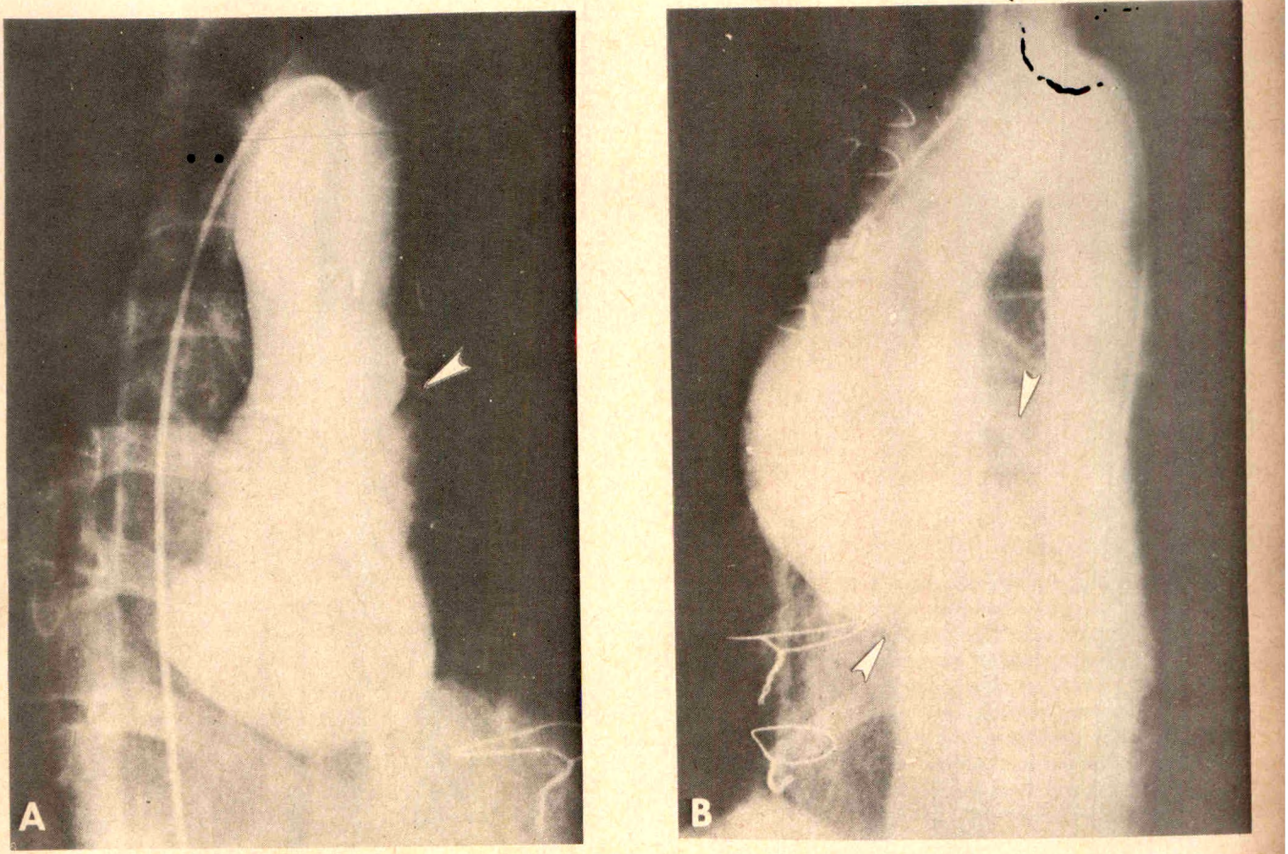

FIGURE 3. Case 3. Aortogram. **A,** right anterior oblique view demonstrating intimal tear **(arrow)** near vein implant site. **B,** left anterior oblique view demonstrating saphenous vein **(upper arrow)** and proximal intimal tear **(lower arrow).**

Autopsy revealed a 1.5 cm intimal tear in the ascending aorta (Fig. 2) continuous with the site of anastomosis of the second vein graft. There was dissection of the intima and media with perforation of the adventitia and associated hemopericardium. There was severe generalized atherosclerosis. Histologic study of the aorta revealed no cystic medial necrosis but severe intimal atheroma.

Comment: This patient with long-standing severe hypertension and severe generalized atherosclerosis documented at autopsy had the sudden onset on the eighth postoperative day of severe precordial chest pain and diaphoresis; he died as a result of dissection of the aorta with perforation of the aorta into the pericardium and cardiac tamponade.

Case 3

A 50 year old white man with severe angina pectoris was admitted for cardiac catheterization. The patient was known to have had severe hypertension for 10 years (diastolic pressure 90 to 120 mm Hg) and renal arterial stenosis in 1973. Angina pectoris of 3 years' duration had become progressively worse during the previous 3 months although he was treated with propranolol (320 mg/day), isosorbide dinitrite, nitrol ointment and digoxin. Physical examination revealed a blood pressure of 130/90 mm Hg. There were a systolic bruit over the left carotid artery and bruits over the abdominal aorta and both femoral arteries. Popliteal and pedal pulses were absent; there was a fourth heart sound. The electrocardiogram revealed old inferior myocardial infarction and left ventricular hypertrophy; the chest roentgenogram was normal. Cardiac catheterization disclosed severe triple vessel and left main coronary artery disease. The patient underwent triple aortocoronary bypass surgery at the University of Alabama Hospital.

The immediate postoperative course was complicated by severe hypertension (diastolic pressure 125 mm Hg), and the patient was treated initially with diazoxide and later with methyldopa. On the eighth postoperative day he was noted to have a grade 3/6 diastolic regurgitant murmur at the lower left sternal border. The chest roentgenogram revealed a dilated ascending aorta, slightly enlarged cardiac silhouette and interstitial pulmonary edema. The patient responded to treatment for heart failure; blood cultures were negative. The aortogram (Fig. 3) documented a dissecting aneurysm limited to the ascending aorta. The patient underwent successful repair of his dissecting aneurysm, with replacement of the ascending aorta with a Dacron® tube and reanastomosis of the proximal ends of the saphenous veins. Postoperatively, he has returned home and does not have angina pectoris or aortic regurgitation.

Comment: This patient with long-standing hypertension and severe peripheral atherosclerosis underwent aortocoronary bypass surgery. On the eighth postoperative day he had aortic regurgitation of new onset and a dilated ascending aorta, revealed with roentgenography. An aortogram documented the aortic dissection, and the patient underwent successful surgical repair of his dissecting aneurysm.

Case 4

A 67 year old man presented with angina pectoris of 3 years' duration that had become progressively severe during the

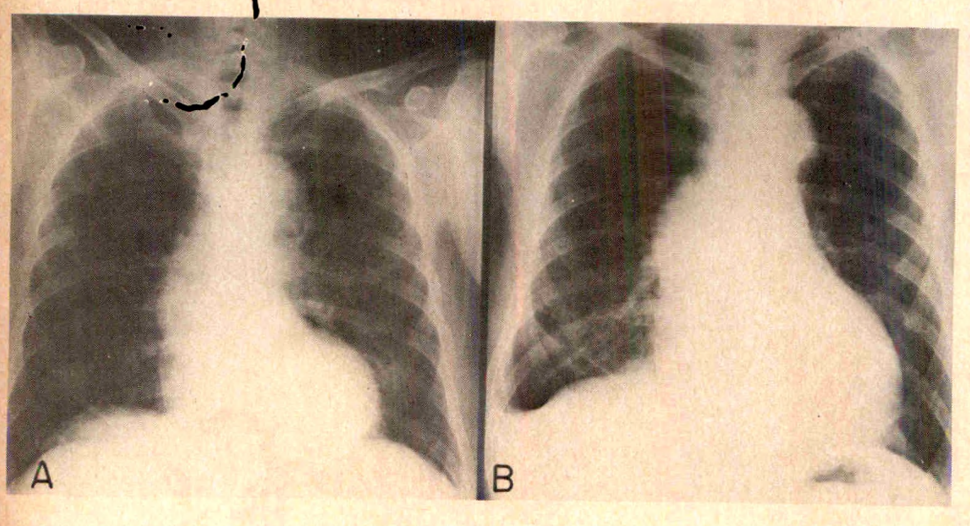

FIGURE 4. Case 4. Chest roentgenograms. **A,** 6 weeks after surgery showing mild dilatation of the ascending aorta. **B,** 10 months after surgery revealing marked dilatation of the ascending aorta, cardiomegaly and right pleural effusion.

previous 3 weeks, causing daily pain on rest. He had had hypertension for 10 years (diastolic pressure 90 to 100 mm Hg). On physical examination the blood pressure was 140/85 mm Hg. An abnormal third heart sound was heard in the left lateral decubitus position. There were no murmurs, and peripheral pulses were normal. The electrocardiogram revealed normal sinus rhythm and an old anterior infarction. The size and shape of the cardiac silhouette were normal on chest roentgenography, and there was no dilatation of the ascending aorta. Coronary arteriography demonstrated 60 percent luminal narrowing of the left main coronary artery and 60 to 80 percent lesions of the left anterior descending, circumflex and right coronary arteries.

At operation (York Hospital, Pennsylvania), three aortocoronary grafts were placed without difficulty. The immediate postoperative course was complicated by three episodes of bleeding requiring exploration. In addition, diazoxide was administered for the control of hypertension (mean arterial pressure 110 to 120 mm Hg). On evaluation 6 weeks after discharge from the hospital the patient was doing well and had no angina on moderate activity and no murmurs. The chest roentgenogram at that time revealed mild dilatation of the ascending aorta (Fig. 4A).

Ten months after operation, the patient presented with a 2 month history of progressive dyspnea and easy fatigability but no angina pectoris. Physical examination revealed blood pressure of 130/75 mm Hg, a laterally displaced and sustained apex impulse, abnormal third and fourth heart sounds and a grade 2/6 diastolic decrescendo murmur at the lower left sternal border. The chest roentgenogram (Fig. 4B) revealed cardiomegaly, marked dilatation of the ascending aorta and interstitial edema. The aortogram demonstrated a large aneurysm limited to the ascending aorta and an intimal flap just above the aortic cusps. Surgery is planned.

Comment: This patient, like the first three, had a history of hypertension (although less severe), and diazoxide was administered during the immediate postoperative period. However, he did not have evidence of peripheral vascular disease. Presumably dissection occurred at the time of aortocoronary bypass surgery but did not become apparent until months later, when severe aortic regurgitation and heart failure developed. Awareness of this complication from our experience with the three previous cases prompted early aortography and recommendation for surgical correction.

Discussion

Previous reports[9,10] of dissecting aneurysm during cardiopulmonary bypass include aortoiliac retrograde dissection from the site of femoral cannulation to the ascending aorta. Also reported[11] was a false aneurysm of the ascending aorta after aortic valve replacement. Dissection of the aorta has occurred as a result of aortic cannulation[12] and after clamping of an extensively atheromatous aorta.[13] In two patients recently reported[8] to have dissection at the site of aortic anastomosis after saphenous vein bypass surgery pathologic examination was not performed, but atherosclerosis was noted at surgery.

Predisposing and provocative factors: A history of hypertension is frequently present in cases of aortic dissection.[14] Our four patients had documented long-standing severe hypertensive cardiovascular disease. Braunstein[15] thought that advanced atherosclerotic lesions predispose to aortic dissection. Generalized atherosclerosis was documented in all four of our patients. Patient 3 had obstructive ileofemoral disease documented angiographically, and Patient 1 had both peripheral atherosclerosis and hypertension and hypothyroidism. The combination of the latter two problems is said to predispose to aortic dissection.[16]

Dissecting aneurysm begins with injury to the diseased aortic wall followed by intramural hemorrhage.[17] This hemorrhage forms an intramural hematoma that may be either preceded or followed by an intimal tear. The progression of the hematoma determines the extent of dissection.

Long-standing severe atherosclerosis and hypertensive disease established weakness in the aortic wall of our patients. Cystic medial necrosis was not present in the two aortas examined histologically, but severe atheromatous disease of the intima was present. The obligate clamping to the aorta at the site of vein graft anastomosis appears to be sufficiently traumatic to initiate hematoma formation and cause the intimal tear

at or near the site of anastomosis, as seen in our patients.

Increased rate of development of pressure (dP/dt) has been shown by Prokop et al.[18] to be highly undesirable in cases of aortic dissection. The use of diazoxide in all four patients during the early postoperative course may also have contributed to extension of the dissecting aneurysm by a reflex catechol-mediated increase in dP/dt of the cardiac stroke volume.[19]

Clinical signs: The patient with dissected aneurysm will present any of several well recognized findings and complications. Aortic regurgitation, a frequent occurrence in aortic dissections (23 to 25 percent),[15,20] was noted in three of our patients as the earliest clinical sign of the underlying diagnosis. Rupture of the aorta with ensuing cardiac tamponade, a well recognized complication of aortic dissection,[15,20] resulted in the death of two of our patients. Severe chest pain is a frequent subjective complaint in aortic dissection[15,20] and was present in two of our four patients.

Surgical precautions, prevention and treatment: Although the four operations were performed by four different surgeons in three institutions, certain elements of surgical trauma were constant. In all patients the proximal vein graft was sutured into the ascending aorta within the confines of a partial occlusion vascular clamp. The clamp was applied to the aorta while either normal cardiac output or partial cardiopulmonary bypass was maintained; that is, there was a significant pressure (normal or hypertensive) in the aorta. Realizing that delayed dissection occurs in the setting of hypertension and generalized atherosclerosis, the surgeon in such cases should modify the operative technique to permit application of relatively atraumatic clamps to the aorta while the patient is rendered temporarily hypotensive by the administration of drugs or by reduction in pump flow if the patient is on partial bypass. In extreme cases of atherosclerosis of the ascending aorta, a totally occlusive clamp should be applied to the aorta just proximal to the site of arterial cannulation while the patient is hypotensive, and the grafts should then be sutured into the aorta, which has totally collapsed.

The patient with long-standing severe hypertension or severe atherosclerotic peripheral vascular disease, or both, is at risk of dissecting aneurysm at the site of vein anastomosis to the ascending aorta. Although clamping of the aorta cannot be avoided, the number of applications should be kept to an absolute minimum, and the aortic pressure should be temporarily reduced to a hypotensive range while the clamp is applied. During the postoperative period the possibility of delayed dissection in such patients should be kept in mind. If signs or symptoms compatible with dissection occur, characteristically on the 6th to 8th day, prompt diagnosis and treatment should be undertaken. This complication must be considered not only in the early postoperative period but also during follow-up studies. The findings of dilatation of the ascending aorta, congestive heart failure or aortic regurgitation of new onset, alone or in combination, should alert one to the occurrence of this complication. Cardiac tamponade and chest pain may also accompany postoperative dissection. Awareness of this complication can provide the opportunity for diagnostic aortography and surgical correction.

Origin of the Second Heart Sound: Clinical Relevance of New Observations

PAUL D. STEIN, MD, FACC
HANI N. SABBAH

Detroit, Michigan

In this day of emphasis upon clinical relevance, and the emphasis placed by governmental granting agencies upon directly applicable research, one wonders if there is any value in detailed investigations related to the mechanism of production of the second heart sound. Points of infinitesimal accuracy are debated, such as whether the second sound starts milliseconds before or after total semilunar valve closure, or whether vibration of nonvalve structures participates in the closure sound. We believe that these issues are important and clinically relevant. Specifically, recent information related to the origin of the second sound permits one to interpret clinical auscultatory phenomena that previously were puzzling and sometimes seemingly paradoxical.

In 1915 Wiggers[1] suggested that there is silent approximation of the semilunar valves and that after-vibrations of the closed valves and the column of blood produce the second heart sound. In 1938 Lewis and Dock[2] indicated that the second sound is of purely valve origin and excluded the myocardium as a structure contributing to the heart sounds. Studies a century earlier by Rouanet[3] indicated that heart sounds (in this case the first sound) could be caused in a fashion similar to sound produced by any membrane as it passes "from flaccidity to tension suddenly." In recent years, many factors have been postulated to contribute to sound production although experimental evidence has been limited in some instances.

Rushmer[4] related the origin of the second sound to oscillations in the arterial and ventricular cavities initiated by the momentum of backward-moving blood, which causes stretch and subsequent recoil of the valve. Coleman[5] attributed the second sound to the sudden snapping together of the corpora arantii, which he postulated provides sufficient energy to vibrate the tensed leaflets. Piemme et al.[6] suggested that the main vibrations of the second sound are related to the magnitude of deceleration of blood during the latter part of ventricular systole. Luisada et al.[7] suggested that several factors contribute to the second sound, including eddies that precede semilunar closure, closure of the semilunar valves and opening of the atrioventricular (A-V) valves. They also suggested[8] that the walls of the ascending aorta, the outflow tract of the ventricle and blood itself as well as the aortic valve constitute the vibrant mass that results in a short series of vibrations recognized as the second sound.

Vibrations of closed semilunar valve as cause of the second heart sound: Investigations in our laboratory[9] indicate that the valve in fact closes silently and that vibrations of the closed valve are the source of the second sound. During early diastole the semilunar valve, being thin, compliant and tense, can be considered to act as a stretched circular membrane. When such a membrane is set into motion by a driving force, it generates compression and rarefaction of the ambient fluid that result in transient pressure changes productive of audible sound. Distension of the tensed leaflets toward the ventricle causes compression of the blood within the ventricle and rarefaction of the blood within the aorta (or pulmonary artery). Recoil of the valve toward the aorta (or pulmonary artery) causes a relative rarefaction of the blood within the ventricle and compression within the aorta. Thus, after silent closure, the valve vibrates as a diaphragm, producing pressure changes that are recognized as sound.[9]

This concept of the origin of the second sound is compatible with the view that valve vibration is primary in its production. A point of critical distinction is that the force productive of valve vibration would seem to be the pressure gradient that exists between the aorta and the ventricle just after valve closure and not the reversed flow or the deceleration of flow. This difference is important in the development of a theory that is compatible with standard concepts of fluid dynamics. Many of the characteristics of the second sound can be explained by considering the diastolic vibrations of the valve as the source of the second sound, and by con-

From the Henry Ford Hospital, Detroit, Michigan. Manuscript received May 13, 1977, accepted June 22, 1977.

Address for reprints: Paul D. Stein, MD, Henry Ford Hospital, 2799 West Grand Boulevard, Detroit, Michigan 48202.

sidering the pressure gradient that develops between the ventricle and arterial chamber as the driving force productive of the vibrations. Numerous auscultatory phenomena now can be explained by further consideration of this concept.

Experimental evidence and theoretical analysis: To substantiate this concept of production of the second sound, two principal avenues of investigation were conducted. First, semilunar valve dynamics were studied in vitro, in animals and in human subjects.[9] The relation of sound to pressure and flow was studied with special emphasis upon the high fidelity recording of intraarterial pressure and intraarterial sound in order to perceive better any minor fluctuations of pressure and sound that may occur. The use of an in vitro model of the cardiovascular system in which high speed motion pictures could relate valve motion and the position of the valve to hemodynamic events was particularly revealing. Second, a mathematical model of the motion of the semilunar valve in early diastole was formulated (Blick EF, Sabbah HN, Stein PD, unpublished observations). The model was derived on the basis of membrane vibration analysis and theories of sound production. The combination of both the experimental evidence and the theoretical analysis, some of which we have confirmed with studies in animals, gave sufficient evidence to support this concept of sound production.

The following experimental results were observed[9–12]: (1) The onset of the second heart sound began after total coaptation of the semilunar leaflets. This was shown with mounted porcine valves in vitro using high speed motion pictures at 2,000 frames/sec in combination with a sound transducer attached to an oscilloscope. (2) These same movies indicated asymmetric closure of the leaflets. A sequential approximation of the margins of the cusps occurred, starting peripherally and moving centrally. Some cusps were completely closed; others were still part open. This nonsimultaneous contact of the valve margins indicated that impact would occur with minimal energy, which in all likelihood is not sufficient to cause valve vibrations. (3) The amplitude of the second sound was shown to be independent of forward or retrograde flow. (4) Vibrations of the semilunar valve after closure were shown to occur in vitro, using 2,000 frames/sec cine film. Analyses of the rate and extent of valve motion from these motion pictures (Sabbah HN, Stein PD, unpublished observations) indicated that this motion may contain the entire frequency spectrum of the second sound previously observed by others. (5) The deflection of the primary vibration and secondary vibration of sound recorded within the ventricle are in a direction opposite to those of the deflections recorded within the aorta (or pulmonary artery). This indicates that, as compression occurs within the ventricle, rarefaction occurs within the arterial cavity, and vice versa. (6) The first major deflection of sound recorded from within the ventricle is invariably inscribed in the direction produced by compression. One would expect this, since the initial motion of the valve after semilunar closure is toward the outflow tract of the left ventricle. Simultaneously, the first major deflection of sound recorded from within the aorta is inscribed in the direction caused by rarefaction. (7) Close inspection of aortic, pulmonary and ventricular pressure recordings in both man and laboratory animals shows during early diastole the presence of transient changes of pressure that are coincident with the components of the second sound. These pressure transients appear to result from the same compression and rarefaction generated in the ventricles and their corresponding arterial chambers as a result of the vibrations of the semilunar valves.

Analysis of membrane vibration can be used to describe the valve motion if one considers the closed semilunar valve during early diastole to act as a vibrating tensed membrane driven by a diastolic pressure gradient. From the derived equations, one can explain and predict clinical auscultatory phenomena related to the amplitude of the second sound. Sound pressure produced by a vibrating membrane relates primarily to the rate of deflection of the membrane; that is, the amplitude of sound relates to the velocity of the valve as it distends toward the ventricle and recoils toward the aorta. Therefore, if an equation could be derived that described the rate of deflection of the valve in terms of the factors that affect its motion, the variables that affect the intensity of sound would be apparent. The solution of such an equation of motion is complex, because the distensibility of valve tissue varies with the extent to which the valve is stretched. A partial solution, nevertheless, shows several features that explain previously unexplained clinical observations*: (1) The amplitude and rate of valve distension produced by the early diastolic pressure gradient between the aorta and ventricle are related to the rate of change of this pressure gradient. Others[13] have found this to be true empirically and we[11] showed it prospectively with this analysis in mind. The rate of change of the diastolic pressure gradient relates closely to the rate of isovolumic relaxation.[11] Consequently, the amplitude of the aortic closure sound relates to the rate of isovolumic relaxation and, by implication, the amplitude of the second sound relates to ventricular performance. This would explain the tictac rhythm and reduced second sound sometimes heard in normotensive patients after an acute myocardial infarction or during heart failure.[14]

Clinical Relevance

Aortic stenosis: Both the modulus of elasticity of the valve and its mass are shown in the equation of valve motion to affect the extent and rate of valve deflection. This has particular clinical relevance in regard to the interpretation of auscultatory findings in aortic stenosis (Sabbah HN, Blick EF, Stein PD, unpublished observations). In acquired calcific aortic stenosis, the valve is thickened and stiffened. Thus, because of its increased mass and decreased flexibility, its ability to vibrate during diastole is diminished. A reduced second sound would therefore be expected with such a valve. In contradistinction, in children with congenital aortic stenosis the leaflets are thin and flexible. Because there is no impediment to diastolic vibration of the closed cusps, a second sound of normal intensity would be expected and it, of course, occurs. The diminished second sound in calcific aortic stenosis, and its paradoxical continued presence in congenital aortic stenosis, is therefore explained on the basis of this membrane concept of sound production (Sabbah HN, Blick EF, Stein PD, unpublished observations).

---

* Unpublished observations. Membrane analysis made by Edward F. Blick, PhD of the University of Oklahoma School of Aerospace, Mechanical and Nuclear Engineering.

Aortic insufficiency: In aortic insufficiency, firm approximation of all portions of the cusps does not occur. In such cases, the ability of the valve to tense and vibrate is reduced. On the basis of the membrane origin of the second sound, the amplitude of the second sound would be expected to be diminished. We[15] have consistently observed a diminished aortic component of the second sound in intraarterial recordings of patients with aortic regurgitation although the published data vary.

Intensity of pulmonary versus aortic component of the second sound: An explanation of the decreased intensity of the pulmonary component of the second sound relative to the aortic component is found by consideration of the factors that affect diastolic vibration of the valves. The rate of isovolumic diastolic relaxation of the right ventricle is lower than that of the left ventricle. Therefore, the rate of change of the diastolic pressure gradient between the right ventricle and pulmonary artery is lower and consequently a lower pulmonary closure sound is produced. This is partially compensated for, however, because the pulmonary valve is larger in diameter and thinner than the aortic valve. Membrane vibration analysis shows that the intensity of sound is dependent upon the diameter of the vibrating membrane, in this case the valve. In addition, because the pulmonary valve is thinner than the aortic valve it is likely to be more distensible.

Sound transients: The low amplitude sound vibrations during the last portion of the second sound, termed sound transients, have been postulated to represent sound induced by arterial vibrations and the opening of the A-V valves.[16] However, studies of mounted valves in vitro showed sound transients; yet the in vitro model of the cardiovascular system contained no structure other than the valve that was able to vibrate. Therefore, it is clear that the valve itself can produce the sound transients. It would seem that these sound transients indicate the late low velocity and low amplitude deflections of the valve just before diastolic vibration ceases. This observation is compatible with the equations of valve motion.

Other factors affecting intensity of second sound: Other factors, in addition to those described, that were not previously recognized to relate to the intensity of the second sound are shown by membrane vibration analysis to affect sound amplitude (Blick EF, Sabbah HN, Stein PD, unpublished observations). These include the density of the blood, the frequency of valve vibration, the volume and geometry of the ventricle, the coefficient of sound absorption of the ventricular wall and the damping force coefficient. The sound absorption of the ventricular wall perhaps may relate to the thickness of the ventricular wall and to the presence of scar. The damping force coefficient relates primarily to the viscosity of the blood, which varies greatly in patients, particularly with varying hematocrit levels.

Conclusion

It is clinically useful to recognize that the second heart sound is caused by vibration of the closed semilunar leaflets just after silent coaptation. If one conceives of the closed valve as a vibrating stretched membrane, then one can recognize the factors that affect diastolic valve vibration and ultimately affect the intensity of sound. These include the rate at which the driving pressure develops (the rate of change of the diastolic pressure gradient), the flexibility of the valve, its mass and diameter, the density and viscosity of the blood, the frequency of valve vibration, the coefficient of sound absorption of the ventricular walls and the geometry of the ventricle. These factors affect the production of the second sound. They are independent of the multiple factors that affect the transmission of sound. Clearly, therefore, the clinical interpretation of the intensity of the second sound is affected by a complex array of variables. In spite of this, understanding of the physiology of production of the second sound permits an understanding of numerous previously unexplained clinical observations. Further analyses of this nature will continue to increase our understanding of auscultatory phenomena.

* (Premature Ventricular Contractions (PVC's) and Premature Supraventricular Contractions with Aberrant IV Conduction)

No other scanning service gives you this report.

Clarity! Brevity! Precision!

These are the qualities every scanning service should offer to save you time and trouble.

But only CBS is equipped to offer ...a lot more important extras – like:

The only total scan system designed by a Cardiologist;

The latest Holter monitors customized by us for improved performance;

Up to 60% more vital information with the most complete report in the industry;

Four monitoring programs available with no capital investment.

To know more about why CBS is the only total scan and supply service clip the coupon and mail it today. If you believe in the importance of Holter monitoring then you owe it to yourself and your patients to look into Cardio-Bionic-Scanning.

EXERCISE TESTING BASICS:

Stress testing is rapidly becoming a standard diagnostic tool. But setting up your own stress testing unit can be costly. The equipment shown here will give you a basic system, flexible enough to build on for years to come.

Select a treadmill that will last. The treadmill is the basic workhorse of the system. It has to be durable. For 16 years, Quinton treadmills have been the standard in research centers, heart clinics and everyday practice.

We build seven models. All feature endless nylon belts for extra long service life, aircraft type honeycombed aluminum decks, lifetime lubricated bearings and heavy duty AC motors with "no jerk" speed control.

Quinton treadmills offer variable speed and elevation with metered readouts for both.

Treadmill Model 18-54

Select a practical multi-channel ECG monitor. Quinton offers a variety of ECG monitors. Our Model 623 two-channel unit has the versatility of multiple channel monitoring without the expense of three channel systems.

The Quinton Model 623 gives you pushbutton lead selection and lets you display and record any two leads simultaneously. With the QRS Sync feature, each consecutive QRS complex can be expanded to the full width of the screen, making even small changes obvious immediately.

No battery packs are required with the 623 and the internal calibration system not only checks the recorder before you conduct a test, it also checks the oscilloscope, patient cables and heart rate meter to assure you of total system accuracy.

Model 623 ECG Monitoring System

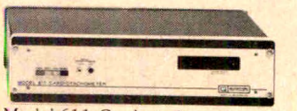
Build the system as your practice grows. Quinton offers a number of special purpose units which will expand the system's capabilities as your needs grow.

A Quinton programmer allows you to concentrate on the monitor and the patient while the test progresses automatically.

Treadmill Programmer

The Quinton ECG Data Computer digitally displays the heartrate, S-T level and S-T slope. It averages the signal to help you "see through" noisy ECG, and it records heartrate, S-T changes, arrhythmias and 20 beat ECG averages.

Model 740 ECG Data Computer

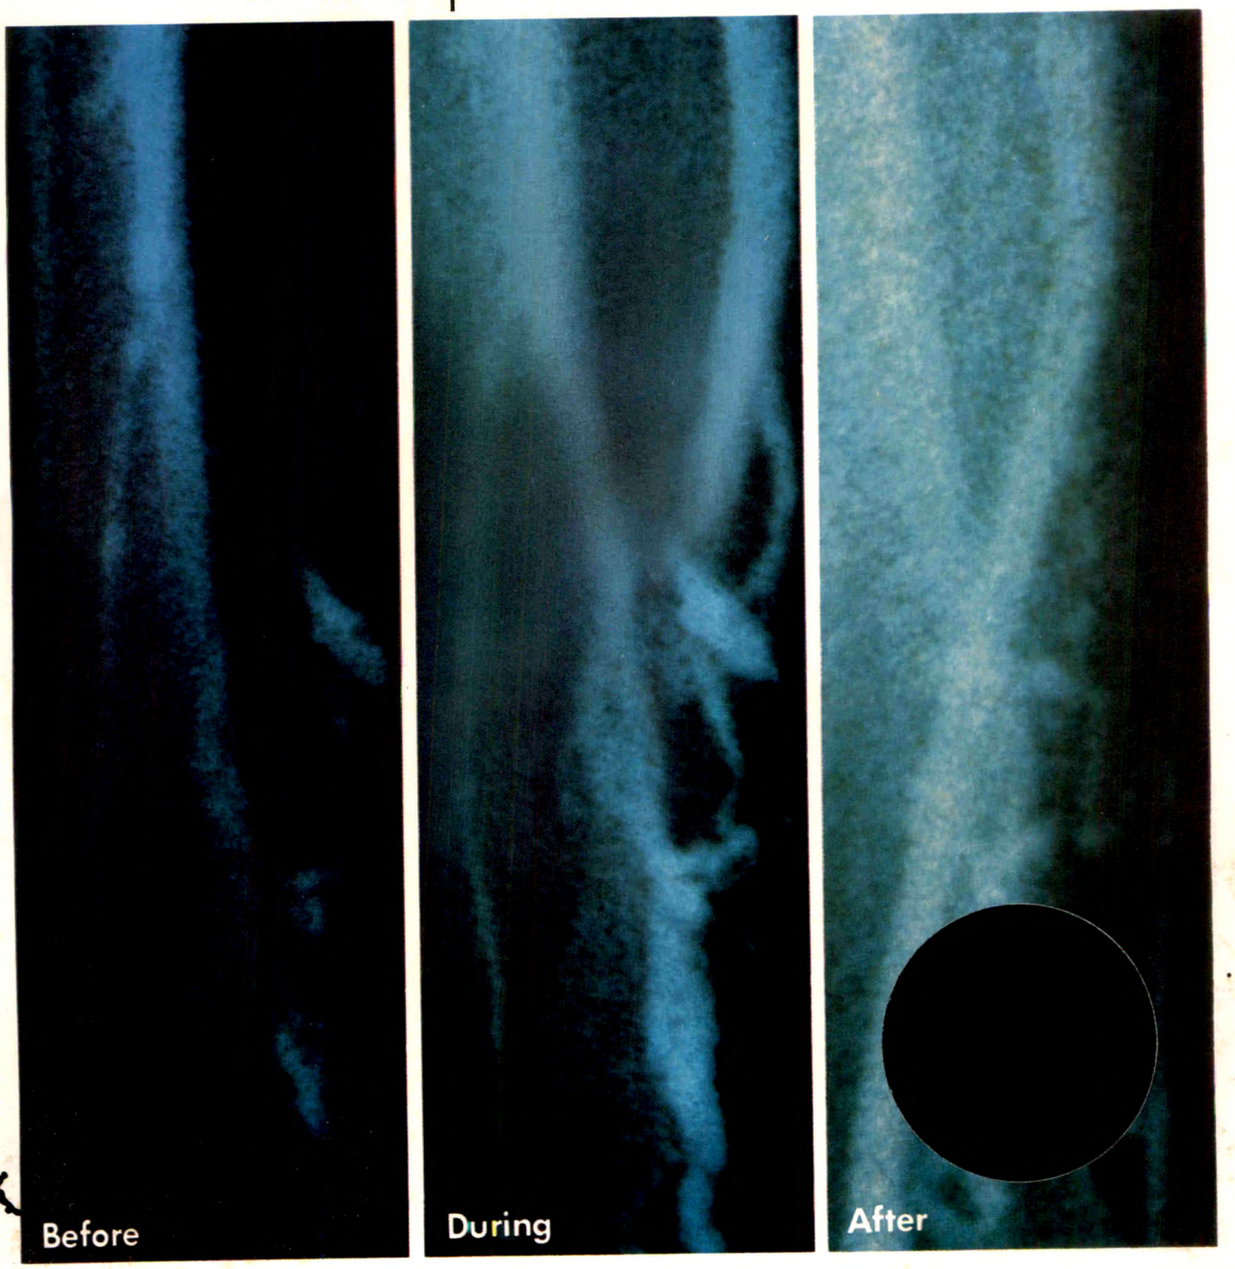


Model 611 Cardiotachometer

The Quinton cardiotachometer computes and digitally displays heartrate on an instantaneous, beat-by-beat basis. For details on all these products, contact Quinton Instrument Co., Dept. E16, 2121 Terry Avenue, Seattle, Washington 98121. Call 206/223-7373 or dial toll free 800-426-0538. **QUINTON**

You are looking at the dissolution of a thrombus.

Time required: 72 hours or less.



Introducing the first thrombolytic agent
for objectively diagnosed deep venous thrombi
and acute massive pulmonary emboli.

Hoechst-Roussel Pharmaceuticals Inc.

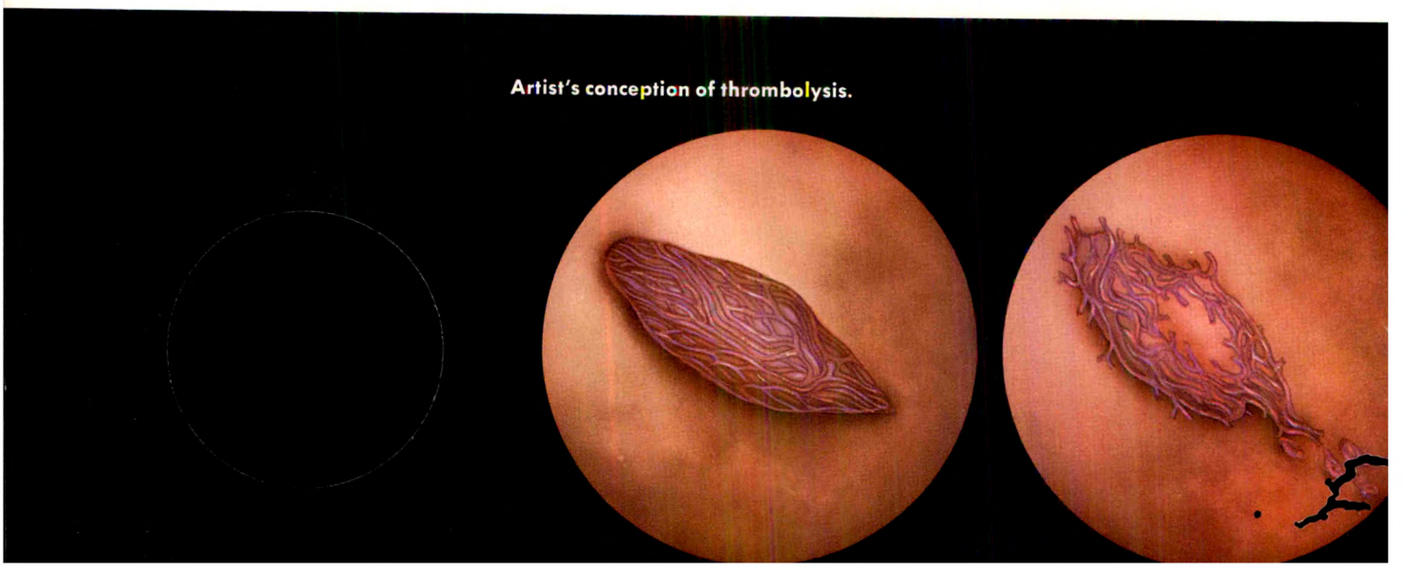
Announces

Streptase®

(streptokinase) I.V.

Now... a new alternative to surgery...

- **avoids the risks associated with thrombectomy.**
- **reduces the need for high-risk pulmonary embolectomy.**



To lyse venous thrombi and pulmonary emboli—intravenous Streptase®(streptokinase). Anticoagulant therapy is given following Streptase to prevent rethrombosis.

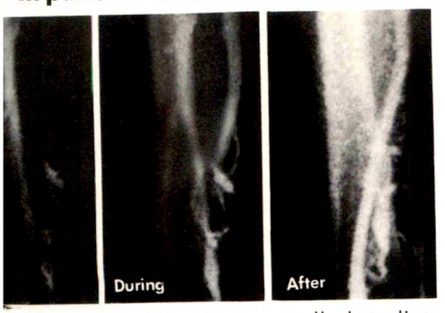
Now physicians have available a medical therapy for the early clearance of deep venous thrombi that is preferable to thrombectomy because it may preserve valvular function and avoid chronic stasis, although long-term benefits have not been established. And acute massive pulmonary emboli may be cleared without high-risk embolectomy.

A unique mode of action

New Streptase is the highly purified form of streptokinase, a bacterial protein derived from β-hemolytic streptococci. It combines with plasminogen to form an activator complex that converts residual plasminogen into the proteolytic enzyme plasmin. Plasmin hydrolyzes fibrin into polypeptides.

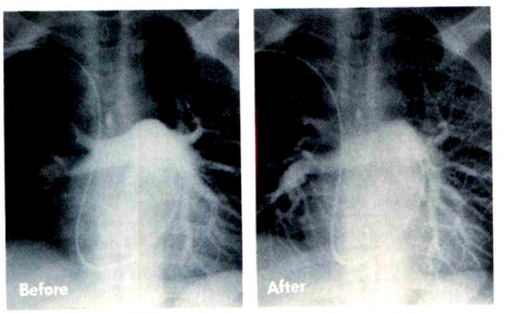
High rate of clinical success demonstrated by angiography:

In patients with venous thrombosis



In comparative controlled studies of 78 patients with venous thrombosis, Streptase produced complete or significant clearing of the thrombosis in 54% of patients while only 7% on conventional heparin therapy showed similar results.

In patients with pulmonary embolism



In studies of 124 patients with pulmonary embolism, complete or significant clearing was seen in 66% of the patients on Streptase but in only 11% of the heparin-treated patients.

Table I
Comparative angiographic results during controlled investigations*

Results	Venous Thrombosis		Pulmonary Embolism	
	Streptase (37 patients)	Heparin (41 patients)	Streptase (36 patients)	Heparin (88 patients)
Complete clearing	22%	5%	22%	5%
Significant, but incomplete, clearing	32%	2%	44%	6%
Minimal clearing	21%	20%	20%	43%
No change	22%	66%	14%	35%
Worse	3%	7%	0%	11%

In most cases, clearance was achieved in 72 hours or less.

For best results, Streptase should be used within 2 weeks after onset of venous thrombosis symptoms and within 5 days after onset of pulmonary embolism symptoms. Please see last page of this advertisement for a brief summary of prescribing information.

*Data on file and available on request from Hoechst-Roussel Pharmaceuticals Incorporated. Pulmonary embolism data include those taken from National Heart and Lung Institute study.

Thrombosis and thrombolysis information available

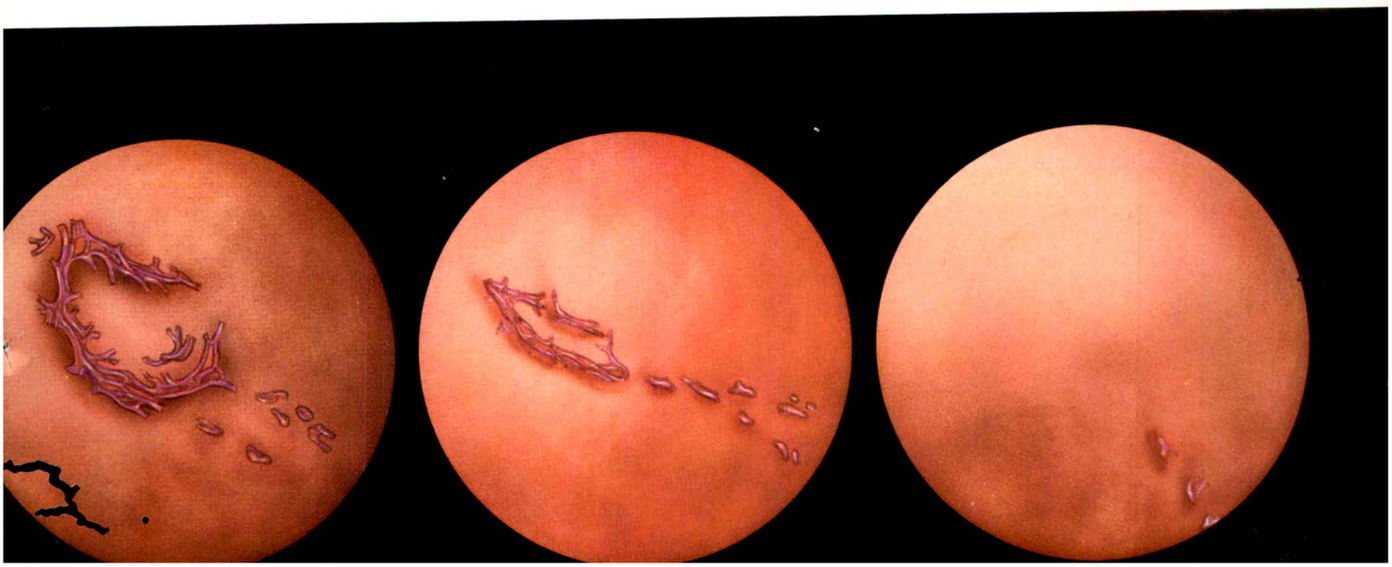
When considering the use of Streptase (streptokinase), comprehensive knowledge of prescribing information and strict observance of the contraindications, warnings, precautions, and dosage and administration instructions are most important to minimize the incidence and severity of adverse reactions, the most significant and frequent being fever, allergy and bleeding. Use of Streptase requires an interdisciplinary effort and therefore should be reserved for those hospitals with facilities for angiography, coagulation testing and volumetric or syringe pump administration of Streptase intravenously.

Hoechst-Roussel has prepared a comprehensive educational program on thrombosis and thrombolysis that includes two films, associated monographs, dosage and administration guidelines and a Speakers Bureau of physicians experienced in the use of thrombolytic therapy.

For information, interested physicians may contact Scientific Services, Room 236, Building M, Hoechst-Roussel Pharmaceuticals Inc., Somerville, New Jersey 08876, (201) 685-2611, or the local Hoechst-Roussel Sales Representative.

For a complete list of indications, contraindications, warnings, precautions, adverse reactions and dosage information, please refer to the full prescribing information for Streptase, a summary of which appears on the following page.

HOECHST-ROUSSEL
PHARMACEUTICALS INCORPORATED
SOMERVILLE, NEW JERSEY 08876



Streptase®
(streptokinase) I.V.

Brief Summary of the Prescribing Information

Streptase® (streptokinase) should only be used by physicians with wide experience in the management of thrombotic disease in hospitals where the recommended clinical and laboratory monitoring can be performed. The full prescribing information should be read for complete details.

When considering treatment with Streptase® (streptokinase) the overall clinical status and history of the patient should be carefully assessed. The hemostatic capability of the patient is more profoundly altered and bleeding more frequent with Streptase® (streptokinase) therapy than with heparin or oral coumarin compound anticoagulant therapy. When bleeding occurs it is also more severe and more difficult to manage. The potential risk of serious hemorrhage relative to such factors as age, physical condition, and underlying bleeding tendency of the patient should be weighed against the potential benefits of treating the patient with Streptase® (streptokinase).

Indications

Pulmonary Embolism: Streptase® (streptokinase) is indicated in adults for the lysis of acute massive pulmonary emboli, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels. It may also be indicated for embolization accompanied by unstable hemodynamics. The diagnosis should be confirmed by objective means. Streptase® (streptokinase) treatment should be instituted as soon as possible after onset of symptoms and no later than five days after onset. Reduction of morbidity or mortality has not been established.

Deep Vein Thrombosis: Streptase® (streptokinase) is indicated for lysis of acute, extensive thrombi of the deep veins in adults. Diagnosis should be confirmed by objective methods.

Streptase® (streptokinase) should be administered as soon as possible after the onset of the thrombotic event (preferably within several days), although slight enhancement of clot lysis has been shown with initiation of therapy up to two weeks after the onset of symptoms.

Contraindications

Predisposition to Bleeding: Because thrombolytic therapy increases the risk of bleeding, Streptase® (streptokinase) is contraindicated when the following conditions exist: surgery within 10 days, liver or kidney biopsy within 10 days, intraarterial diagnostic procedure within 10 days, ulcerative wound, recent trauma, visceral carcinoma, parturition (within 10 days), ulcerative colitis or diverticulitis, hypertension, liver or kidney disease, thrombocytopenia or other evidence of defective hemostasis, active tuberculosis, subacute bacterial endocarditis, gastrointestinal bleeding within 6 months.

Predisposition to Allergy: Streptase® (streptokinase) is contraindicated in patients with a history of a previous severe allergic reaction to Streptase® (streptokinase) or who present a significant risk of an allergic response.

Recent Cerebral Embolism, Thrombosis, or Hemorrhage: Treatment with Streptase® (streptokinase) is contraindicated for at least two months.

Predisposition to Systemic Infection: Use of Streptase® (streptokinase) in septic thrombophlebitis may be hazardous because of the risk of inducing systemic infection.

Warnings

Bleeding: Activation of the fibrinolytic system with Streptase® (streptokinase) results in a more profound alteration of the hemostatic status of the patient than does anticoagulant therapy. Although the aim of Streptase® (streptokinase) therapy is the production of sufficient amounts of plasmin for lysis of intravascular deposits of fibrin, other fibrin deposits are also destined for lysis and bleeding may result. The possibility of bruising or hematoma formation especially with intramuscular injections is high.

Bleeding at sites of recent invasive procedures may occur. Should an arterial puncture be *absolutely* necessary, the femoral artery must be avoided and the radial or brachial artery used. Also, invasive venous procedures should be performed as carefully and infrequently as possible. If the bleeding from an invasive site is not serious, treatment may be continued with appropriate clinical observations.

Spontaneous bleeding from internal sites may also occur.

Should serious spontaneous bleeding occur, the infusion of Streptase® (streptokinase) should be terminated immediately.

In addition to its fibrinolytic action, plasmin also degrades fibrinogen, Factor V, Factor VIII, and other proteins. These products possess an anticoagulant effect and should be monitored by serial thrombin time determinations.

Predisposition to Cerebral Embolism: Treatment with Streptase® (streptokinase) of patients with conditions in which there is possible risk of cerebral embolism may be hazardous because of the risk of bleeding into the infarcted area.

Allergy: Streptase® (streptokinase) is antigenic, thus, allergic reactions including anaphylaxis may occur.

Recipients of Streptase® (streptokinase) should be observed carefully during the first few hours of therapy. Patients with known allergies to other antigens are more likely to react. If significant changes in blood pressure or asthmatic symptoms occur which might be due to allergy, the infusion should be terminated and symptomatic treatment employed.

Other mild allergic manifestations have also been observed but generally are not serious enough to require discontinuation of therapy.

Use of Anticoagulants: Concurrent use of anticoagulants with Streptase® (streptokinase) is not recommended and may be hazardous. A thrombin time of less than twice the normal control value is adequate for starting Streptase® (streptokinase) infusions safely following the use of heparin. Heparin should not be started following Streptase® (streptokinase) therapy until the thrombin time has returned to less than twice the normal control value.

In order to minimize rethrombosis, the use of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following Streptase® (streptokinase) therapy.

Use in Pregnancy and in Children: Streptase® (streptokinase) therapy during pregnancy and in children is not recommended.

Precautions

If the patient's history gives rise to suspicion of elevated resistance, the streptokinase resistance test should be used to determine the proper loading dose. When resistance levels in excess of 1,000,000 I.U. are found, Streptase® (streptokinase) should not be administered.

Streptase® (streptokinase) infusions have been associated with altered platelet function. Concurrent use of drugs that may potentiate this effect should be avoided.

Adverse Reactions

Incidence and Management

Bleeding: Severe spontaneous bleeding has been documented in 6 of 292 patients during Streptase® (streptokinase) treatment. Several fatalities due to cerebral hemorrhage have occurred during Streptase® (streptokinase) therapy. Less severe spontaneous bleeding has been observed during Streptase® (streptokinase) treatment at approximately twice the frequency as that occurring during heparin therapy. In several instances, spontaneous bleeding has been traced to concomitant anticoagulant treatment which is not recommended.

Management of Severe Bleeding: Streptase® (streptokinase) therapy must be discontinued. If very rapid reversal of the fibrinolytic state is required, treatment with aminocaproic acid (EACA) can be instituted.

Plasma volume expanders are indicated to replace blood volume deficit. If blood loss has been large, Red Blood Cells (Human) may also be indicated. If only Whole Blood (Human) is available, it may also be used.

Allergic Reaction

Incidence: Reactions determined to represent possible anaphylaxis have been observed in 7 of 292 patients treated with Streptase® (streptokinase). These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling, or angioneurotic edema. Other milder allergic effects have been observed in approximately 12% of patients. There was no apparent relationship to dosage.

Management of Allergic Reactions: Mild and moderate reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase® (streptokinase), with corticosteroids administered intravenously as required.

Fever

Incidence: One-third of patients treated with Streptase® (streptokinase) have shown increases in body temperature of 1.5°F or more; the incidence of fever ≥104°F was 3.4%.

Management: Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is recommended.

Phlebitis: Phlebitis near the site of intravenous infusion of Streptase® (streptokinase) has occurred in less than 2% of patients.

How Supplied

Streptase® (streptokinase) is supplied as a lyophilized white powder in 6.5 ml vials (in packages of 10) with color-coded labels corresponding to the amount of purified Streptase® (streptokinase) in each vial as follows: 100,000 IU (yellow), 250,000 IU (green), 750,000 IU (blue).

In each vial there is a 20% overfill above that stated on the label. Each vial also contains 25 mg cross-linked gelatin polypeptides and 25 mg sodium L-glutamate as stabilizers.

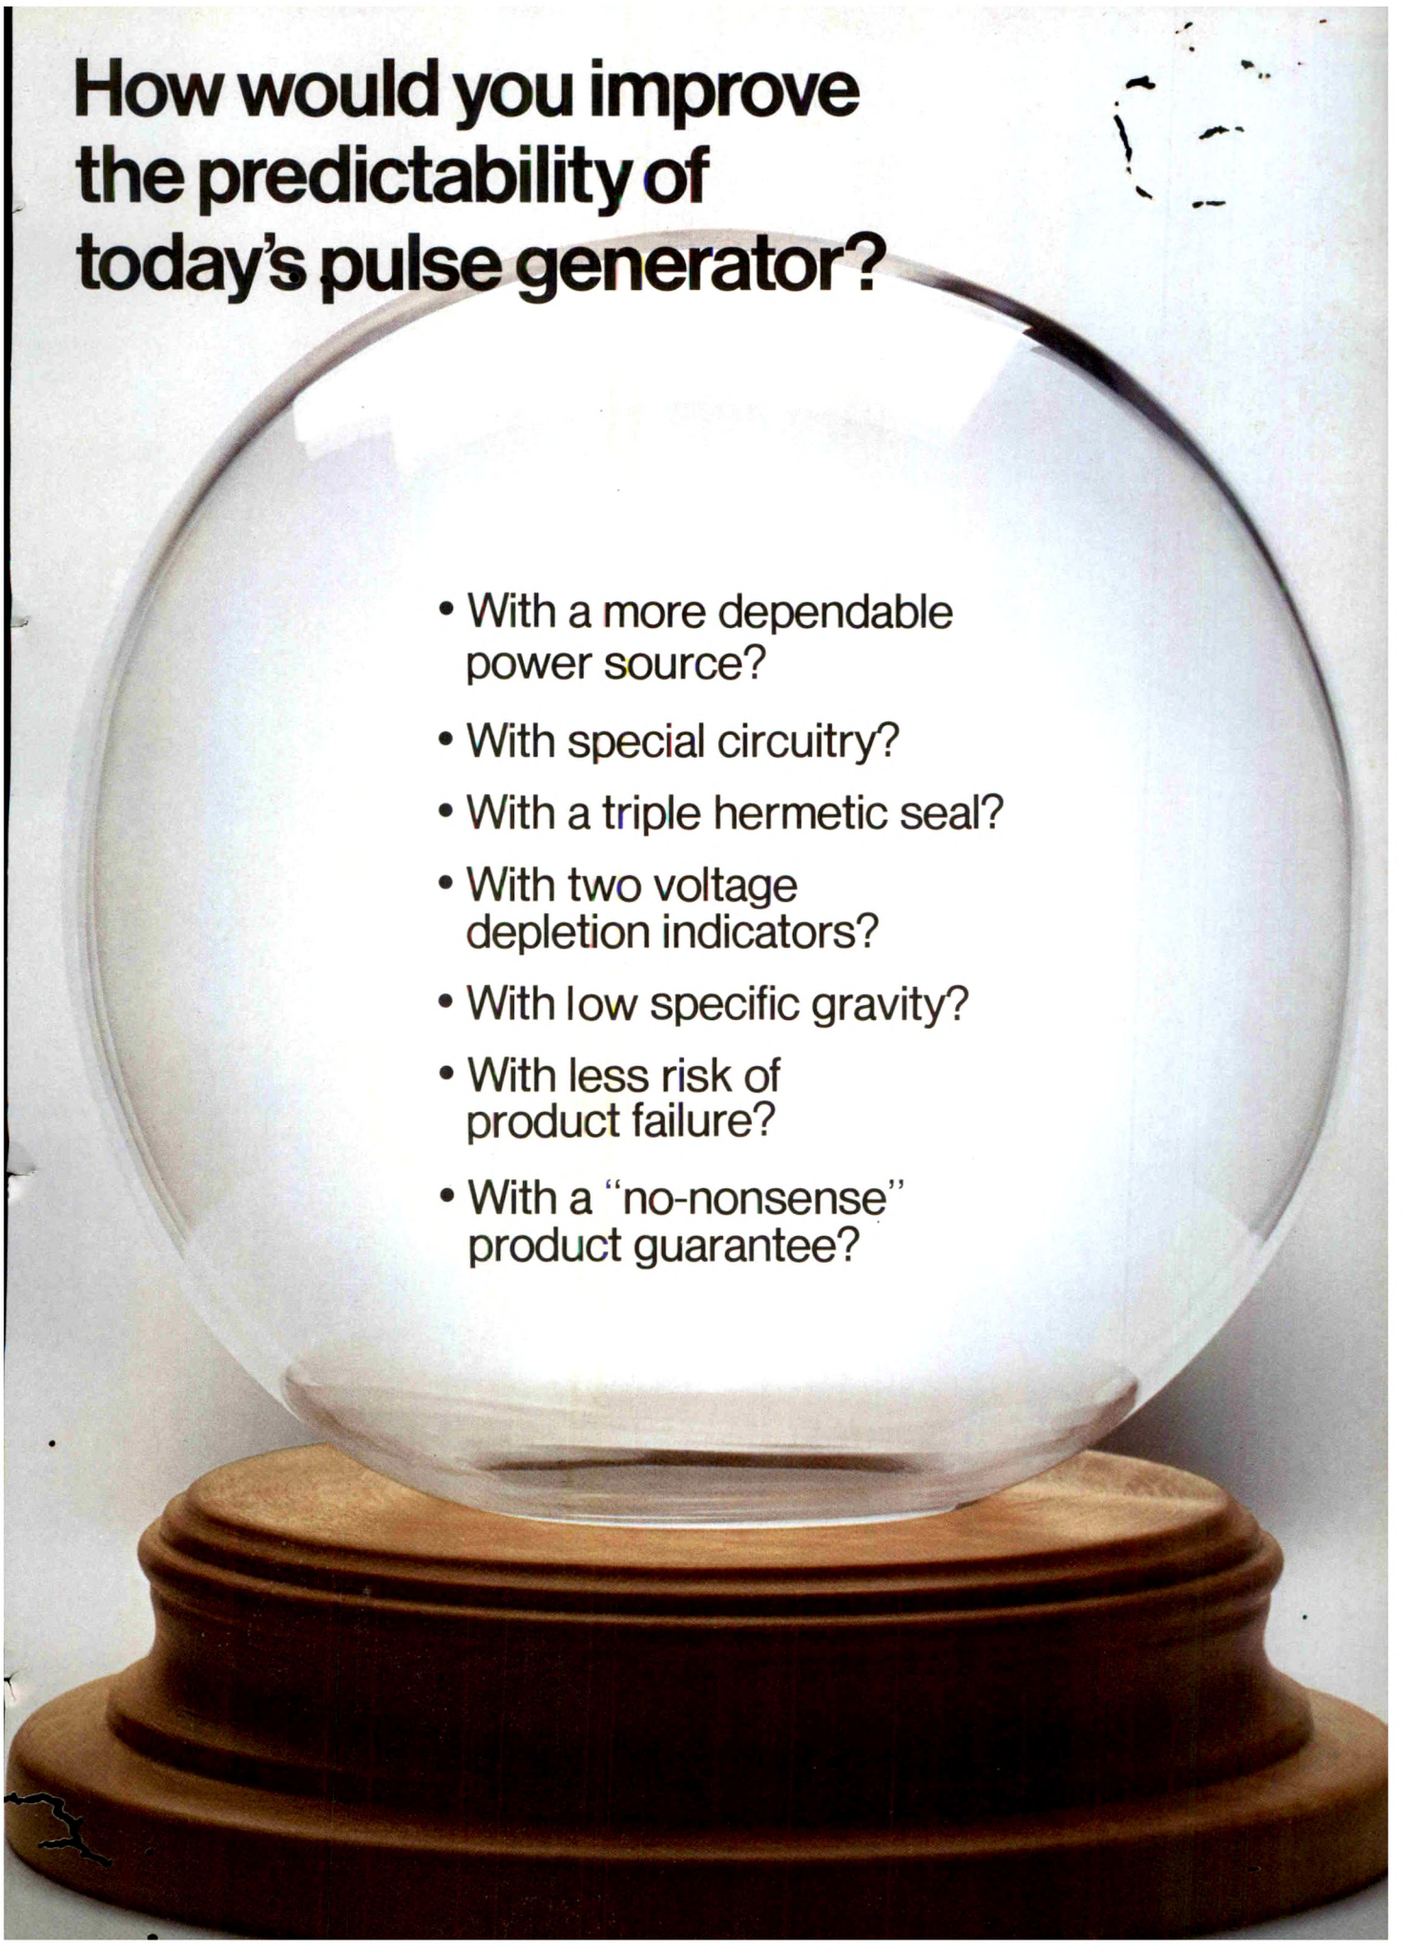
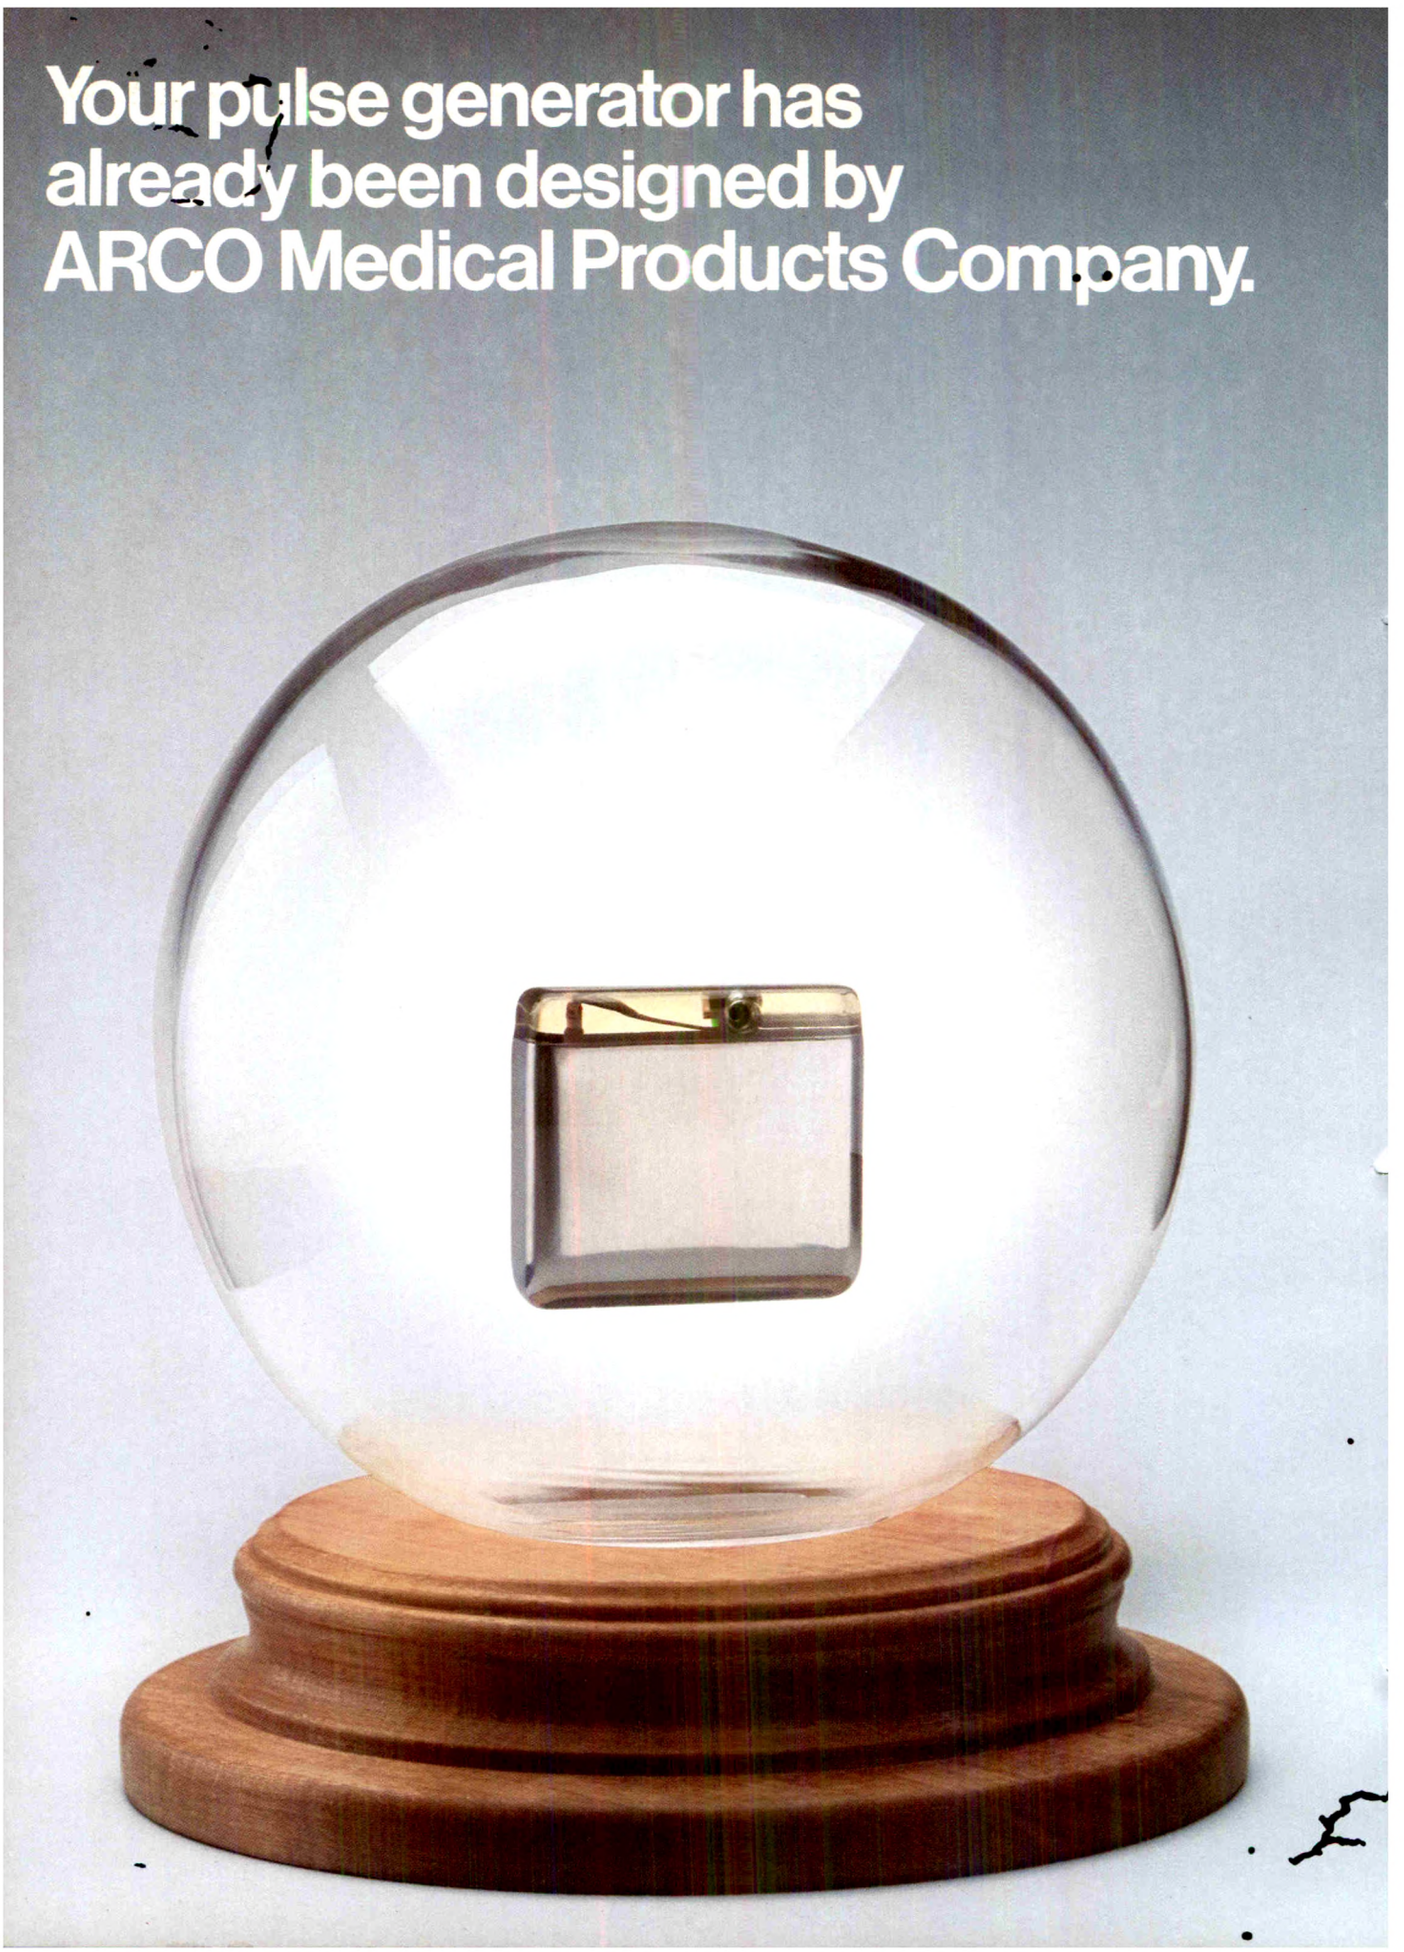
How would you improve the predictability of today's pulse generator?



- With a more dependable power source?
- With special circuitry?
- With a triple hermetic seal?
- With two voltage depletion indicators?
- With low specific gravity?
- With less risk of product failure?
- With a "no-nonsense" product guarantee?

Your pulse generator has already been designed by ARCO Medical Products Company.



Improved predictability with the only lithium thionyl chloride power source.

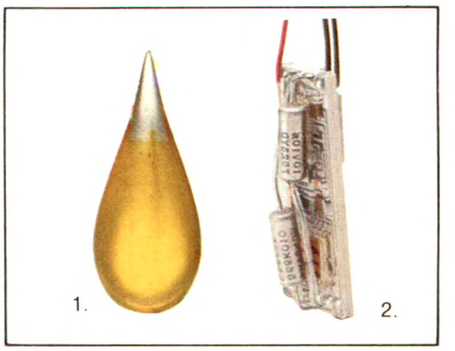
Lithium thionyl chloride, with one of the highest energy densities presently known, permits a small, lightweight battery that is longer lasting than other cells of comparable size in any given application. Individual cell hermetic sealing and no generation of internal pressure contribute to the fact that there has not been a report of a single power source failure in clinical use (1).

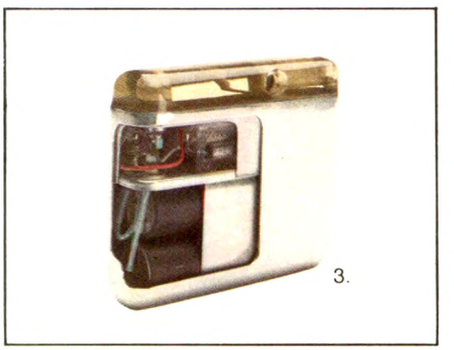
Improved predictability with specially designed circuitry.

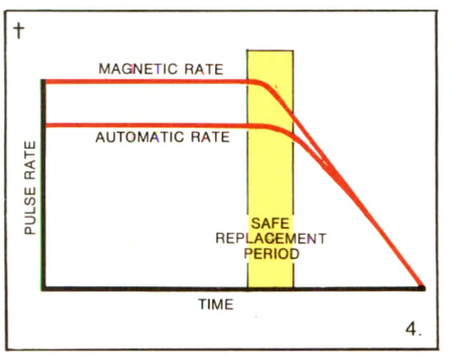
Developed specifically for use with our exclusive power cells, this circuitry offers long life and reliability. In fact, our power cells are electrically connected in a truly redundant fashion, which assures uninterrupted operation even if one cell should fail (2).

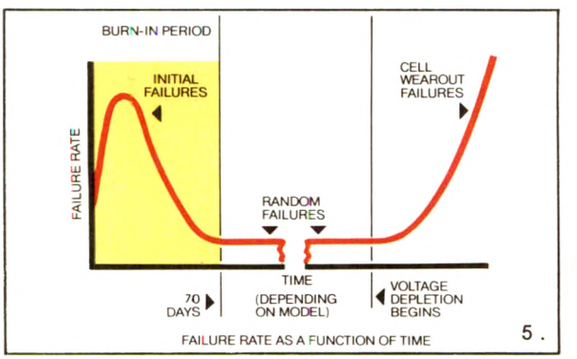
Improved predictability with a triple hermetic sealing process.

The power cells, the electronics, and the outer case of corrosion-resistant titanium are all individually hermetically sealed to provide dual protection and virtually isolate components from the invasion and migration of body fluids (3).









Improved predictability with two voltage depletion indicators.

Both an automatic and magnetic pulse rate provide advance warning of cell voltage depletion. The magnetic rate begins to decrease a number of months prior to the automatic rate to provide ample replacement time (4).

Improved predictability with a more natural specific gravity than most pulse generators.

The specific gravity of ARCOlith™ pulse generators is just slightly greater than that of the body's tissues; thus, migration is minimized for added patient comfort.

Improved predictability with an extended "burn-in" test.

Prior to market release every unit must undergo 70 days of operation. This virtually eliminates initial implant failure and assures you and your patients of effective performance and long life (5).

The predictability of ARCOlith™ pulse generators has been so improved they carry a "no-nonsense" product guarantee.

In essence:

1. Should an ARCOlith pulse generator become defective for any reason up to and including 60 days following implant, we will replace it and pay *all* reasonable surgical and hospital costs.*

2. Should an ARCOlith pulse generator become defective for any reason after 60 days up to the end of the warranty period,* we will replace it and pay up to $200 in surgical and hospital costs.*

*See warranty for specific details. Warranty applies in U.S.A. only.
†Idealized graph based on extrapolated data.

ARCOlith™ 12, 6, and 4 are now the trade names for pulse generator models LI-2, LI-4 and LI-3.

Every ARCOlith™ pulse generator offers you these predictable features:

- Titanium and epoxy casings proven corrosion resistant to body fluids and compatible with human tissue over long periods of time
- EMI shielding, high-reliability filtering components, and special circuits help to protect against electromagnetic interference
- Higher interference rate than the basic pacing rate provides additional protection against PVCs and competition, which may occur at lower levels
- High-input impedance enhances R-wave sensing
- Output stage contains voltage pulse doubler, which allows truly redundant power cells
- Visible temperature indicator informs whether unit has been subjected to excessive temperature prior to implant
- Readily adaptable to most leads
- Captive set screw-in lead connector
- 24-hour telephone diagnostic monitoring of pulse generators available at no extra cost

Disclosure Statement
ARCOlith™ Implantable Pulse Generators

Intended uses: Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to symptomatic bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses).

Contraindications: There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing systems and implantation procedure used by the physician.

Warnings: Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator.

Precautions: The physician should be aware that all pulse generators will ultimately cease to function, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, and elevated thresholds, and that proper operation may be affected by electrical interference from equipment using electrical energy, or medical complications.

Side effects: Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Optimal Electrocardiography—1977: Introductory Comments

DEAN T. MASON, MD, FACC

In my capacity as president of the American College of Cardiology, I have the pleasure and privilege of opening this Bethesda Conference on Optimal Electrocardiography and of welcoming the present task force participants in the formulation of position papers on standardization, record quality, computers, clinical application, cost effectiveness, and future goals and objectives. My introductory comments will be brief, intended to provide a selected perspective derived from my own view of the subject as a cardiologist.

Modern cardiology now includes a nearly overwhelming array of complex diagnostic procedures of such diversity and sophistication that mastery of all of them is virtually impossible for even the most dedicated specialist. Of these procedures, the first to be introduced and still the most fundamental is electrocardiography. Indeed, until the widespread use of cardiac catheterization over the past two decades, diagnostic cardiology was almost entirely focused upon the electrocardiogram, stethoscope and roentgenogram. A thorough knowledge of conventional electrocardiography remains an essential hallmark of cardiovascular practice. However, it is my general impression that the younger cardiologist today is less proficient in electrocardiographic interpretation than was the case several years ago. This observation is also of concern to the Cardiovascular test committee of The American Board of Internal Medicine, and it is planned that electrocardiographic analysis will be emphasized in future examinations. This deficiency probably reflects a relative overemphasis on more dramatic nonelectrocardiographic techniques in current cardiovascular training programs.

Of substantial importance are the economic costs of electrocardiography to the hospital and consumer, as well as to the clinician. These are difficult to evaluate because of disparities in hospital types and sizes, local situations, financial arrangements, patient charges, equipment and personnel, physician utilization of electrocardiography and other factors in addition to lack of precise data on costs. Nevertheless, with the help of Dr. Zakauddin Vera, director of clinical electrophysiology at our institution, the Sacramento Medical Center University Hospital at the University of California at Davis, we estimated the annual cost of standard 12 lead electrocardiography for all such tracings obtained from inpatients and from outpatient clinics for all hospitals nationally. The 1976 edition of Hospital Statistics lists 1.5 million total U.S. hospital beds with 36.2 million admissions and 254.8 million outpatient visits to all U.S. hospitals in 1975. Prorating these figures to our 400 bed hospital in which we take 25,000 electrocardiograms a year, it is approximated that nearly 84 million hospital electrocardiograms are taken in the U.S. yearly. Assuming noncomputer systems and the hospital expenditure of $3 a tracing at our institution, total U.S. hospital costs for electrocardiograms would be $252 million a year. Thus, total national hospital expenditures for standard 12 lead electrocardiograms appear to account for approximately 0.5 percent of all hospital expenditures (total U.S. hospital expenditures were $48.7 billion in 1975). Another figure of interest is that the Bureau of Medical Statistics of the Department of Health, Education, and Welfare reports that 25 percent of the total U.S. population over 40 years of age has at least one standard electrocardiogram a year. Not included in this analysis of costs and patient utilization are the several additional procedures involving electrocardiography such as vectorcardiography, exercise stress testing, 24 hour ambulatory monitoring, intensive care unit monitoring, pacemaker function assessment and His bundle electrography.

Principal issues requiring resolution and implementation are physician competence and the training and personnel required for interpretation of electrocardiograms. These matters are of particular concern in nonuniversity affiliated hospitals without certified

cardiologists, community hospitals in which the electrocardiography concession may be used as an inducement for hospital admissions and small hospitals that have no internist-cardiologist available. Fortunately, this critical topic is to be thoroughly considered by the members of the present Bethesda Conference and it is anticipated that a core curriculum and an examination in interpretation may be recommended for the purpose of qualification.

Another important subject to be addressed by Conference participants is computer applications in electrocardiography. Computers will be the primary subject of one specific task force, and various aspects of their utilization will be considered by all of the other task forces. My view is that computerized electrocardiographic interpretation has yet to prove itself for routine clinical use. It appears that a person highly interested in these techniques tends to become more of a computer programmer than an electrocardiographer. Computer-aided electrocardiographic analysis may have an important role in certain circumstances, but most investigators emphasize the need for final physician review. Computer systems may approach reasonable accuracy in identifying normal electrocardiograms, but they lack precision in interpretating abnormal configurations, and arrhythmia diagnosis seems to be particularly difficult. Efforts devoted to monitoring programs appear to be more clinically practical at present. However, this is a highly charged topic and there are authorities present who report remarkable success with computerized electrocardiography. The final position paper will be studied with considerable interest.

Finally, I will conclude my remarks on a personal note by paying tribute to the memory of a revered person in my early medical life. This cardiologist, Dr. Robert P. Grant, is well recalled by everyone as the highly effective director of the National Heart Institute in 1965. I remember him most for his kind attention to me in the summer months of the mid-1950's when I was a medical student working at the Institute in Bethesda. He arranged his limited time so that we could meet each day for scheduled teaching periods, during which I was the fortunate recipient of his personal instruction in the concept he introduced of spatial vector electrocardiography. He was a stimulating educator and the first nationally known cardiologist who took a special interest in me. I am deeply grateful for the invaluable experiences with him, and I still have my notebook of those enlightening sessions. Certainly he would be here with us today if it were not for his untimely death.

First the Electrocardiogram—Then What?

A System for Decision-Making by Computer

HOMER R. WARNER, MD, PhD

Electrocardiography has been the proving ground for many of the basic concepts of medical decision-making by computer. This paper describes a system in which these concepts have been generalized for application to the whole field of medical practice.

The HELP system[1] of computerized medical decision-making has been designed to provide the physician with processed information that will assist him in his role as decision-maker. When a system that has access to current medical knowledge in the form of criteria for making deductions and drawing conclusions from observations is coupled to a file containing data on a patient, it can go beyond the task of retrieving and reformatting data. It can help the physician make appropriate diagnostic, prognostic and therapeutic decisions. Decision-making represents the primary role of the physician, and he must bring to this task an ever-growing body of medical knowledge. This rapid increase in new medical knowledge has led to increasing specialization on the one hand and frustration of the generalist on the other. The HELP system is designed to provide consultation based on current medical knowledge to the specialist caring for a patient who has problems outside his special area of expertise and to the generalist who is faced with a problem he may not recognize or a situation in which he lacks experience. Because the system reacts automatically to each new data entry by examining new data in the context of all pertinent previous data on this patient according to rules specified by the medical logic stored in the form of decision criteria, the appropriate medical knowledge will always be promptly brought to bear on each patient's problem. When new knowledge is acquired an additional modification can easily be made to the appropriate component of the system and that new knowledge will automatically be applied to the solution of each patient's problem from that moment on.

Design of HELP System

The basic design considerations of the HELP system and the hypotheses upon which these design features are predicated are shown below.

1. Because experience both in our hospital and elsewhere has shown that it is difficult to entice a physician to enter information into a computer, the HELP system is designed to acquire most of its information about a patient automatically or through paramedical persons. It is designed to make the physician the recipient of information primarily and only in special instances the provider of data.

2. Because the most common type of decision error in medicine is the result of a failure to consider the proper decision, the HELP system is designed to be data-driven. This means that each time a new item of information is added to a patient's file any decisions that make use of that information are automatically processed at that time.

3. Because decision logic is not static over time but changes as new medical knowledge is acquired, logic in the HELP system is stored independently of the computer program that executes it. As new medical knowledge becomes available the decision criteria can be modified without changing any programs in the computer. A common program processes all medical logic and only this common program need be implemented on another computer in order to transfer the medical ware directly.

4. Because the decisions made by the HELP system are to be used in the actual care of patients it is necessary that a physician be responsible for the logic behind each decision. For this reason HELP decisions are expressed in natural language so that a medical expert with no computer experience can generate the logic with enough confidence to assume responsibility for the decisions the computer makes. The decision logic is therefore self-explanatory, which again facilitates transfer of logic developed at one institution to another setting.

5. Because the system is data-driven, the logic for at least one decision is processed almost any time an item of information is entered into any patient's file. It is important, then, that this logic be processed efficiently in order to keep computing costs at a minimum. To accomplish this the natural language source statements representing the medical logic are converted to a tightly coded form ready for efficient processing before they are stored on disc for use by the system. Much effort has gone into this kind of optimization.

6. Because simple approximations to the real logic used by an expert in making subtle decisions will not be accepted in the real world of patient care, the HELP system has been designed to allow the user not only to use sophisticated logical and probabilistic expressions but also to specify complex relations in time sequences among the data required to make a decision. The system, in addition, is hierarchical in order that some decisions may be based on other decisions as well as on raw data to any level desired.

7. Because a very large number of possible decisions might be incorporated in such a system, HELP is designed to be modular so that it can start performing a useful service even with a small subset of its eventual complement of decision logic. This modularity also facilitates division of responsibility for the system logic among experts, each one managing the decisions in his area of expertise. Without this, maintenance of a system with this complexity would become overwhelming.

8. With the rapid advance of medical science, the opinions of experts today may not be considered the best basis for de-

cisions of tomorrow. The HELP system has been designed to provide much of the information needed to improve upon its current decision logic. Thus, there is reason to believe that although decisions made by HELP at the outset are no better than the logic provided by the experts, the system itself can provide data that will form a basis for improved logic in the future.

Source of Data for Decision-Making System

The HELP system incorporating these features has been implemented at the LDS Hospital in Salt Lake City. This is a 550 bed general hospital manned almost exclusively by a staff of 290 specialists in private practice. Of the 150,000 patient records currently in the system, 4,000 are maintained on the active patient disc at all times.

The sources of data for the decision-making system are the following:

1. Each patient on elective admission to the hospital takes a self-administered history while sitting at a terminal.[2] From the answers to these questions HELP decisions are processed on the basis of conditional probabilities to provide the attending physician with a list of suggested diagnoses and the reasons for these suggestions. This procedure and the other components of the screening process are designed to detect secondary problems that may alter patient management because most patients whose physicians use the HELP system are coming into the hospital for elective surgery.

2. *An electrocardiogram* is obtained on each patient during the screening and processed on-line by the computer.[3] The variables extracted by the electrocardiographic program and stored in the patient record are interpreted by the HELP system, both from screening and from signals transmitted from the patient's room over his telephone later in his hospital stay. Comparison of serial electrocardiograms is also made by the HELP system.[4]

3. *Spirometry* is also performed on-line as part of the screening operation. A report of these first three items of information is printed in the screening facility and taken to the ward with the patient.[5]

4. *In the pulmonary function laboratory* several more sophisticated breathing functions, as well as blood gas values, are measured using instruments connected on-line to the computer.[6] Processed data as well as interpretations based on HELP logic are fed back to the technician as part of the quality control process.

5. *In the exercise laboratory* three channels of electrocardiographic information are processed on request from the technician or monitoring cardiologist at various stages of exercise. Signal averaging after rejection of extrasystoles is employed to provide a clean signal for interpretation.[7]

6. *In the cardiovascular laboratory* all hemodynamic data are acquired on-line during the procedure.[8] Left ventricular angiograms are recorded on video disc and then processed by computer to determine left ventricular border coordinates for each frame during a cardiac cycle. A model based on the synchrony of border motion is used to detect areas of abnormal contraction.[9]

7. *The clinical laboratory,* including chemistry, hematology, microbiology and various special procedures, is on-line to a stand-alone laboratory computer system, which in turn interfaces to the HELP system. When these data are verified by each responsible technician, they are transmitted to the HELP system for storage in the patient file. This triggers the processing of any logic that uses that particular data item.

8. *Three files are maintained in the blood bank on each unit of blood*—a donor file, a unit file and a record in the file of the patient who receives the unit of blood.

9. *Every prescription sent to the pharmacy* is entered by the pharmacist through a terminal.[10] The computer prints labels, maintains a drug file for each patient and uses HELP to decide whether that prescription is potentially hazardous to the patient in light of his known sensitivities, other drugs he is taking, his kidney function or other variables that might be deduced from laboratory or other data in his file. If an alarm is generated the clinical pharmacist goes to the ward to bring this information to the attention of the responsible physician or nurse.

10. *Demographic information* obtained during the admitting process may be used for certain decisions.

11. *In the record room* additional information, including the discharge diagnosis, is abstracted from the patient's written chart.

12. *Thirty-one intensive care unit and coronary care unit* beds are monitored directly by the computer for a variety of hemodynamic and rhythm measurements and recordings.[11] Observations by the nurse are entered through the terminal in order to provide a computer record that contains all the information needed for patient care.

13. *Finally, there are terminals on all 31 nursing stations* which are used for entering certain types of information such as increased patient temperatures. However, these terminals are primarily used for reviewing patient data.

Modes of Decision Output to Physician

The decisions made by the HELP system and the data used for these decisions are available to the physician in three modes:

There are four types of routine reports upon which HELP decisions may appear. These include the reports from all of the laboratories, the admissions screening report, the 8 hour shift reports, the cumulative 5 day reports in the intensive and coronary care units and the printed gummed labels attached to the electrocardiograms placed in the chart. A physician may gain access to HELP decisions on his patients through a keyboard TV-type terminal in the doctors' lounge, at each nursing station or in any of the intensive care units. He does this by calling a program that asks him for his code number and then displays a list of patients who are his responsibility. The list of current decisions on any patient may then be examined, as well as the latest data from the sources just described. In addition, from the doctors' lounge or in the intensive care unit, he may obtain a hard copy printout of any of this information.

The third mode of decision output is represented by alerts to the clinical pharmacist in the case of potential adverse drug reactions to a prescription, to a nurse clinician for problems such as an increase in the patient's temperature or laboratory values that indicate several electrolyte disturbances that are not being managed appropriately. In the intensive care unit certain decisions may turn on a red light on the monitoring panel. When a nurse or resident presses that light switch a message describing the alert is displayed on the terminal. Finally, programs are operational that provide the chief of any service with the facility to follow the course of all patients in any category he describes by any logical combination of HELP decisions in the system.

For instance, the chief of pathology is now following up on a day to day basis all patients who have a hypochromic microcytic anemia but who have not undergone a serum iron and iron binding capacity tests.

Illustrative case examples: An example of a HELP sector designed to evaluate the probability that a patient taking the self-administered history has a hiatal hernia as the explanation for his symptoms will serve to illustrate one form decision logic may take in the HELP system (Table I). Items A thru G are variables, each represented by 2 bits in the patient's record. The first bit indicates whether the question was asked and the second whether it was answered "yes." On each question there are delimiters that specify that the last entry of this type of data from 1 month before now until now should be used. Items H thru M specify the parameters of the sequential Bayesean probability estimates to be performed on variables A thru G. The number 14 is the a priori probability expressed as 14 per 1,000 patients in this population being screened who have hiatal hernia. The next two numbers, 570 and 120, in the case of item H represent first the probability of getting a "yes" answer to question A—"Do you have pain made better by milk or antacids?" in patients with hiatal hernia, and the second number, 120, is the expressed frequency per 1,000 "yes" answers to this question given by patients who do not have hiatal hernia. The results of this calculation will become the value for item H and looking at item I item H is then used as the a priori probability in the next stage of the process.

Another type of decision format is shown in Table II. This type not only makes a decision, but also calculates a value that is inserted into the message displayed

TABLE I

to the pharmacist. The top message indicates that the patient is receiving potassium therapy both intravenously and orally amounting to a total of____ milliequivalents daily; daily monitoring of serum potassium is suggested. "Inhibit Logic = 5" simply states "Do not print this message if sector 5 is true." (Sector 5 decides if the patient already has hyperkalemia.) Item A prescribes a search of the patient's file for a data field indicating that he is currently receiving potassium replacements intravenously. The GET statement requests the dose (D) multiplied by 24 and divided by (E), the number of hours between doses. This will be the amount of potassium received by the patient in a 24 hour period and will become the value of item A. It will be taken from the *last* field in the time interval specified by 2 months before now and 24 hours before now. Items B and C are identical except for the route, which is, respectively, intravenous drip and oral. Item D is an exit statement that essentially says that if neither A nor B is found in addition to C, do not continue the calculation. Item E calculates the total dose of potassium received by all routes in a 24 hour period. Item F causes the program to exit if the total dose is less than 60 mEq/day. Item G searches for a serum potassium measurement in the last 24 hours and item I for a measurement sometime in the last 48 hours. If potassium has not been measured for 24 hours and the measurement the preceding day showed a value of more than 4 mEq/liter the sector is true, and a message suggesting monitoring for the potassium level will be printed.

STRATO Program

To facilitate the research needed to improve the decision logic of the HELP system a program called STRATO has been developed. With this system a user can create HELP sectors that can then be used to generate subpopulations that fill the criteria of these HELP sectors. For instance, subpopulation 1 might be those patients who had left ventricular angiograms performed before a bypass graft was placed in the anterior descending coronary artery and whose graft was patent 6 months postoperatively while subpopulation 2 filled the same criteria except that the grafts were not functional on follow-up study. A third sector may then be created to define a variable such as that describing left ventricular wall motion in the area supplied by the left anterior descending artery before surgery. The distribution of values for this variable can then be compared in patients from the two populations and the results used to define new decision logic for assisting the physician in choosing patients for this operation in the future.

Clinical Implications

What does the future hold for a system like HELP?

Public pressure is demanding quality assurance and cost control in medicine, and government is responding. The physician dislikes auditing his colleagues. HELP and its counterparts provide a means for providing quality review while corrective measures are still possible for the patient. A system of prompters, probably with a human intermediary such as a nurse-clinician, will prompt the physician when the situation calls for it.

Experience already has shown that such prompting is acceptable only if the evidence for suggesting a particular course of action is convincing. Because much of what we do is based on anecdotes and personal opinion, honest differences exist. Where variations in management plans are not based on scientific evidence, consideration of cost alone may be the appropriate deciding factor.

The ability of HELP to generate data for analysis of medical practice may prove to be its most valuable feature. The accuracy of such data will be enhanced as the decisions made from these data become an integral part of the care of the patients involved. Thus a positive feedback situation is created in which dependence on and utilization of the system by the responsible decision-maker leads to insistence on improved accuracy of data, which in turn facilitates improvement in the analyses done to derive an improved logical criteria for future decisions—and this improvement and verification of decision criteria will influence the physician to place even more confidence in the system.

Indeed, electrocardiographers set a powerful new force in motion when they first used the computer to make interpretations. They should, therefore, assume some of the responsibility for directing the use of this tool into productive channels that will work for the long-range benefit of all patients.

Electrocardiography and Electrophysiology Are (or Should Be) Friends

HARRY A. FOZZARD, MD, FACC

My purpose is to emphasize that electrocardiography is an application of the well developed scientific discipline of electrophysiology. Because the science of electrophysiology is healthy and growing, we must expect change in our understanding and use of the electrocardiogram. Therefore we must define the latter quantitatively so that it can be kept in step with its science. A second factor that impels me to speak for quantitation in electrocardiography is responsibility to our patients. The electrocardiogram has become such a widespread clinical tool that it has a great potential for good or for harm. We can guarantee its proper use only if we define it.

Origins of the Electrocardiogram

Early in their study of electricity, physicists recognized that it played an important role in biologic events. Not only did electric shocks cause responses in such tissue as muscle, but the muscle itself generated electric currents. During those halcyon days when physicians and physiologists belonged to the same union, the cardiac electrogram was identified by men such as Waller, Burdon-Sanderson and Bayliss. But the great step forward occurred when Einthoven developed a reliable and practical recorder—the string galvonometer. In an obituary for Einthoven, A. V. Hill[1] stated, "Einthoven, *in spite* of his medical training and his office, was essentially a physicist, emphasizing the way in which an aptitude, in Einthoven's case a genius for physical methods, can aid in the solution of physiological problems."

There has been a long and productive exchange between the hard sciences and medicine, with traffic in both directions. I see no reason for it to end. Certainly the development of amplifiers is unlikely to be the pinnacle of scientific contribution to this field.

The Empirical Phase

With the availability of the tool, physicians rapidly began to correlate the electrocardiographic signals with human disease, as in the excellent book by Thomas Lewis.[2] This was a necessary developmental step, but the application of the electrocardiogram soon outran the available understanding of cardiac science. Responsible physicians used the electrocardiogram in spite of the scientific lag, but often found themselves in the realm of science fiction. This empirical use of the electrocardiogram reached its zenith for me when Schaeffer and Haas[3] stated in 1962 that the only justification for the study of the electrocardiogram is its clinical application.

This empirical phase has its giants. I can mention only those I have known personally, and they can stand as examples of the best of this phase. The trio at Michael Reese Hospital—Katz, Langendorf and Pick[4]—have brought a powerful intuition to bear on the electrocardiogram, pointing the way for a generation of electrophysiologists.

Three areas in which electrocardiography has paved the way for physiologic advances are:

1. *Heart muscle as an electrical syncytium.* For years, the evidence for electrical coupling between cells of the heart was obvious from electrocardiographic studies. Only in the last 10 to 15 years have cell physiologists begun to recognize and explore the nature of the gap junction.

2. *Calcium channel* as the basis for excitability in the atrioventricular (A-V) node and other tissues. Although electrocardiographic evidence that the A-V node had a different excitability and conduction mechanism from the rest of heart muscle was overwhelming from the time of Wenckebach and Mobitz, every effort was made to force the A-V node into the "sodium hypothesis." Now we see what should have been obvious, that the inward current system in the A-V node, and perhaps in the sinoatrial (S-A) node, is quite different and depends partly on calcium current.

3. *Accumulation and overdrive suppression.* The influence of a rapid firing rate on subsequent pacemaker rates was clear early in electrocardiography. This has led to the discovery of zones of limited diffusion, near cells, where accumulation and depletion can occur; in this case, accumulation is responsible for overdrive suppression in both the heart and the brain.

Cell Electrophysiology

As the field of electrophysiology recovered from World War II, it prepared for a scientific revolution. With the foundations laid by K. C. Cole,[5] Hodgkin and Huxley showed the ionic basis of the nerve action po-

tential. Armed with the tool of the glass ultramicropipette, cardiac electrophysiologists began to sort out the electrical properties of heart muscle. In spite of warnings from his mentor, Silvio Weidmann began the new era of quantitative cardiac cell electrophysiology with his studies of the Purkinje fiber. After arriving in the United States, Hans Hecht[7] began his work in Utah.

In general, clinicians have contributed little direct effort to this new field. In the "quiet" of laboratories in Brooklyn, Bern, Utica and elsewhere, a scientific foundation for proper understanding of the electrocardiogram has been built, thus contributing greatly to the general field of cell physiology.[8]

Three areas in which cell electrophysiology has contributed to electrocardiography are:

1. *The Hodgkin-Huxley concept.* Hodgkin and Huxley demonstrated the ionic basis of the action potential, with time- and voltage-dependent membrane conductances. These ideas were applied to the heart by Weidmann and many others and demonstrated, for example, the central role of the resting potential in excitability and conduction.

2. *Pacemaker phenomena.* The characteristics of spontaneous discharge have been demonstrated and great progress has been made in understanding of the membrane events responsible for pacemaker activity. The processes involved in pacemaker events have contributed greatly to our interpretation of rhythm disturbances.

3. *Excitation-contraction coupling.* The key role of membrane voltage in turning on or modifying contraction has emerged from studies of potassium contractures and voltage clamps. It is now clear that the action potential shape and firing pattern determine the size of contraction of heart muscle. We are only beginning to recognize the electrocardiographic changes associated with these electric cell events.

Merging of Electrocardiography and Electrophysiology

As the science overtakes the clinical use of the electrocardiogram we will have an exchange between the fields that will be to the benefit of both. *Possible areas of future growth include:*

1. *The role of cell to cell coupling in S-T segment changes and arrhythmias.* We are learning that the gap junctions can rectify. Further, they may change their properties with an increase in cell sodium or calcium or administration of digitalis.

2. *The relation between regional QRS and repolarization currents to contraction.* Knowing that the membrane voltage controls contraction opens up the possibility of electric interactions.

3. *The mechanism of action of a wide range of drugs and hormones.* Day by day our treatment of arrhythmias is becoming more effective and rational through cooperative basic and clinical studies.

The Computer

Nothing is inherently more boring than scanning routine electrocardiograms. I have read perhaps 100,000 tracings, and this number is no doubt small for an active cardiologist. No important case can be made that creative electrocardiographic thinking is directly correlated with simple numbers of tracings read. A machine may assume the bulk of this burden now, but it is fair to ask if it will prevent future progress by cutting us off from our roots. I will argue the opposite. If we use the computer correctly, by defining carefully what it does, it can be a great stimulus to electrocardiographic research. The definition of its task will be to permit growth of our understanding, not to maintain the status quo.

Present Status of Computer Interpretation of the Electrocardiogram: A 20 Year Overview

CESAR A. CACERES, MD, FACC

The basic questions regarding health care viewed as a societal issue refer to costs, quality and accessibility. It is difficult to review the whole field. But it is possible to take one small area in which these three questions can be looked at and perhaps answered. Current results tend to suggest that computer electrocardiography can serve as a model for technology's capability in health and medicine and provide insight into use of other technologic aids in medicine. That was, incidentally, the primary goal of my group in the Heart Disease Control Program of the Public Health Service back in the late 1950's,[1–2] when work on computer electrocardiography began.

There has been a 20 year well documented development in computer electrocardiography with relatively complete feedback after a feedforward time period.[3] It is now possible to review the experiences in many centers and to identify whether or how introduction of a technologic innovation has affected cost, quality and accessibility of health care.

To gain insight our analysis must be a medical analysis as well as one in medical economics.[4] It may also have to deal with public policy on health care.[5] The analysis must substantiate whether after 2 decades health planners, developers, scientists, physicians (and perhaps patients) have formed general opinions on computer electrocardiography.[6] We must identify whether we can, from them, define the pertinent questions regarding advantages and disadvantages and reasons for use and nonuse of this tool. From such an analysis we may arrive at a description of the present status of computer electrocardiography and also make recommendations for the future.

Basic Questions

This presentation is confined to an indication of some of the limitations and advantages of computer electrocardiography as I view them looking back over the 20 years since I entered this field. An excellent technical review in this conference by Rautaharju et al.[7] well summarizes other areas. Computer electrocardiography is only a part of this Bethesda Conference on "Optimal Electrocardiography." The real question, as I see it, is how many practitioners recognize computer electrocardiography as an integral part of optimal electrocardiography in the 1970's and beyond?

Electrocardiography is the brainchild of the first systems analyst in the medical field—a physicist turned engineer integrating work previously done in the biologic area with the modern technologic advantages of the communications field, photography and motor drive systems available in the first 5 years of this century. Computers and other newer electronic components have now been added to that technologic complex to allow routine analysis of the wave forms in order to make interpretations. The basic question is whether the introduction of modern technology to the technology of the early 1900's has had a significant impact on patient care.

A recent editorial[8] asked some basic questions, such as whether expenditure of funds on computerization of electrocardiography has reduced inaccuracies in electrocardiograms caused by errors in recording, mounting and reporting. It asked as well whether computerization could aid in validating electrocardiographic results. The first three operational points are easily and quickly answered in a positive manner.

A computer can write or signal significant recording errors to the technician. There is only a minute chance that a computer printout and its electrocardiographic tracing can be mismounted. Additionally, most of the modern commercially available systems have built-in reporting systems that facilitate return of interpretation in seconds to minutes. These attributes, although not clinical, are highly significant to patient care. I am not currently aware of any noncomputer electrocardiographic processing system that can routinely compete with computer electrocardiographic systems in terms of decreasing technician error, mismounting or increasing productivity. At the same time unit costs for these functions with a computer system are lower than those of current manual systems. Yes, more hard data are necessary, but no documented study appears to be available that shows a contrary view. We do not delve too much into those areas when we train students, yet those attributes focus directly on costs, quality and accessibility—today's real medical-societal issues.

The physician must recognize operational attributes as being not less important than the electrocardiographic interpretation itself. In Washington, D. C., as in other areas, third party carriers may pay for the electrocardiographic recording separately from its interpretation. They have properly assessed each component as of identical value. We should not therefore concern ourselves with quality of interpretation as the sole factor for computer electrocardiographic use.

Management and operational attributes have been ignored, in many instances, and systems have not been placed in use because some physicians have looked only at the interpretative side. In such instances physicians may be overlooking part of their responsibility to overall patient care. If half the medical-societal problem is improved, even with the least helpful interpretative program, automation may have overall benefit. It is

necessary to stress a total system concept and to ascribe correct values to each component.

Repeatability of a Computer Answer

The current repeatability (or lack thereof) of diagnosis by the computer using any lead system (or the human being) is much influenced by the fact that in practice the cut-off criteria in electrocardiographic diagnosis are like cliffs. If the R wave amplitude is 1.2 mv, for example, in lead aVL and if we follow certain criteria, we may say that the electrocardiogram is positive for left ventricular hypertrophy. A deep breath in or a deep breath out makes all the difference in the world when such criteria are used. In such instances, a computer analysis, sometimes because of its precision, may not be repeatable, because our textbook criteria have not included considerations of probability (absent as well in all medical school electrocardiographic classes as far as I can determine).

Why is a heart rate of 100 beats/min significant and why is one of 90 beats/min often given little importance? One must consider heart rates, for example, in a population as an increasing slope, and a person's position on that slope has a different probability of abnormality at every level. That is true for any other measurement. We are after accuracy and not precision in medical diagnosis, but our criteria give us only rules for precision—which computers follow better than human beings and are therefore sometimes in error. This suggests that computers need better determination of the ranges we consider "normal." Diagnosticians also need such data. Computers may, as an aside to their basic purpose, help us to obtain what we need.

Computer Analysis in Determination of Standards and "Normal" Ranges

The ultimate purpose of obtaining medical data is to describe the indicators of each stage of disease in a patient so that they can be predictive and lead to prevention of morbidity and mortality in a disease process. Every patient who leaves the hospital with a "healed" myocardial infarction represents a failure or gap in the science of medicine because the infarction was not averted. A basic reason for computer studies is to develop more precise logic so that we can place all possible obstacles in the pathway of disease, even at the earliest stages. This implies that our simple conventional means of separating normal from abnormal is crude. We must obtain numerical values for thresholds all along the course of disease progression. With every change in subject or patient status we should ask the question of where to set "milestone" and "predictive" thresholds.

Toward this end we have been collecting electrocardiographic data from several populations for the last several years, to begin to define various groups by signal data. We have used the electrocardiogram as a model signal. We infer that what we have observed is equally applicable to other medical data.

I can give a summary of impressions. Although we have processed several hundred thousand electrocardiograms, and others have now processed millions, relatively few records have been statistically tabulated, and relevant subclassifications are not available. At present, I can only discuss the general overview of distributions and characteristics of electrocardiographic measurements. However, from the overview of what is still relatively minimal population data we can see that we can begin to gain insight as to what to look for in the specific person.

Electrocardiographic Criteria and Computers

From current computer electrocardiographic data we know that at age 20 to 30 years, 25 percent of persons can be expected to have questionable findings. At age 50 to 60 years, the percentage is about 35; after age 70, it is 51 or more. These observations suggest that the time for a test is not after age 40 or 50 or at the time of a heart attack, but well before age 20, and that repetitive testing is necessary if we are to try to prevent disease.

Consider a group of young teenage boys who have high values for QRS voltage, similar to those meeting the criteria for left ventricular hypertropy. Can we find those boys who do have left ventricular hypertrophy? To determine that a questionable finding exists, a physician generally looks subjectively at levels of measurement. From the conglomerate of those observations, he subsequently determines that there is an atypical, borderline or abnormal situation. The suspicion of abnormality evolves from syndromes of data. When we try to have a computer duplicate physician procedures, we quickly learn that these procedures must be precisely defined. This can be done if we obtain accurate data and clearly tabulate and weight the data that bear on the syndrome.

How can we conclude that a person has a normal heart? If we review data from nonhospitalized ambulatory presumably normal persons and in-hospital populations and tabulate distributions it becomes evident that both hospitalized and nonhospitalized ambulatory subjects have similar value distributions for many measurements. To classify a patient as normal or nonnormal the basic question is, "Is location within the distributions significant as a predictive threshold for disease or possible disease?" In hospitalized groups higher values, such as increased duration of the QRS complex, are clearly related to disease entities. The next question is, "Should the 'normal' population in the portion of the distribution with similar high values be followed up and considered as possibly falling into the same disease categories?"

For another electrocardiographic measurement, the P-R interval, both low and high values in the distribution are associated with abnormality, and the question is, "Where should we set the values for predictive thresholds?" Generally, the P-R interval is considered diagnostic at 0.2 second. This criterion encompasses the upper 5 percent of the population. But are we defining only the classic case and missing the person with a developing trend to the abnormal determination?

Among 25,000 subjects in our studies, 25 percent had Q waves in lead II. Standard practice asks us only to look for a Q wave of a certain width before considering it so we miss what is perhaps an important question, "Is the

very presence of a Q wave of significance and should it have some weight as a predictor of heart disease?" Among the 25 percent that had Q waves it was the hospitalized subjects who tended to have Q waves of greater amplitude.

Should we continue to set cut-off values in our criteria so that only the upper or lower percentile values are used in medical judgments? This seems to be what we now teach medical students. These analyses suggest that varied weighting must be given to each value and each signal. The value of the generally used two dimensional concept of normality and abnormality is limited and will become increasingly limited as computer use continues. Because we are capable of making distinction as to placement within a distribution with computer use, we should do so. We may find that "normality" as distinct from "abnormality" does not exist.

Electrocardiographic Results

A computer system does make mistakes, but any of its results can be validated in an objective manner. Validation of criteria with postmortem findings is often suggested. This is not very practical because most electrocardiograms, for therapeutic use, are taken long before such terminal events. Postmortem study is an ancillary but not necessarily a definitive criterion except in certain circumstances and it should be considered equal in value to an angiogram, a cardiac catheterization or a biochemical determination, all of which should be used for continuing feedback to alter the criteria in computer (and human) programs.

A computer can agree with a criterion set by a panel of cardiologists or one based on cases diagnosed with other means. If computer system error data are contrasted to data on human observer variability it becomes apparent that the computer can help in stabilizing human decisions based on their electrocardiographic interpretations. This is important. Such stabilization can be expected to aid in validating electrocardiographic results.

Computer agreement with a panel of cardiologists (and this really means with textbook criteria, not with the physicians themselves) is perhaps the most usual way of validating results. But past experience shows that once a computer has interpreted an electrocardiogram on the basis of any defined criteria, the computer program designers rapidly receive feedback from those who have other data from other sources. I dare say that data on electrocardiographic criteria and clinical correlation may be far more complete at any large "commercial" electrocardiographic processor's office than in any single academic heart station.

It should be stressed that there is no reason why a computer cannot provide two sets of answers, or more if desired, based on entirely different criteria or lead systems. There is no need for an "either-or" decision, although that is current practice in commercially available programs. I hope that this statement will stimulate that sort of computer output—not to find out which are the better criteria or lead systems but to discover complementary characteristics.

The need for an objective electrocardiographic measurement data pool, as suggested at the onset of computer electrocardiography,[9] still exists. Unfortunately, there has been too much effort and expenditure on studies to determine which program does what best and not enough on studies for constructive changes to the electrocardiographic criteria that physicians use or should use, which could then be easily emulated, and added to, by any or all existing computer electrocardiographic programs.

Computer-Caused Disease?

Some complain because a computer can make a diagnosis (based on real data) that human physicians sometimes omit. In one study with computer electrocardiograms in parallel, physicians based their medical decisions on their electrocardiographic readings and other clinical data, as opposed to the computer's strict follow-up of its preprogrammed electrocardiographic criteria.[10] It became evident that misclassification of subjects was more prevalent among the physician readers of electrocardiograms. Five years later the patients classified by the computer as probably having had cardiac morbidity before the start of the study (and in whom the physicians ignored the computer results) had a statistically significant greater incidence of new episodes of cardiac disease.

The ideas of the 1940's and 1950's about "miseries of heart disease of electrocardiographic origin" are interesting but perhaps should be considered folklore in a day when patients are rapidly and correctly becoming well educated about many of their illnesses. It is necessary, in many clinical instances, to have patients know of aberrations in such detail that they understand the exact meanings of such findings and the problems they may induce. We must explain to patients that there are findings that are atypical and in upper percentile groups electrocardiographically. Patients of the 1970's can well understand the problems of their electrocardiogram if their physician understands and can explain them.

The Problem of Use and Nonuse

The closing paragraph of a Lancet editorial[8] on computer electrocardiography observes that the same mistakes are made over and over again. Unfortunately, the editorial rests its case by suggesting that the European community apparently repeats the mistakes made in the United States by emphasizing efforts to develop standards for evaluating computer programs. The widespread demand for computer electrocardiography has already attracted sufficient suppliers who will adhere strictly (for solid business reasons) to whatever standards are agreed upon for interpretation of tracings *by human beings*. Why evaluate computers first? They will duplicate whatever it is that we wish a human being to do—and then help him to improve that performance!

The clinical limitations of computer-processed electrocardiograms have been studied.[11] Not withstanding these, one can be quite happy that documentation now available shows that the arguments used in 1957 and 1958 to stimulate development of the pioneer system projects were valid. Further, computerization has shown

itself to be a valid answer to clinical as well as medical-societal problems.[4,12]

Recent cost analyses confirm what was postulated from the beginning—for example, that computer electrocardiographic systems can solve some economic problems of concern and thus can be a model for use of other technology in medicine.[12,13] Unfortunately, the government seems to be oblivious of the existence of the model as such, even though it has paid for studies that prove its existence. Recognition of this model for what it is is necessary to maximize its effectiveness. For this reason it is now time for the important bodies that control electrocardiography to recognize the basic user-oriented problems in the field of computer electrocardiography and to implement solutions rather than hedge about the problems.

Can the computer programs solve daily problems in terms of cost, quality and accessibility? The answer, based on the documented literature, is yes. But the utilization of these systems is still small, in contrast to the volume of the ordinary electrocardiogram. We must ask ourselves why growth has been slow and why there has been little acceptance in many medical circles. Three entities stand out, each represented in this room today, as the cause of nonuse. It is time that they were singled out. Industry and many in private sectors have done their part. However, major teaching institutions, government health agencies and professional societies have been waiting in the wings. That should not be their role.

The Academic Institution's Need to Face Grass Roots Problems

A recent request for a proposal from the National Heart, Lung, and Blood Institute is a good example of the problems that must be faced by those concerned with a real-life need to improve quality, decrease costs and increase accessibility of medical care. The proposal is for an electrocardiographic center in a trial secondary prevention program to combat coronary heart disease. One realizes the problems in the use of technology in medicine when a center for advanced research and teaching, such as the National Institutes of Health, considers "one channel ECG recording equipment" "standard" and at the same time considers that "quality control" exists when each electrocardiogram is coded by two coders with "intercoder differences of interpretation . . . adjudicated by the principal investigator or his designate."[14]

Twenty years after computer electrocardiography was considered and developed (outside of the National Institutes of Health), the Institutes still seem stunned by it[15–17] and have moved at a snail's pace into the modern technologic electrocardiographic era. Their sponsored research has therefore been tainted by the fact that their own researchers and those that must bid on their contracts or grants have been deprived or must deprive themselves of higher quality tools and use uneconomic machinery. One could perhaps cite studies that have cost millions and whose results might be adversely influenced by the use of outdated electrocardiographic systems. Yet criticism has been heaped on the pioneer Public Health Service program by academicians at the National Institutes of Health who have not used it and apparently want the world to wait until they develop a better program.[15–17] It is time for parochialism to be brought out into the open, not in a derogatory sense, but to ensure that research institutions understand their role properly.

Until advanced teaching and research centers become intimate with currently available technology it will be impossible, on a broad grass roots scale, to diminish costs, improve quality or make medical care more available. These centers need rapidly to learn about today's cost-reducing technology to be capable of teaching others correct and noncorrect use of technology.

The Need for a Role of Government in Technologic Change

The job of the government is to coordinate, to look at the medical planning aspects of health, to provide guidelines for cost, quality and availability and not, as we increasingly hear from some in government, to complain that practicing physicians are not providing these services. We have seen several government-sponsored studies in the area of computer electrocardiography. They are all good.[4,5,12] However, although almost a decade has gone by, the results and suggestions in those reports have not been implemented. Government officials planning health care are somewhat to blame. One former official in high office, for example, recently wanted to see proof that technology can reduce expenditures for health care but would not spend time discussing even the reports his department funded, much less fund analytical reviews of them to further understanding of potential benefits.

If one uses documented and some government-funded data, one can surmise that there is an average savings in a computerized electrocardiographic system of at least 25 cents a tracing[4,12,13]; the last year has cost our patients some $20 million through noncomputer use. What explanation can health planners in government give for, effectively, the waste of $200 million in the last decade? Is the government really concerned with cost? Is it itself responsible for higher costs by its nonintroduction of cost-reducing technologic measures?

A philosophizing government health planner may tell us that the purchase of electronic equipment is a significant cost. However, $20 million saved in 1 year of computerized electrocardiography could, at present prices, purchase 200 systems for computerized electrocardiography. Modestly, 200 systems, each processing one electrocardiogram a minute (very slow indeed) could process 105 million electrocardiograms a year. We perform only 80 million electrocardiograms a year in the United States. What is wrong with the government economist? The savings in 1 year alone are sufficient to purchase the hardware needed to do the entire nation's job. Yes, coordination would be required to solve problems of implementation and that implies costs, but that's what we already pay the civil servant for. In any event, the basic arithmetic is simple.

The Need for Professional Society Stimulus

The professional society, too, may have ignored some of its responsibility. From the standpoint of the professional society, the views of its members individually or as a group are not in themselves very important. The professional society, because it is not a union, must answer to the public and not to its members. Therefore, the society has to ask itself, "Why aren't we emphasizing the proper utilization of cost-reducing techniques using computers if they can, as the data indicate for computer electrocardiography, improve turn-around time and increase available services (particularly in small hospitals) in the emergency rooms and in rural areas?"

Various professional societies gladly accept exhibit fees from electronics manufacturers, including those that process electrocardiograms by computer, but some associations have been otherwise inactive in this area. The American College of Cardiology sponsored sessions in computer electrocardiography for several years. That was not endorsement but it aroused interest and provided momentum for people to do research and for industry to see what could be done; it also initiated, to a great extent, user trials. I am pleased that the College has again renewed its interest in this model field for use of technology in medicine.

The Professional's Responsibility

Some suggest that cardiologists are expressing their own fears by not using computer electrocardiography. Is there fear that a machine can take over? The question has to be raised whether the answer is positive or negative. I don't particularly care if anyone answers it or not so long as it is brought out into the open.

The new automated radiographic head scanners have not replaced the neurologist; indeed they have increased demands for their services, but at the same time the length and cost of hospitalization for neurologic diagnostic procedures have decreased and the risk to patients from angiography, lumbar puncture and pneumoencephalographic procedures has been reduced. I have not seen the automated blood analyzer displace pathologists—it may even have increased their income; at the same time, unit costs have decreased for their patients and accessibility to more precise tests has increased.

Were the automated blood chemistry analyzers always as good as they are now? Have there not been serious errors in early versions of every medical product—capably circumvented by the wise user thereof? Why is the cardiologist afraid? Is it concern about income? Is it fear of displacement? Is it really considerations of quality?

Conclusion

The basic documentation is in. We should not, I believe, do more studies. We should not wait another 20 years and lose the $20 million a year in patient savings with computerized electrocardiography, lose 60 percent of cardiologists' time spent in reading electrocardiograms[18] or lose half of the time of the clerical services in the heart station, and continue to have inconsistent, unstandardized answers with the observer variability that is common to all of us.[19] A logician once said it was worthwhile pointing out faults if they are correctable. I have highlighted in my overview what I think are faults, but I do so only because of faith that the academic institution, the government, the professional society and the cardiologist will correct the existing faults for the benefit of the patient.

The Quest for Optimal Electrocardiography

LEO G. HORAN, MD, FACC

For in the study of nature the human mind may really approximate that god-like objectivity which it fondly, but erroneously, imagines itself to possess when it studies the facts of human history. In the field of history it is no pure mind which observes the facts, but an anxious reason, organically related to an anxious ego, reacting with pity or scorn, with fear or pride, to the greatness or the weakness, to the promised support or the threatened peril, of this or that competitive expression of human vitality.

—Niebuhr[1]

There is a distinct hazard that, in attempting to interpret history, we will discover only the fruits of the biases we brought initially to such study. Nevertheless, we need to look at the past both to understand the present and to plan for the future. Mindful equally of the hazard and of the need, let us look briefly at the history of electrocardiography and then examine three topics related to the quest of this Bethesda Conference: the nature of electrocardiography, the ingredient of human engagement in human enterprise and the identification of the optimum or the best.

Nature of Electrocardiography As Seen in Its Development

To determine the scientific basis for a clinical practice is a relatively straightforward undertaking, but to trace the scientific origins of any clinical advance is a nearly impossible task. Recently, however, Comroe and Dripps[2] published a careful and scholarly examination of the scientific history of 10 major advances in cardiovascular and pulmonary medicine since the 1940's. They found that 137 different scientific fields formed the necessary background and that more than 2,500 significant events or publications contributed to the development of these fields. More than 500 articles (1 of 5) were called key in that they were essential to subsequent development and eventual clinical application. I have derived Figure 1 from their tabulation of the events and publications in the development of electrocardiography. The labeled steps correspond to Comroe and Dripps' assessment that they were key to subsequent clinical advance.

The background leading to electrocardiography has passed through successive but overlapping phases: the era of electricity, the era of bioelectricity (differentiating into cardiac electricity) and the era of cardiac electrical sequence. First, electricity in nature had to be identified, and an instrumental means of reproducing it on demand had to be devised. Next came the successive concepts of electrically active tissues, the relation of muscle contraction to electrical discharge, cardiac action currents and the systolic refractory period. Then, as the actual recording of the electrocardiogram in animals and man passed through instrumental refinement, there simultaneously proceeded the serial discovery of anatomically distinct cardiac tissues: Purkinje fibers, atrioventricular bundle, atrioventricular node and sinoatrial node. The recording apparatus and the anatomic-physiologic identifications were necessary to begin the study of the excitation and recovery sequences. Study of the normal sequences began to lead to expectations for surface electrocardiographic wave forms. These expectations became generalizable in the vector concept of Wilson and, from these expectations, diagnostic clues concerning orientation, chamber size, myocardial gain (hypertrophy), myocardial loss (infarction) and altered recovery emerged. From the study of abnormal sequences the foundations of arrhythmia analysis were laid. And as each successive layer of knowledge accumulated and the more exquisite detail of recording and interpretation appeared, our understanding of cardiac electrical activity grew and became more complex.[3–6]

Three messages may be derived from consideration of the data in the diagram in Figure 1: (1) The worth and development of each discovery depends upon preceding and succeeding contributions of others. To the events not labeled is attached an impressive catalog of illustrious names. (2) Only initiating or trigger articles from an extensive volume of published work are indicated; many significant contributions that have fleshed out the body of knowledge of electrocardiography are not even listed. (3) Because of the pragmatic criterion of eventual clinical application, the steps from 1925 onward may soon come under dispute. In this transient view, instruments such as the cathode-ray oscilloscope, the silicon diode and the digital computer are convenient but not yet established as clinically necessary. Similar exquisite knowledge of ion currents in electrically active cells and of cardiac potential distribution over the body is interesting but not yet empirically useful. At any rate the list will be appreciably augmented when reviewed and reassessed in the year 2000 in the light of the then manifest clinical advances in cardiovascular and pulmonary medicine.

Finally, the diagram and the discussion have hinted at the nature of the field called electrocardiography. It is a process rather than a product. This distinction can save us from much anguish whether we consider the field either in its illuminative aspects or in the derivative narrower view of pragmatic diagnostic applicability. Neither diagnostic nor investigative electrocardiogra-

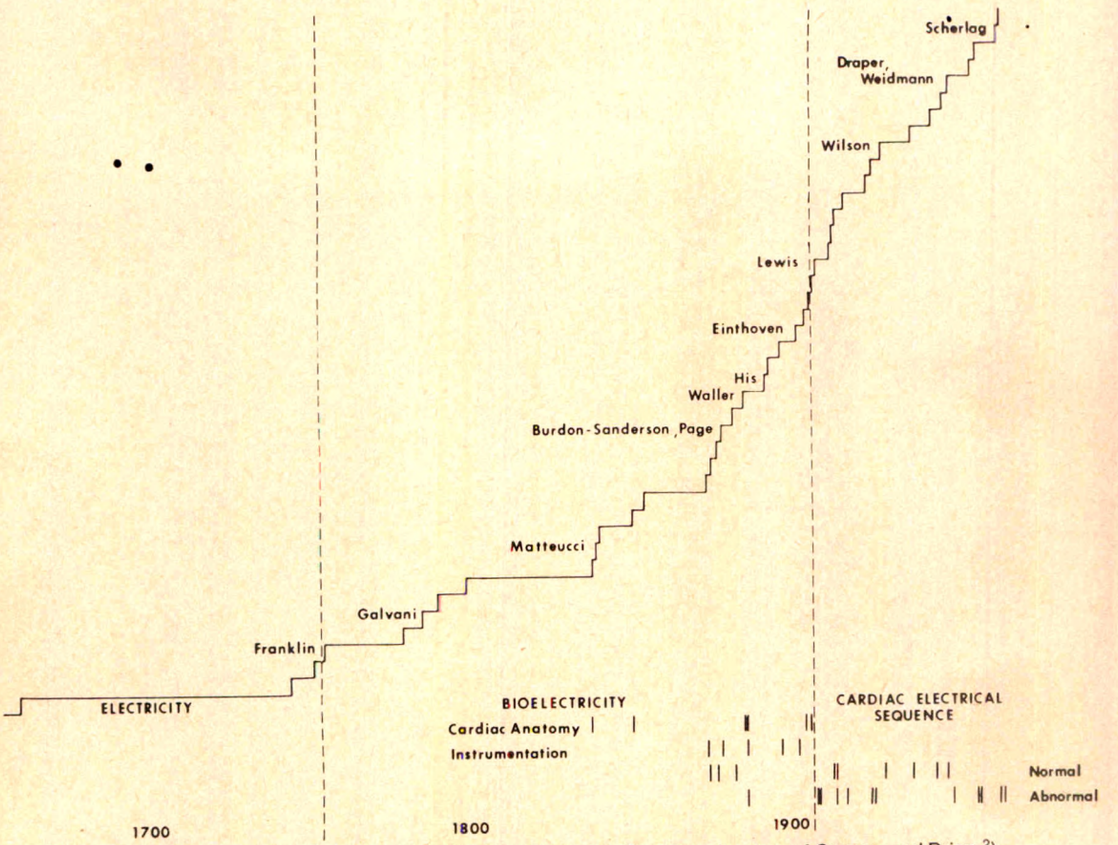

FIGURE 1. Steps in the development of electrocardiography. (Based on the data of Comroe and Dripp.[2])

phy is a product; both are processes. What is the product of each? I think the answer is not—and should not be—neatly forthcoming. For some, the product of diagnostic electrocardiography is an array of scalar wave forms clearly mounted and displayed; for others, the measurements and verbalization describing those wave forms; for still others, both. Further variations as to what actually constitutes the product may include interpretive remarks concerning recognized or suggested categories of abnormality or statements about the probability of their association. Scalar display, description and categorization may be extended to vectorcardiographic counterparts.

The current products of investigative electrocardiography are quite varied in form: His bundle electrograms, body surface potential maps, membrane action potentials—all displayed, described and interpreted in contexts related to their locale and purposes of origin. The great variety of these approaches is significant because each in its individual format yields data rapidly becoming valuable to the clinical electrocardiographer.

Human Engagement in Human Endeavor

Let us turn aside momentarily to examine in analogy the relation between purpose and means in three fields of human enterprise: warfare, biology and medicine. The parallels run in this fashion: The practice of war is a subspecialty of politics and has to do with whether or not one group of men does or does not impose its will upon another group. In war the offensive purpose is to be able to cause the other group to do what we want them to do; the defensive purpose is to prevent the enemy from being able to dictate the manner of daily life to our group. The methodology or strategy requires that the practitioner engage the enemy in battle and destroy his warmaking capacity. Note the phrase "engage the enemy." Bruce Catton[7] points out that the Union cause did not proceed militarily until Lincoln placed in command a general who understood the basic premise of engagement. Let us borrow the term engagement and use it to mean thorough, skillful, wary, energetic and "hands-on" involvement.

By analogy, the practice of biology is an inquiry into the processes of life, and the practice of medicine is the diminution of illness and its sequels. The strategy in biology requires the practitioner to encounter the various life processes wherever they may be found but then to engage them on terrain wherein he can observe them, test them and perhaps even understand or predict them. The strategy in medicine requires that the practitioner encounter the problems and phenomena of human illness and arrange to engage them under conditions where they may be comprehended and altered, attenuated or accepted.

There is a need in any worthwhile human endeavor for substantive engagement. In biology the engagement is with the processes of life; in medicine, with the problems of the sick. In electrocardiography, it is with electrical outpourings of the heart. We have talked thus far largely about the object of engagement rather than the subject. In war if we are to engage the enemy, someone must be trained to do it. The group that depends completely on storing all the information from the last war in libraries, computers or arteriosclerotic generals has made either a vastly incomplete or a vastly unnecessary investment.

In brief, for these three endeavors (war, biology and medicine) the respective purposes are to win (that is, enslave or be free according to viewpoint), to understand or to heal. For each the means are twofold: to engage (the enemy, the processes of life, the problems of illness, respectively) and to apply available knowledge, experience and technical skills—either intrinsic to the endeavor or borrowed from other fields—in order to master the object of the engagement.

From the purposes and strategies of the two major fields of biology and medicine, electrocardiography must draw its value system; from our interpretation of the term optimum we may decide whether the study of the electrical activity of the heart is to be viewed more as a means or as an end. Armed with these brief considerations let us examine the concept of the best.

Identification of the Optimum

Optimum (or optimal) has two basic meanings. The first is that which is most conducive to a given end; the second is that which is the best result under the given circumstances. Thus optimal electrocardiography may describe either the best *means* or the best *result*. This immediately raises the question of whether we consider electrocardiography a means or an end. If a means, a means to what: Is the role of electrocardiography exclusively that of an agent of clinical inquiry? If so, what is the form most likely to lead to the maximal sensitivity, specificity, utility and economy of presentation of evidence? On the other hand, is the art of electrocardiography an end unto itself? Is the study of the electrical activity of the heart complete? Or is it worthy of still more attention and contribution from physicians, physiologists, physicists and engineers? If so, what forms are likely to lead to the deepest insights?

There is an old folktale about the key flower. When a wanderer found and plucked the flower, the hillside opened revealing the entrance to a cave. Inside sat a kobold who welcomed the visitor, "Come in; take all you want, but don't forget the best." With a wave of his hand the elf indicated a vast storehouse of riches: gold, silver, precious gems and lovely works of art. The visitor stuffed his pockets, his sleeves, his socks, his hat; adorned himself with rings, bracelets, necklaces. But each time he started to leave, the elf repeated the injunction "Take all you want but don't forget the best." So the man would rush deeper into the cave exchanging what he carried for something that seemed finer or more precious until at last he felt his survey complete and staggered out. The hillside closed and he began to examine his finds. But his pockets contained dull rocks, dry leaves and the fortune withered before his eyes. He was indignant and turned back. There was no seam in the hillside and no clue of a way back into the cave. He then remembered the flower—that magnificently beautiful but simple key to the hidden store. But it lay prematurely forgotten and now irretrievable somewhere on the floor of the cave.

Examine now with me a random sampling of the many goods that come from or that may arise from electrocardiography. Then let us imitate the wanderer in the legend and nominate which of all these goods is the best of electrocardiography and most worthy of presentation.

1. *Diagnostic signs:* Electrocardiography contains a treasure of well recognized diagnostic clues to structural and functional abnormalities: atrial and ventricular enlargement, myocardial infarction-injury-ischemia, acute electrolyte imbalance, cardioactive drug effect, acute intracranial injury, cardiac conduction defects, simple cardiac arrhythmias.

2. *Monitoring capacity:* The electrocardiogram provides a convenient monitoring device in a variety of states. These range from heart rate and rhythm and S-T segment monitoring during sample days of the patient with unexplained syncope to similar but tethered monitoring of the resting patient in the cornary care unit with a suspected ischemic event or to the exercising patient with suspected limitation of perfusion.

3. *Arrhythmia analysis:* In addition to these two large groups of readily codifiable abnormalities or criteria, the body of electrocardiographic understanding has come to include a distinctive field of arrhythmia analysis. Such analysis cultivates detective-like skills in the clinical observer, causes him to examine the cycle length-coupling interval relation, to search for "motive" and opportunity and to construct and validate from such search clinically appropriate hypotheses as to the immediate problem in impulse formation and conduction.[3] This approach is uniquely human, and not likely to be easily, economically or appropriately imitated by computer programming.

4. *Direct physical evidence in the physician's hands:* Clearly allied to the billions of observations made by human observers that led to codifiable signs and criteria and the hundreds of thousands of analyses that led to the variations on the ladder diagram is a distinctive—almost unique—property of the electrocardiogram on the clinical chart: it is a form of nonverbal communication from the patient's heart to the physician. When properly and systematically recorded it permits the doctor to relate wave form and time relations to the other characteristics of the particular patient. The words and fashions of an impersonal reader may sometimes be contributory but the presence of the raw data provides direct communication and an unblinded reference for future comparison.

The role of the continuing student of electrocardiography in practice has still another aspect. Anyone acquainted with current medical practice is familiar

with the two-edged nature of the laboratory procedure that has left the immediate control and direct examination of the appropriate clinician. On the positive side of the ledger are the advantages of such a transfer: (a) economy from centralization and mass production, (b) the increased likelihood of standarization by increased concentration or volume of production, (c) disinterested interpretation and certification, and (d) the possibility of greater technical quality control by a supervisor not beset by competing clinical, investigative or administrative responsibilities or interests. On the negative side of the ledger are the disadvantages: (a) the previous economy may be offset by the expense of overcoming the problems of misrouting, delay and loss in an extensive communicative network, (b) the psychology of standardization proves a serious obstacle to necessary change in technique as the state of knowledge changes, and (c) the supervisor who is interested only in the statistics and economy of mass production not only resists change but fails to make the key observations from which innovation springs and, even worse, fails to bring previous and current knowledge to bear in interpretation.

5. *The continuing engagement of human intelligence:* Regardless of the acknowledged difficulties with lack of uniformity in readers, the great number of physicians with direct access to and deep interest in the raw material of the electrocardiogram has produced a continuously evolving body of knowledge. I would nominate as one of the great goods of electrocardiography the breadth and intensity of interest that has caused such a flow of information between the basic scientist and clinician. The electrocardiographic clues to electrolyte shifts have predicted ion currents whose study in turn has led to deeper perception of electrocardiographic morphology. The ping-pong from the clinically evolved concept of concealed conduction to the laboratory-evolved concept of the dual A-V nodal pathway to its clinical recognition began a productive interchange that continues to reciprocate between clinic and laboratory. Indeed, the His bundle electrogram daily reminds us of the dynamic fusion between clinical and laboratory observation, characteristic of the history of electrocardiography.

I believe that electrocardiography serves two inextricably linked purposes: the understanding of the biologic processes of the heart and diagnostic perception of problems in cardiac structure and function. I believe that in the service of these purposes, from the tradition of Waller, Einthoven, Lewis, Wilson and a succession of giants, we have evolved a large and sophisticated cadre of electrocardiographers: dedicated life-long students of the heart, skilled observers, skilled analysts and patient discoverers. I believe that whatever we do further to standardize, codify or reduce to programmatic form that portion of the body of electrocardiography susceptible to such management, we must take extraordinary pains to preserve the stimulus and opportunity that keeps that cadre fit. We may program computers to read electrocardiograms; we must not deprogram doctors. We must continue to learn and to teach electrocardiography as it continues to evolve so that tomorrow's physicians and scientists will be equipped to share tomorrow's knowledge for the solution of tomorrow's problems. It is critical for us as custodians of the resources that we must eventually bequeath to those who follow that we carefully make no choice that purchases transient economy by the creation of massive ignorance.

Otherwise we will have forgotten the best.

Acknowledgment

We are grateful to Charles Scribner's Sons for permission to use the quotation from Niebuhr.

Task Force I: Standardization of Terminology and Interpretation

BORYS SURAWICZ, MD (CHAIRMAN), HERMAN UHLEY, MD (CO-CHAIRMAN), RAYMOND BORUN, MD (CO-CHAIRMAN), MICHAEL LAKS, MD (CO-CHAIRMAN), LAMAR CREVASSE, MD, KENNETH ROSEN, MD, WILLIAM NELSON, MD, WILLIAM MANDEL, MD, PATRICK LAWRENCE, MD, LARRY JACKSON, MD, NANCY FLOWERS, MD, JAMES CLIFTON, MD, JOSEPH GREENFIELD Jr., MD, AND ETIENNE O. ROBLES DE MEDINA, MD

The development of a soundly based, widely acceptable uniform terminology for electrocardiographic interpretation is difficult. Physicians frequently disagree about the classification of features in an individual record, and similar disagreements occur in reports generated by different computer programs.[1–10] Some disagreement results from technical error, but the remainder arises from differences in measurement technique, terminology and criteria. Standard rules for measurement, classification and description of electrocardiographic features appear desirable to improve patient care by improving the consistency and quality of the report as well as communication between the interpreter and the user. The standards should be flexible enough to provide for continuing incorporation of improvements in electrocardiographic diagnoses, for classification of features from different populations and for different categories of users.

Standards for medical procedures are more readily accepted if they are logical, easily understandable and authoritative.[11] However, significant variability in electrocardiographic classification persists even when physicians agree to use identical criteria.[4–6] Imprecise identification of the onset and offset of electrocardiographic deflections is one source of variability in classification procedure, but this type of error can be minimized by proper selection of criteria.[12,13]

There is no comprehensive list of definitions and criteria designed for the use of electrocardiographic interpreters. The New York Heart Association monograph on nomenclature[14] focuses on comprehensive cardiac diagnosis rather than the electrocardiographic report. One of the best known digital coding systems, the Minnesota Code, has precisely defined criteria for classifying electrocardiographic features but is more useful in large scale clinical studies than in the interpretation of routine clinical reports.[15,16]

Types of interpretive statements: Selecting criteria for each electrocardiographic interpretive statement may be more difficult than selecting terminology. Statements can be divided arbitrarily into three types: (1) Type A refers to an anatomic lesion or pathophysiologic state that can be verified by nonelectrocardiographic evidence; this includes hypertrophy, infarction, ischemia, pulmonary disease and drug and metabolic effects. Selection of optimal criteria for type A statements depends on confirmatory nonelectrocardiographic information, which is limited in many instances at present. (2) Type B refers to an anatomic or functional disturbance that is detectable by the electrocardiogram itself (including special intracardiac leads). Criteria for these statements are based on characteristic features, and pertain mostly to arrhythmias and conduction disturbances. (3) Type C refers to electrocardiographic features that do not fit into type A and B categories. These include electrical axis, nonspecific T wave abnormalities, "premature repolarization," and unusual voltage. It appears reasonable to define interim standards for types B and C statements at this time, with the understanding that they may be modified by additional information.

Selection of criteria: For any type of electrocardiographic statement criteria should be selected with regard to sources of uncertainty that determine the accuracy of the statement; this principle is common to all medical diagnoses.[11,17–21] With respect to electrocardiographic diagnosis, numerous sources of uncertainty include physiologic variations from complex to complex or from day to day, variations in recording equipment or technique, recognition and measurement of the recorded wave forms, morphologic and etiologic classification of electrocardiographic features, and inadequate communication between the interpreter and user of the report.[2,22,23] Criteria for classification into different categories should not depend on a difference between measurements resulting from chance variations.[2,24] Borderline regions should be defined on the basis of total precision for both the measurement and the criteria.

The definition of pathologic states responsible for the electrocardiographic changes is not necessarily precise. This may complicate establishment of valid criteria. The problem of classifying "microinfarcts" in a correlative study of electrocardiographic criteria is one example of this situation.[25]

Variations in electrocardiographic measurements associated with age and other constitutional factors make it imperative that all comparisons be made between similar population samples. Collection of data from large samples of healthy and diseased populations

will be helpful in estimating the performance of various criteria. The same principles can be applied for data from multivariate statistical analyses or from recordings with special leads.[26–28] Comparison among electrocardiographic criteria should be based on sensitivity and specificity for a series of limits rather than for a single point. Plots of this information provide sensitivity-specificity curves that demonstrate relative performance of different criteria for various circumstances.[11,17–20,26] (Similar curves have been described as "receiver operating characteristic" or "diagnostic operating curves."[11–17]) A particular level of sensitivity or specificity can be selected from such curves for a given purpose.

Terminology: Preferred terms should be selected according to their scientific accuracy, understandability, simplicity and current use, in that order of priority. A critical evaluation should be made of supporting logic and data before selecting any new or uncommonly used term. A recent study of arrhythmia nomenclature illustrates the importance of this approach.[29] Care must be taken not to discard commonly used terms to gain a small or hypothetical improvement in scientific accuracy at the expense of a significant loss in understandability. Abbreviations, acronyms, slang, parochial terms, rare eponyms, jargon and complex terms should be avoided. Terms should be selected and grouped in a consistent manner. Exceptions to these guidelines may be desirable if they improve understandability.

Definitions for the selected terms should be provided; statistical and other information on which these criteria are based should be described and reasons given for the choice when commonly used alternative criteria are available. A concise set of instructions for use of these terms should be provided along with a list of modifiers to indicate such items as probability, location and age of lesions. These are discussed later.

General Classification Terms

Two different meanings for *normal* are currently used in medical practice. One is based on prevalence and the other on health. When the meaning based on prevalence is used, *normal* is defined in Dorland's Illustrated Medical Dictionary and Stedman's Medical Dictionary as "typical," and "agreeing with the established type," and abnormal is defined as "contrary to the usual. . . ." However, when the meaning based on state of health is used, *normal* is defined as "healthy" and abnormal as "not healthy."

There are limitations to the usefulness of each of these meanings. Some physicians have a preference for one of the two, and others use both. A serious error can result from a misunderstanding as to which meaning is being used in a specific situation. The different preferences of physicians make it unlikely that unanimity could be achieved by an appeal for standard terminology. A recent suggestion that the term *normal* be discarded and replaced by more meaningful synonyms seems unrealistic for the same reason.[30] A different approach consists of requiring that *both* prevalence and health conditions be satisfied when either the term *normal* or *abnormal* is used. Electrocardiographic features that are not usual for a healthy population and not commonly associated with disease would be classified as *atypical* rather than as abnormal. This should lessen conflict and misunderstanding in use of the terms.

Definitions

Healthy population: Persons constituting a category without disease.

Healthy population sample: A representative sample of ambulatory noninstitutionalized persons without medical complaints or evidence by history or examination of any disease or dysfunction that may impair health or affect the electrocardiogram. The sample should be stratified by age, sex, race and body build characteristics. Healthy persons with other special characteristics that may affect the electrocardiogram (such as unusual physical activity or altitude acclimatization) should be considered separately. The logic and methods for selecting and stratifying a healthy population sample have been described and used by Simonson.[2]

Normal: An electrocardiographic feature that is within a specified normal range limit for a sufficiently large and appropriately stratified healthy population sample. It is preferable to establish the normal limit from a percentile distribution rather than from the standard deviation or the extreme range for the distribution.[2,30–32] The standard deviation is less preferred because some important electrocardiographic features do not have symmetrical (Gaussian) distribution.

The most complete source of electrocardiographic information analyzed in this manner is in the monograph by Simonson.[2] This information is suitable to define normal limits for current use, but it would be desirable to record and analyze a larger sample from healthy persons, using multichannel recorders and computer techniques, and perhaps establish other percentile distributions (such as 1 and 99, 5 and 95, and 10 and 90) for both individual and selected groups of electrocardiographic features.

Abnormal: An electrocardiographic feature that is outside a normal limit and has a significantly greater prevalence in diseased than in otherwise similar healthy persons. Correct classification of an abnormal feature presents difficulties when the measurement overlaps between the distribution curves for healthy and diseased populations. In such cases probability of correct diagnosis depends on the proportion of healthy and diseased persons in the total sample of interest.

Atypical: An electrocardiographic feature that is outside a normal limit and does not have a significantly greater prevalence in diseased than in otherwise similar healthy persons.

Borderline: This term is a modifier for normal and abnormal. It denotes uncertainty as to the particular side of a criterion demarcation line a finding belongs on. The accuracy and variability of an electrocardiographic measurement, the location of a criterion demarcation line or a combination of these factors may be the source of the uncertainty. The borderline zone may encompass only a few milliseconds or microvolts for a measurement that has a high degree of precision and accuracy but may be considerably wider if the degree of precision or accuracy is low.

Borderline normal: An atypical electrocardiographic feature that is outside a normal limit by less than the sum of chance error for determination of both the limit and the individual measurement. Simonson[2] suggested that *borderline* be defined as a measurement that exceeds the percentile limit by less than four times the standard error for the limit plus the standard deviation for the measurement.

Borderline abnormal: An electrocardiographic measurement that is closer to a criterion for abnormality than 1 standard deviation for the measurement error.

Normal variant: This descriptive term may be used for an atypical electrocardiographic feature or one that exceeds a criterion for abnormality in a person known not to have the disease suggested by the criterion.

Classification of the total electrocardiogram: The classification of a clearly normal or abnormal record is simpler than classification of one that contains atypical or borderline but no definitely abnormal features. It has been suggested that at least one atypical or borderline measurement will be present in any electrocardiogram from a healthy person as a result of chance because of the large number of measurable variables. Furthermore, it appears likely that multivariate analysis would reveal an association between some groups of atypical or borderline features and disease.[27,28] In the face of insufficient information, we recommend a conservative statement such as "Electrocardiogram contains borderline findings, otherwise normal."

Choice of terms: Some terms refer to a specific anatomic or physiologic state; others are simply a description of an electrocardiographic feature with an option for suggesting one or more possible causes.

Preferred terms: Selection of preferred terms is based on factors mentioned earlier in this report. Alternative terms are mentioned if they are in common usage or are considered equivalent to the preferred ones.

Modifiers: These are used to indicate an estimated probability that a statement is correct, an anatomic location or age of a lesion or the frequency of an intermittent feature.

Age: Terms relative to age are used most frequently as modifiers for statements on myocardial infarction. The phrase "age undetermined" may be followed by a probability modifier and one of the other age terms; for example, "age undetermined, possibly recent" or "age undetermined, probably old." The terms "acute" and "recent" may be used with statements that relate to a pathophysiologic condition, such as *myocardial ischemia* or *injury*, if there is adequate supporting evidence. In some cases the term "chronic" may be more appropriate than the term "old" to indicate the prolonged presence of active disease.

Terms	Approximate Time Range
Acute	Less than 3 days
Recent	Less than 1 month
Old	More than 3 months
Age undetermined	Unspecified

Frequency: Terms involving frequency are used with statements that describe recurrent features in the electrocardiogram, such as ectopic complexes. Ideally, the number of events should be stated in precise numbers per unit of time. The term "frequent" or "multiple" can be used if the feature occurs several times in a tracing mounted in a conventional manner. The term "occasional" can be used if it occurs only once or twice but is less advisable than stating the number.

Pediatric electrocardiogram: This report was prepared without the benefit of consultation with pediatric electrocardiographers, and the discussion is therefore limited to electrocardiograms of adults.[33–45] The terms used in pediatric electrocardiography are essentially the same as for the adult, but specific quantitative criteria and clinical correlations may differ in various pediatric age groups.

Vectorcardiography: Space does not permit inclusion of specific problems related to vectorcardiography. However, the technique differs from scalar electrocardiography in the display but not in the underlying theory or the data base.

Nomenclature versus criteria: In the following portions on contour and arrhythmias, emphasis is placed on nomenclature rather than on detailed, specific criteria. This approach appears desirable for the following reasons:

1. The proper application of the current knowledge and of the subsequent developments in electrocardiography depends on the availability of carefully chosen terms.
2. Although the electrocardiogram has been in use for almost a century, sharp boundaries between "normal" and "abnormal" have not been established. It does not seem appropriate at this time to recapitulate what is available in standard texts or review articles.
3. A meaningful list of criteria should be not only complete but also exhaustive and well founded and should include indications of their sensitivity and specificity. This would require a much larger Task Force and text.
4. Many criteria are more qualitative (morphologic) than quantitative (numerical) and would require illustrations to be meaningful. The number of illustrations that would be needed could not be incorporated within this report.

List of Standard Terms: Contour

Most Common Normal Variants

The following are the normal variants most often noted:[46–60]

Increased QRS amplitude: The term lacks precision because there are no precise values of upper limits of normal for each type of body build and chest wall thickness.

Low voltage: The term lacks precision because there are no precise limits of normal amplitude for different leads, different types of body build and variable chest wall thickness.

Abnormal amplitude of initial QRS deflection: These result in (a) abnormal Q waves (amplitude or duration) in one or more of the following leads: I, II, III, aVL, aVF, V_4 to V_6; (b) abnormal R waves (amplitude) in one or more of right and mid precordial V leads.

Prolonged Q-T_c interval: A corrected Q-T interval (QT_c) greater than 115 percent of normal without prolongation of the S-T segment, without increase in T wave amplitude or any other abnormalities. The pattern is sometimes due to neurogenic repolarization changes, but the clinical significance is frequently unknown.

S-T segment elevation: This may occur in one or more of the standard limb or chest leads as a normal variant, attributed to "premature repolarization."

Horizontal or depressed S-T segment: This is a rare normal variant with S-T segment depression ≤ 0.1 mv in one or more of the standard limb or chest leads, nearly always in women.

Inverted T waves in one or more of the right and mid precordial leads (V_1 to V_4): These are sometimes attributed to the persistence of "juvenile pattern."

Tall T waves: No upper limits of normal have been established.

Increased U amplitude: No upper limits of normal have been established, but the amplitude must be related to heart rate because U wave amplitude usually increases with increasing R-R interval.

Diphasic or negative U wave: If not exercise-induced, and not associated with other electrocardiographic abnormalities, this is frequently associated with left ventricular hypertrophy or coronary artery disease but occasionally occurs without obvious heart disease.

Notched QRS complex: This may be due to myocardial disease but frequently occurs in the absence of heart disease.

Poor R wave progression: This term is not precise, and its use is to be discouraged. If used, it should not be interpreted as evidence of myocardial infarction or other structural abnormalities.

Dextrocardia: The pattern in the limb leads is identical with reversal of right and left arm electrodes, but the pattern is characteristic in the precordial leads.

S1, 2, 3 pattern: This pattern may occur as a normal variant, particularly in young persons, but is sometimes present in patients with right ventricular enlargement or chronic lung disease.

Rotations: The outworn terms "clockwise," "counterclockwise," "apex forward" and "apex backward" rotation of the heart should be discouraged because they lack precise meaning and may be misleading.

Junctional S-T segment depression, J point depression, junctional depression: These terms are widely used to characterize deviation of the initial portion of the S-T segment from the baseline; such deviation is believed to be caused in many cases by atrial repolarization.

Chamber Enlargement (Hypertrophy)

Electrocardiographic diagnosis of chamber enlargement[61–92] is based on various wave form changes resulting from one or more consequences of hypertrophy, dilatation, conduction disturbance or change in chamber position. The criteria are not uniform, and the terminology is partly unsettled. For the atria, the preferred term is *enlargement*. The term *atrial hypertrophy* should not be used because there are no sufficient correlations between the electrocardiographic changes and atrial weight. For the ventricles, both *ventricular hypertrophy* and *ventricular enlargement* have been widely used. Although both terms have some advantages and some drawbacks, the term *enlargement* is preferred by the majority of Task Force members and consultants.

Left atrial enlargement: The criteria are based on P wave duration and alterations in the direction and amplitude of the terminal P wave vector. The specificity of these criteria is low. The term *P mitrale* should be discouraged because it may be misleading. The terms *left atrial overload* and *left atrial abnormality* have some proponents but no uniform acceptance.

Right atrial enlargement: The criteria are based on the increase in amplitude of the anteriorly directed P wave vector and the less specific inferiorly directed deviation of the P wave vector. The latter effect produces a pattern known as *P pulmonale*, a term widely used to describe a tall frequently peaked P wave of normal duration in leads II, III and aVF. Use of this term should be discouraged because a P pulmonale pattern may occur in the absence of both lung disease and right atrial enlargement, and it may be precipitated by such conditions as tachycardia, hyperthyroidism or low diaphragm position. It should be noted that the term *right atrial enlargement* is not always synonymous with *P pulmonale*.

The term *P congenitale* is to be discouraged. The terms *right atrial overload* and *right atrial abnormality* have some proponents but no uniform acceptance.

Left ventricular enlargement (hypertrophy): The diagnostic criteria include various combinations of the following changes: increased QRS voltage; posterior and sometimes leftward deviation of the mean QRS vector; increased duration of the QRS complex; delayed intrinsicoid deflection; widening of the QRS/T angle; and incomplete left bundle branch block.

Use of the following two terms should be discouraged: (1) *left ventricular strain*; this term can be replaced by the designation *hypertrophy* (or *enlargement*) with secondary repolarization abnormalities; (2) *left ventricular (systolic or diastolic) overload pattern,* because it lacks precision and sound electrophysiologic basis.

Right ventricular enlargement (hypertrophy): Several types of patterns may occur depending on the degree of enlargement and the clinical condition responsible for the anatomic change. The most common diagnostic criteria are based on the presence of one or more of the following changes: increased rightward anterior QRS vector (or decreased posterior QRS vector); increased rightward posterior QRS vector; complete or incomplete right bundle branch block; abnormal amplitude of the terminal QRS vector in a complete or an incomplete right bundle branch block; and right axis deviation.

Use of the following terms should be discouraged: (1) *right ventricular strain;* this term can be replaced by the designation *enlargement* (or *hypertrophy*) with secondary repolarization abnormalities; (2) *right ventricular (systolic or diastolic) overload pattern,* because it lacks precision and sound electrophysiologic basis.

Combined enlargement (hypertrophy): The term *combined* is acceptable as are the terms *biatrial* and *biventricular*.

Axis deviation: *Abnormal left axis deviation* and *abnormal right axis deviation* are acceptable terms; they should be used with caution in the absence of information about age, height and weight of the patient.

Septal hypertrophy: This term should not be used because criteria are not precise and the electrophysiologic mechanism underlying "abnormal Q waves" in certain patients with left ventricular hypertrophy (particularly obstructive cardiomyopathy) has not been clarified.

Myocardial Ischemia, Injury and Infarction

The manifestations of ischemic injury in the myocardium often produce sequential changes of varying degree.[93–112] The electrocardiographic interpretation of such changes should be correlated with other independent data and integrated into the total clinical picture.

Ischemia: This term is widely used by electrocardiographers to characterize abnormalities of ventricular repolarization, but there is no general agreement on the

morphologic criteria characteristic of "ischemia" because some electrocardiographers use the term to refer to S-T segment changes, some to T wave changes alone and others to both S-T segment and T wave changes.

Injury (subepicardial, subendocardial): This term is widely used by electrocardiographers to describe deviations of the S-T segment from the baseline (elevation, depression).

Nontransmural infarction: This term is widely used by electrocardiographers to describe ventricular repolarization changes without abnormalities of the QRS complex. The assumption is that the infarction does not involve the epicardial surface. The synonymous term *intramural infarction* is less desirable.

Transmural infarction: This term (see location list) is used in the presence of typical change in the direction (and usually duration) of the initial QRS vector. The assumption is that the infarction involves the epicardial surface.

The likelihood of infarction can be expressed in the following terms: (1) cannot exclude (<25 percent); (2) possible (25 to 49 percent); (3) probable (50 to 90 percent); and (4) characteristic of (>90 percent).

The localization of infarction is useful although it is not always precise. Pathologic studies show that the distribution of the lesions frequently is patchy. Locations based on the presence of Q wave (leads in parentheses) include (1) septal (V_1, V_2); (2) anterior (V_3, V_4); (3) anteroseptal (V_1–V_4); (4) lateral (I, aVL, V_5, V_6); (5) anterolateral (I, aVL, V_3–V_6); (6) inferior (a synonymous but less desirable term is diaphragmatic) (II, III, aVF); and (7) posterior (wide R wave in V_1–V_2).

The age of the infarction should be stated if possible in the following terms: (1) possibly acute; (2) probably acute; (3) characteristic of acute; (4) age undetermined, probably acute; (5) age undetermined; (6) age undetermined, probably old; (7) probably not acute; and (8) old. The less desirable but commonly used terms are *evolving, evolution, healing* and *subsiding.*

Ventricular aneurysm: This is a widely used term. The electrocardiographic criteria are not precise and the specificity is limited.

Terms To Be Avoided in Describing Ischemia or Infarction

Hyperacute: This may be a useful concept clinically to describe certain changes similar to those observed in the experimental laboratory, but the specificity is very low. The term implies an early stage of acute ischemia or acute ischemia and injury, and can be more precisely referred to in those terms.

Poor R wave progression: This is a nonspecific pattern, which frequently leads to incorrect diagnosis of infarction.

High lateral infarction and high posterior infarction: Use of these terms is discouraged because the power to localize with this degree of precision has not been borne out in postmortem data.

Coronary insufficiency: This is an ambiguous term, with widely divergent meanings and implication.

Acceptable Terms in Describing Infarction

Apical infarction: This term has merit because often inferior infarction slightly overlaps the apex and manifests itself in Q waves in leads V_3 or V_4 as well as in II, III and aVF. However, the term may be misleading because it has been used in the past to describe massive circumferential involvement of the entire apex.

Anterior-inferior (transseptal infarction): This is similar in meaning to apical. Q waves are usually present in leads II, III, aVF and in one or more of leads V_1 to V_4.

Posterolateral infarction: This is manifested by Q waves in leads I, aVL, V_6 and wide R waves in leads V_1 and V_2.

Segmental infarctions (such as basal segment of inferior wall or apical segment of posterior wall): These terms have a limited supporting data base derived from correlations with angiography and ventriculography, but wide use of such terms is not yet recommended.

Subendocardial infarction: Some elect to use this term in cases of subendocardial injury (S-T depression) with an upright T wave (in leads I, II or V_2 to V_6) in the presence of appropriate clinical findings, particularly when the changes persist for hours or days.

Drugs and Electrolytes

In referring to drugs and electrolytes,[113–125] *the following terms are acceptable:*

Digitalis effect: When appropriate, it may be possible to add: no evidence of overdosage; possible overdosage; probably toxic; toxic.

Quinidine effect: When appropriate, it may be possible to add: nontoxic; possible overdosage.

Procainamide effect: It may be possible to add: nontoxic; possible overdosage.

Phenothiazine effect: This class of drugs may produce minor nonspecific T abnormalities, and (rarely) prolonged Q-T_c and increased U amplitude (thioridazine more commonly than other drugs).

Hypokalemia (hypopotassemia): This term reflects low plasma potassium ion concentration; electrocardiographic changes tend to parallel the severity of hypokalemia.

Hyperkalemia (hyperpotassemia): Electrocardiographic changes tend to parallel the severity of hyperkalemia.

Hypocalcemia and hypercalcemia: These terms are used, respectively, to reflect changes of low or high plasma calcium concentration.

Use of the term *electrolyte imbalance* is to be discouraged because it lacks precision. Only these four electrolyte abnormalities (hypokalemia, hyperkalemia, hypocalcemia and hypercalcemia) produce diagnostically useful electrocardiographic changes.

Miscellaneous Abnormalities

Various abnormalities may appear in the electrocardiogram:[126–141]

Pulmonary embolism, or acute cor pulmonale: Other terms, right heart overload (acute) and right

ventricular strain (acute), are less desirable. The specificity of the electrocardiographic changes is low. Criteria include changes in heart rate, rhythm and P wave, QRS axis shifts, appearance of incomplete right bundle branch block and T wave abnormalities.

Pericarditis: If possible, it should be stated whether the condition is acute, subacute or chronic. Criteria are based on abnormalities of S-T segment, P-R segment and T wave.

Myocarditis: There are no precise criteria. Usually the T wave changes are similar to those in pericarditis.

Nonspecific (nondiagnostic) T wave abnormalities: This term should be limited to patterns without S-T segment abnormalities and without marked Q-Tc lengthening, as in "cerebrovascular pattern."

"Cerebrovascular pattern" (neurogenic T wave abnormality): This term usually indicates prolonged Q-Tc, abnormal T wave amplitude and polarity, occasionally abnormal U wave amplitude.

Nonspecific (nondiagnostic) S-T segment and T wave abnormalities: This term reflects a combination of abnormal initial and terminal repolarization abnormalities.

Postextrasystolic T wave changes and abnormalities: These may occur in one or a few complexes after a premature complex.

Tachycardia and posttachycardia T wave abnormality: The change is limited to amplitude and polarity of the T wave without S-T segment abnormalities.

Hypothermia: "Deep" hypothermia (temperature less than 25° C) can be recognized in the electrocardiogram by the presence of a characteristic slow, usually positive wave, called an Osborn wave, inscribed during the terminal QRS portion.[38] Moderate hypothermia (for example, that occurring after exposure to cold), can be frequently suspected in the presence of bradycardia and prolonged Q-Tc interval.

Electrical alternans: Alternans may involve single, several or all electrocardiographic deflections. It is commonly present in patients with a large pericardial effusion or cardiac tamponade.

List of Terms: Procedures

The electrocardiogram can be used to monitor an almost unlimited number of events or physiologic interventions.[142–152]

Exercise (Stress) Test

It is desirable to state the method (for example, treadmill, bicycle or atrial pacing) and the purpose (such as detection of myocardial ischemia, study of arrhythmia, evaluation of physical fitness or evaluation of treatment).

Widely accepted terms are as follows:

Normal exercise test: This is synonymous with a negative exercise test (for myocardial ischemia). Type of test, duration of test, heart rate response, blood pressure response and other pertinent observations and measurements are usually included in the report.

Abnormal exercise test: This is synonymous with a positive exercise test (for myocardial ischemia).

Borderline abnormal exercise test: Changes are close to the criteria for an abnormal test.

Unsatisfactory exercise test: Results are not amenable to evaluation. Reasons should be specified.

Junctional S-T segment depression: Normal variant assumed to be due to atrial repolarization.

Hyperventilation and Orthostatic Electrocardiograms

In many laboratories the routine electrocardiographic stress test is preceded by a tracing recorded after 30 seconds of vigorous hyperventilation with the patient in the recumbent position, and one recorded immediately after standing up. This is helpful in the evaluation of exercise-induced repolarization changes, particularly in the differential diagnosis of myocardial ischemia.

Electrocardiogram After Smoking and During Other Procedures

Under certain circumstances, the effects of various interventions on the electrocardiogram may be of interest. This may include monitoring the effects of intravenous administration of drugs, inhalation of drugs and breathing of various gas mixtures.

Long-Term Ambulatory Monitoring (Holter)

Several techniques have been developed to record continuously one or more leads on magnetic tape. Some systems have been designed to record only specifically preprogrammed cardiac events such as multiple premature beats, rate and atrioventricular deviations. It is acknowledged that the recognition of rhythm or conduction abnormalities is dependent on the proficiency of the technician analyzing the Holter tapes.

Terms for Cardiac Rhythm and Conduction[153,154]

Preferred Terms Referring Predominantly to Impulse Formation

Arrhythmia (dysrhythmia): This term refers to any cardiac rhythm that is not a regular sinus rhythm at a normal rate. Such a rhythm may be of either sinus or ectopic origin, and may be regular or irregular. An arrhythmia may be due to a disturbance in impulse formation or conduction, or both. Not every arrhythmia is pathologic. An example of physiologic arrhythmia is the respiratory variation of sinus rate (sinus arrhythmia).

Inherent rate: This is the rate at which the impulse formation usually occurs at a given pacemaker localization. *For the adult the following figures are thought to represent a rough guide:*

Sinoatrial (S-A) node	50–100/min
Atrioventricular (A-V) junction	40–60/min
Ventricle	30–40/min

Pacemaker: A fiber or a group of cardiac fibers initiating one or more activations. This definition does not take into account the various mechanisms that may be

involved in generating a cardiac impulse. The *primary pacemaker* is the sinoatrial node. *An ectopic or subsidiary pacemaker* is any pacemaker outside the sinoatrial node.

Bradycardia: Three or more consecutive impulses from the same pacemaker at a rate less than the lower limit of its inherent rate.

Tachycardia: Three or more consecutive impulses from the same cardiac chamber at a rate exceeding 100/min. The site must be specified.

Premature impulse (activation, complex, discharge): An activation that precedes the expected discharge of the prevailing rhythm. This applies to premature depolarizations, echoes, captures and manifest activation from a parasystolic pacemaker. Premature impulses may occur singly or in pairs. When three or more are recorded in succession, this is by definition a tachycardia. A premature impulse is usually of ectopic origin.

Escape (impulse): One impulse or two consecutive impulses (atrial, A-V junctional or ventricular) arising as a result of undue delay in the formation or arrival of the prevailing rhythm. (See also descriptions of escape rhythm and premature impulse.)

Escape rhythm: Three or more consecutive escape impulses at a rate not exceeding the upper limit of the inherent rate of that particular pacemaker. (See also descriptions of escape (impulse), accelerated rhythm, and inherent rate.)

Accelerated rhythm: Three or more consecutive impulses from the same pacemaker at a rate exceeding the upper limit of its inherent rate, but less than 100/min. In any specific case the rate and site of impulse formation should be indicated.

Interpolation: The phenomenon in which a premature impulse, usually of ectopic origin, occurs between two consecutive impulses of another pacemaker.

Fusion complex: Simultaneous or nearly simultaneous activation of either the atria or ventricles (atrial or ventricular fusion complex) by impulses coming from different directions. This results in an electrocardiographic complex that is intermediate in form between the pure complexes resulting from the differently originating excitation waves (see also description of capture).

Paroxysmal supraventricular tachycardia: A tachycardia usually characterized by an atrial rate of 140 to 240/min and by an abrupt onset and termination. It may or may not be associated with intact A-V conduction. Special electrophysiologic studies may elicit specific mechanisms, such as retrograde and anterograde pathways and sites of reentry.

Flutter: Rapid and regular electrical activity of atria or ventricles that is characterized electrocardiographically by the absence of an isoelectric line in at least one lead.

Atrial flutter: The rate of the atria is usually in the range of 250 to 350/min, and typically displays a sawtooth appearance in leads II and III.

Ventricular flutter: The ventricular rate usually exceeds 250/min, but the components of the QRS complex and T wave cannot be clearly identified or separated.

Fibrillation: Irregular, totally disorganized electrical activity of the atria or ventricles, or both.

Arrest: Cessation of electrical activity of the heart or a specific pacemaker. Arrest may be caused by different electrophysiologic mechanisms that should be defined if possible (for example, exit block of one or more impulses). (See description of exit block.)

Controversial or Nonprecise Terms

Wandering pacemaker: A rhythm characterized by gradual alteration of the P wave contours and sometimes cycle length.

Extrasystole: A premature impulse (S-A nodal, atrial, A-V junctional or ventricular) that usually shows a fixed relation to the preceding discharge of another pacemaker. The term is to be discouraged because it may not be an extra complex and does not always result in mechanical systole. However, the term is widely used in practice. (See also description of premature impulse and echo.)

Atrial flutter-fibrillation: This term implies some characteristics of atrial flutter and some of atrial fibrillation. Such a record is best classified as atrial fibrillation when the criteria of atrial flutter are not satisfied. It should not be mistaken for the alternation of atrial flutter and fibrillation in the same record.

Terms To Be Avoided

Bradyarrhythmia: Not a specific electrocardiographic term.

Tachyarrhythmia: Not a specific electrocardiographic term.

Beat: Use of this term in electrocardiographic nomenclature is inappropriate because it connotes the mechanical event after excitation of a cardiac chamber.

Depolarization: Decrease of membrane potential (less negative). Because depolarization occurs at a cell level, its use is best restricted to the description of the electrophysiologic phenomenon. In clinical electrocardiography, when referring to a deflection that represents the electrically active state of the myocardium, better terms are discharge, activation, excitation or impulse.

Paroxysmal atrial tachycardia: The specific role of the atria in the mechanism of paroxysmal tachycardia is difficult to determine without special electrophysiologic studies. (See description of paroxysmal supraventricular tachycardia.)

Paroxysmal A-V junctional or A-V nodal tachycardia: The same considerations apply as described in the preceding paragraph.

Nonparoxysmal tachycardia: What is meant in most cases is accelerated impulse formation.

Pseudofusion beat: Superimposition of an artificial pacemaker artifact on a spontaneous P wave or QRS complex. This indication serves no special purpose and creates confusion.

Idioventricular tachycardia: The term *accelerated ventricular rhythm* is preferred.

Terms Referring Predominantly to Impulse Conduction

Preferred Terms

Block: This refers to delay or failure of impulse propagation. Conduction disturbances of various degrees may occur in many different locations within the heart, and may reflect delay or failure of propagation in either the antegrade or retrograde direction, or both.

Intraatrial conduction delay: Conduction delay within the atria resulting in abnormal widening or distortion, or both, of the P wave.

First degree block: Delayed conduction within the heart with a 1:1 conduction ratio. In any individual case, the conduction time and site of delay should be specified when possible. (See also descriptions of second and third degree block.)

Second degree block: A conduction disturbance in which not every impulse is propagated from its site of origin. This conduction disturbance can be expressed as a conduction ratio. Second degree block is subclassified into type I, type II and advanced block.

Advanced (second degree) block: A form of second degree block in which either alternate or two or more consecutive impulses fail to be conducted. This includes 2:1, 3:1 and 4:1 block. (See descriptions of second and third degree block.)

Third degree block or complete block: Complete failure of impulse propagation usually associated with independent activation of the chamber distal to the site of block.

Intraventricular block: The anatomy and function of the intraventricular conduction system remain controversial. It is clear that there are two distinct bundle branch systems (right and left). The left bundle branch appears to consist of two groups of functioning fibers (fascicles), anterior and posterior. Several workers have also described groups of interconnecting septal fibers ("septal fascicles").

Accepted electrocardiographic patterns are described for block in the left bundle branch, the individual divisions of the left bundle branch, the right bundle branch, and the right bundle branch in combination with either division of the left bundle branch. The representation of block within the septal division of the left bundle branch lacks clearly defined criteria. The term *complete bilateral bundle branch block* implies *complete* interruption of the intraventricular conduction system with resultant complete A-V block. Confusion occurs in utilizing the terms unifascicular, monofascicular, fascicular, bifascicular and trifascicular block. It is recommended that conduction defects be described specifically in terms of the structure or structures involved (for example, "right bundle branch block with left anterior fascicular block," rather than "bifascicular block").

Fascicular block: This is an electrocardiographic (electrophysiologic) concept that ascribes certain wave forms to particular patterns of disturbed intraventricular conduction. (See also description of intraventricular block.)

Monofascicular block: See description of intraventricular block.

Bundle branch block: A conduction disturbance within one of the bundle branches (see also block). It may be complete or incomplete, permanent or intermittent, or unilateral or bilateral.

Bundle branch block, complete: This pattern indicates the absence of conduction in a bundle branch, or a delay of such magnitude that ventricular activation occurs largely or exclusively through the contralateral bundle; in adults this causes widening of the QRS complex to 0.12 second or more.

Bundle branch block, incomplete: This pattern often indicates delay in activation of the ipsilateral ventricle by way of that bundle branch, or sufficient delay to allow partial activation by way of the contralateral bundle.

Nonspecific intraventricular block: This applies to any type of intraventricular conduction disturbance that cannot be ascribed to block in a specific portion of the specialized conduction system.

Atrioventricular (A-V) dissociation: A descriptive term indicating at least two independent rhythms, one arising in the atria, the other in A-V junctional or ventricular tissues. *A-V dissociation is never a primary disturbance of rhythm but rather a consequence of a basic disorder of impulse formation or conduction.* It may be due to failure of impulse formation (default) or increase in the rate of the subsidiary pacemaker (usurpation). Dissociation may occur for single activations, or may last longer. In the presence of captures, dissociation is *incomplete.* When there are no captures during the time of recording, dissociation is considered complete. Dissociation should not be used as a synonym for complete A-V block, which may be one of the possible underlying mechanisms. (See also descriptions of block, capture and parasystole.)

Controversial or Nonprecise Terms

Hemiblock, left anterior and left posterior: These terms are synonymous with left anterior fascicular or divisional block and with left posterior fascicular or divisional block, respectively.

Periinfarction block: Specific conduction defects existing in the presence of myocardial infarction should be identified. The term periinfarction block implies conduction disturbance near the site of infarction. This can seldom be recognized with certainty.

Terms To Be Avoided

High degree block or high grade block: By definition, this is still a form of second degree block. Therefore, it seems appropriate to classify this conduction disturbance as *advanced second degree block.*

Intramural conduction disturbance: This term suggests a conduction disturbance within the ventricles, which causes a specific widening or slurring (or both) and notching of the QRS complex. In most cases, however, the exact site and extent of the conduction ab-

normality are not known. Therefore, the noncommittal term *nonspecific intraventricular block* is preferred.

Parietal block: This term is not descriptive of a specific site or type of conduction disturbance. (See description of intramural conduction disturbance.)

Arborization block: The term lacks specific meaning. (See description of intramural conduction disturbance.)

Interference: Rarely has a term created so much disagreement and confusion. Some have used it to indicate the short disturbance of the rhythmic action of one pacemaker by the activity of another (for example, resetting of a junctional or ventricular pacemaker by a ventricular capture during incomplete A-V dissociation); others have defined it as the expression of a physiologic mechanism, namely, delay or failure of impulse conduction due to induced normal refractoriness of a conduction pathway or the myocardium (collision of two impulses coming from the opposite or the same direction). For clarity, it is advisable to avoid the term interference.

Terms Referring Predominantly to Specific Mechanisms Operating in Arrhythmias

Preferred Terms

Parasystole: A rhythm consisting of dual activation of a single cardiac chamber in which one pacemaker (the parasystolic one) is protected intermittently or totally from discharge by the prevailing rhythm. At times two or even more parasystolic rhythms may coexist (*multifocal parasystole*).

Multifocal tachycardia (multiform): Supraventricular or ventricular tachycardia characterized by varying cycle length and configuration of atrial or ventricular complexes.

Coupling interval: The time interval between two impulses, usually an ectopic impulse and a preceding nonectopic impulse.

Conduction ratio: The ratio of the number of impulses that arrive at a site of block to the number that are propagated.

Aberrant conduction: The abnormal spread of an impulse through the normal or expected pathway, resulting in an altered electrocardiographic wave form from the chamber distal to the site where the impulse originates. Thus, aberrant conduction may occur within the ventricles or the atria. It is preferred to reserve this term for conduction delays within the normal pathway, thus excluding altered configuration due to preexcitation. Whenever possible, use of the term aberrant conduction should be related to a functional, rate-related mechanism underlying the altered spread of excitation.

Second degree block, type I (Wenckebach): Intermittent failure of impulse conduction in which the blocked impulse follows a number of impulses with varying degree of prolonged conduction relative to the first impulse conducted after the block. This may also be termed *Wenckebach periodicity* and *Mobitz type I block.*

Second degree block, type II (Mobitz, type II): Intermittent failure of impulse conduction following a number of impulses conducted without changes in their conduction time. The diagnosis of *Mobitz type II block* is supported by the finding of an unchanged conduction time of the impulse after the blocked impulse. (See also description of second degree block, type I.)

Anterograde or orthograde conduction: Conduction of a cardiac impulse in the direction of normal cardiac activation (from the atria to the ventricles).

Retrograde conduction. Conduction of a cardiac impulse in a reversed direction; the term is usually used to indicate ventriculoatrial conduction.

Entrance block: Delayed or failed penetration of an impulse into a pacemaking center. When an impulse fails to penetrate and reset (discharge) a pacemaker, the pacemaker is said to be protected. When there is delayed or only occasional resetting, protection is incomplete. (See also description of exit block.)

Exit block: Delay or failure of a pacemaker impulse to discharge surrounding myocardium. (See also description of entrance block.)

Ventriculoatrial (V-A) block: Delay or failure of an impulse to be conducted from the ventricles to the atria.

Capture: Usually premature activation of the atria (atrial capture) by a ventricular or junctional impulse conducted in retrograde fashion, or premature activation of the ventricles (ventricular capture) by a supraventricular impulse conducted in anterograde fashion.

Concealed conduction: Propagation of a cardiac impulse in such a manner that it influences subsequent events but does not manifest itself as a specific wave form.

Supernormal conduction: Conduction that is more rapid than expected.

Supernormal excitability: Activation resulting from a subthreshold stimulus, that at other times in the cardiac cycle fails to elicit a response.

Gap in A-V conduction: A period in the cardiac cycle during which an atrial impulse is not conducted to the ventricle, whereas earlier or later atrial impulses are conducted. This phenomenon can be seen in other tissues. (See description of supernormal conduction.)

Reentry: The phenomenon in which the same cardiac impulse enters a circuit and returns *to* or *toward* its area of origin. Reentry may result in one or more activations of the heart or cardiac region, but it may remain concealed. *Concealed reentry* may occur.

Echo: Return of an impulse to its site of origin.

Bigeminy: A repetitive pattern of two relatively closely spaced impulses, usually followed by a longer interval. (See also description of trigeminy.)

Trigeminy: A repetitive pattern of three relatively closely spaced impulses, usually followed by a longer interval. The third impulse ordinarily is a premature complex; less commonly, one sinus impulse is followed by two consecutive premature ectopic complexes.

Preexcitation: Excitation of a cardiac chamber, or part of it, earlier but not necessarily in a different

manner from what is expected. Thus ventricular preexcitation can be defined as excitation of the ventricles or a portion of the ventricles that occurs earlier than would be expected when the supraventricular impulse propagates through the normal A-V node-His bundle system. (See descriptions of Wolff-Parkinson-White and short P-R patterns.)

Short P-R interval (without delta waves): The P-R interval is shortened to less than 0.12 second (in adults), and there are no delta waves. There are many causes for this phenomenon.

Wolff-Parkinson-White (WPW) pattern: Preexcitation of the ventricles by means of an additional and abnormal anatomic A-V connection. In such cases, excitation by way of the accessory pathway will cause shortening of the P-R interval, a delta wave and widening of the QRS complex. Absolute values for P-R interval, delta wave and QRS width are variable. The electrocardiographic manifestations may be intermittent and the anatomic substrate for reentrant tachycardias may be present (although undetectable) in the routine surface electrocardiogram (concealed preexcitation). By definition, *Wolff-Parkinson-White syndrome* requires association with ectopic tachycardias.

Controversial or Nonprecise Terms

Atrial dissociation: A dual atrial rhythm in which independent activity in each atrial chamber can be established using special electrophysiologic techniques of recording.

Wedensky effect: This refers to an electrophysiologic observation of a subthreshold stimulus resulting in an effective activation when it is preceded at a given time interval by a suprathreshold stimulus, which itself results in an effective activation.

Wedensky facilitation: This refers to an electrophysiologic observation of a properly timed stimulus, which can cause dissipation of a conduction block for variable times.

Vulnerable period: A period during the cardiac cycle when stimulation or activation by a propagated impulse results in a repetitive response or fibrillation. The term is primarily used in the laboratory setting.

Circus movement: A phenomenon of repetitive reentrance in which the site is seldom discernible in the electrocardiogram. This is mainly an electrophysiologic term.

Terms To Be Avoided

Chaotic rhythm: This term is better avoided since it is difficult to define. (See description of multifocal tachycardia.)

Reversed coupling (return extrasystole): Resetting of the sinoatrial node by an ectopic atrial impulse or ventricular impulse conducted in retrograde manner. This causes a fixed time relation between the ectopic impulse and the following sinus discharge. However, considering the definition of coupling (see description of coupling interval), there seems to be no need for the term *reversed coupling*.

Antegrade conduction: See description of antegrade conduction.

Reciprocation: Continued reentry (circus movement) leading to several activations of a cardiac chamber. (See description of reentry.)

Reciprocal or reentrant impulse: See descriptions of reentry and reciprocation.

Lown-Ganong-Levine (LGL) pattern: A pattern characterized by a short P-R interval and normal QRS complex. The Lown-Ganong-Levine syndrome implies the presence of tachycardia.

Accelerated conduction: This term implies an electrophysiologic mechanism that has not been demonstrated.

Preferred Miscellaneous Terms

Cardiac electrogram: A unipolar or bipolar record of electrical activity of the heart, taken with the electrode or electrodes within a cavity of the heart or in contact with the myocardium (direct leads) (for example, intracavitary electrogram or epicardial electrogram). Cardiac electrograms can be further defined according to the position of the recording electrodes, that is, according to the proximity of the structure whose activity one wishes to record. Thus, intracavitary electrograms may be recorded from the right or left atrium (high or low), from the region of the atrioventricular (A-V) junction (A-V junctional electrogram), from the ventricles, and so forth. An A-V junctional electrogram may be labeled a *His bundle electrogram* (*HBE*) when a His bundle deflection is recorded.

Refractory period: The period in the cardiac cycle during which the conduction system or the myocardium (or both) demonstrates an altered response or no response to a stimulus.

Relative refractory period: That interval in the cardiac cycle during which the excitability threshold is higher and conduction is slower than during recovery (diastole).

Absolute refractory period: That period in the cardiac cycle during which the heart is not excitable.

Electronic Pacemakers

In describing the function of the pacemaker, the following observations should be made: pacing function (capture-noncapture, status of sensing) in both demand and fixed (magnetic) modes, configuration of paced complexes, pacing rate and interpretation of intrinsic or competing cardiac rhythms. The chamber paced is identified by V for ventricle, A for atrium, and D for double (both atrium and ventricle) (Table I).[155] The chamber sensed is again labeled V for ventricle, A for atrium. The mode of response, if any, is either I for inhibited, a pacemaker whose output is blocked by a sensed signal, or T for triggered, a unit whose output is fired by a sensed signal. The letter O indicates that a specific comment is irrelevant. Hence, the most commonly used pacemaker (ventricular-inhibited) would be designated VVI.

Complicated pacing systems can also be described functionally by no more than three letters. For example, when *two* pacemakers are implanted to achieve A-V synchrony, the ventricular pacemaker senses the atrial

TABLE I

Code for Identification of Pacemakers

1st Letter: Chamber Paced	2nd Letter: Chamber Sensed	3rd Letter: Mode of Response	Generic Description	Previously Used Designation
V	O	O	Ventricular pacing; no sensing function	Asynchronous; fixed rate; set rate
A	O	O	Atrial pacing; no sensing function	Atrial fixed rate; atrial asynchronous
D	O	O	Atrioventricular pacing; no sensing function	A-V sequential fixed rate (asynchronous)
V	V	I	Ventricular pacing and sensing, inhibited mode	Ventricular inhibited; R-inhibited; R-blocking; R-suppressed; noncompetitive inhibited; demand; standby
V	V	T	Ventricular pacing and sensing, triggered mode	Ventricular triggered; R-triggered; R-wave stimulated; noncompetitive triggered; following; R-synchronous; demand; standby
A	A	I	Atrial pacing and sensing, inhibited mode	Atrial inhibited, etc. (See VVI, but substitute atrial P wave for ventricular R wave)
A	A	T	Atrial pacing and sensing, triggered mode	Atrial triggered, etc. (See VVT, but substitute as in AAI)
V	A	T	Ventricular pacing; atrial sensing, triggered mode	Atrial synchronous; atrial synchronized; A-V synchronous
D	V	I	A-V pacing; ventricular sensing, inhibited mode	Bifocal sequential demand; A-V sequential

A = atrium; A-V = atrioventricular; D = double chamber; I = inhibited; O = not applicable; T = triggered; V = ventricle.

pacemaker that both stimulates and senses the atrium.

Format of the Electrocardiogram

The electrocardiographic report is a consultation for the use of physicians in patient management. The key factor is the competence of the interpreter, who should have adequate theoretical knowledge and practical experience. The electrocardiographer should be familiar with the fundamentals of cardiac electrophysiology, which include (1) the genesis of electric activity, that is, cardiac action potential; (2) the spread of activation; (3) properties of the volume conductor; and (4) lead system and recording apparatus. Further, the electrocardiographer should understand the principles underlying the role of the electrocardiogram in determining cardiac position, extracardiac influences, detection and localization of various acute, transient and permanent structural abnormalities, pharmacologic and metabolic effects, and analysis of events related to automaticity, conduction and refractoriness.

The electrocardiographic report should not include evaluations of functions that are beyond the scope of electrocardiographic analysis, such as hemodynamics, and should not contain unsupported statements about the presence or absence of heart disease.

Optimal formats for conventional electrocardiography and computerized electrocardiography may differ somewhat because of the technology employed. Many automated electrocardiographic processing programs are currently in existence[156] and, with further developments, more ways of arranging formats of display and interpretation can be expected.[157] Ideally, logic, clarity and practicality should supersede historical precedence, which now dominates the field. The format of the electrocardiogram to be described constitutes recommended guidelines rather than a rigid model for universal use. It may be modified in various ways to serve the specific needs of the users.

Electrocardiographic Display Format

Multichannel recording of several leads simultaneously is more advantageous than single channel recording, for the following reasons: (1) It allows more precise measurements of the onset and offset of deflections; (2) it captures transient events in multiple leads; (3) it provides better understanding of the activation and recovery process; (4) it facilitates production of several tracings, one of which may remain with the patient's record for the physician's immediate inspection; (5) in addition, it allows presentation of all data on a single sheet of paper, which can fit into a standard chart, thereby eliminating or simplifying the cutting and mounting.

A simultaneously recorded 12 lead electrocardiogram may be desirable; however, it is technically difficult at this time. With present techniques it is possible and practical to record three or six leads simultaneously, and obtain four sets of three leads or two sets of six leads, respectively, recorded sequentially.[158] Multichannel printouts are easily accomplished with computer techniques, but at this time telephone transmission of more than three channels is not uniformly available.

Lead Sequence

The usual sequence of recording for single channel machines is lead I, II, III, aVR, aVL, aVF, V_1, V_2, V_3, V_4, V_5 and V_6; with three channel machines, the same sequence is used in groups of three leads at a time. The three channel record is displayed with leads I, II and III aligned vertically, followed by leads aVR, aVL and aVF, then V_1, V_2 and V_3 and finally V_4, V_5 and V_6. Sometimes orthogonal vector leads X, Y and Z are recorded. Six

channel machines customarily record leads I, II, III, aVR, aVL and aVF vertically then leads V_1, V_2, V_3, V_4, V_5 and V_6. A different sequence for displaying the limb leads has also been proposed.[159] Occasionally, additional leads such as V_3R, V_4R, V_7 or leads made at higher or lower intercostal spaces are recommended.

Duration of recording: Complex to complex variations in electrocardiographic records due to cardiac or extracardiac effects make it desirable to display several cardiac complexes in each lead. Some computer programs use 5 seconds of data from each lead; this results in a 12 lead record, which occupies two conventional sheets of paper. Shorter records, using, for example, 2.5 seconds per lead, may not be as advisable for interpretation but can be displayed on a single sheet of paper along with an interpretive report. An additional continuous record (rhythm strip) is recommended when an arrhythmia is present; it should be recorded with leads that show prominent atrial activity, such as lead V_1. The rhythm strip should be at least 10 seconds in duration, and may be considerably longer in cases with intermittent or complex rhythm disturbances.

Report

Whenever practical, it is desirable to place the electrocardiogram and the basic components of the report on the same sheet of paper. The report consists of (1) identifying data, (2) essential measurements, (3) description, and (4) interpretation.

Identifying data: Each electrocardiogram should be identified with the patient's name, patient identification number if available, and the location, date and time of the recording. To minimize the possibility of error, this information should be placed on each sheet of the record immediately after completion of recording. The addition of a code number identifying the technician and recording instrument is recommended for quality control. The minimal patient information required for electrocardiographic interpretation includes age, sex and history of cardiac medications. The absence of this information seriously hinders preparation of a definitive report. Other information useful for interpretation are race, body build, blood pressure, tentative clinical diagnosis, clinical status (preoperative, for example) and noncardiac medication such as phenothiazines that may affect the electrocardiogram. The body build may be described by height and weight measurements, but if these are not readily available, a code may be used to identify body build (obese, slender, and so forth). Observations by the technician concerning an unusual position of the patient during the recording procedure (for example, sitting), or presence of thoracic deformity, amputation, respiratory distress or muscle tremor should be included in the report.

Measurements: Measurements should include atrial or ventricular rate, or both, and P, P-R, QRS and Q-T (Q-Tc) intervals. The mean P, QRS and T axes may be included. In some formats, electrical position is included under measurements or description.[160]

Description: The description of the various components of electrocardiographic complexes, if relevant to establishing the criteria for interpretation, should be made in logical order from P to U waves. The relevant changes from previous tracings should be indicated.

Interpretation: This should include (1) statements concerning the rhythm (for example, sinus rhythm with ventricular premature complexes); (2) diagnostic statements; (3) comparison with previous tracings; (4) comments; and (5) classification statement.

If the technical quality of the electrocardiogram is not satisfactory, the report should state the reasons (for example, incomplete electrocardiogram, baseline wander, noisy tracing, artifact present, muscle artifact, 60 hertz artifact, poor frequency response, overdamped, underdamped, incorrect mounting, upside down lead or leads, mislabeled lead or leads, calibration absent, calibration error [specify in millimeters per millivolt]).

Diagnostic statements may describe specific cardiac disease, such as inferior myocardial infarction, or unusual findings that do not have a known relation to pathologic states, such as nonspecific (nondiagnostic) T wave changes. The most likely cause or causes of electrocardiographic features may be added whenever feasible.

Comments reflecting the interpreter's impression are useful at the end of the report: These include, when pertinent, recommendations for serial studies or special studies.

Classification: The classification should summarize the interpreter's overall impression of the measurements, description, rhythm and changes. The record may be classified as normal, abnormal, borderline (probably normal), borderline (probably abnormal), atypical or normal variant. From a practical standpoint, such classification is very helpful to the nonelectrocardiographer.

Physician identification: The report should identify the physician who prepared or reviewed the record.

Summary and Conclusions

The format of the electrocardiogram and the report must be comparable in quality to a consultation, but the format may be tailored to the specific needs of the user. The report may be arranged differently and may be omitted or combined. In the final analysis, the aim of the electrocardiographic report is to assist the clinician in managing the patient.

The use of standard terminology, criteria and format should decrease variability and error in interpretation and communication of electrocardiographic information. This should be true regardless of whether the information is conveyed in a computer report or in consultation between physicians. We recommend the best standards available at the present time and development of additional ones as indicated. We also recommend that a project to identify criteria for electrocardiogram-based statements be completed as soon as feasible, and that collection of a data base for evaluation of criteria requiring nonelectrocardiographic confirmation be continued and expanded.

Acknowledgment

We are indebted to WHO Task Force on Definitions and Classifications of Cardiac Arrhythmias for permission to review their Draft Report,[154] which formed the basis of this report.

We are deeply indebted to the following consultants for their critical review:

Task Force 1A: Development of a Data Base for Electrocardiographic Use

ARTHUR HAGAN (CHAIRMAN), COLIN BLOOR, RAY BORUN, LARRY JACKSON, CHARLES GOETOWSKI, HERMAN WOLF, JOHN HOLT, DONALD C. HARRISON, WARD CHAMBERS, BOB STRATBUCKER, P. M. RAUTAHARJU, PATRICK LAWRENCE

Although considerable effort has been expended to develop criteria and terminology for standardized electrocardiographic analysis, controversy remains. Much of this controversy results from failure to reach agreement on widely acceptable electrocardiographic criteria for defining cardiac abnormalities. To assess the correlation between cardiac abnormalities and electrocardiographic findings it is essential to have extensive independent data.

The goals of this Task Force were to determine what independent data are necessary to establish diagnostic criteria and validate electrocardiographic interpretations. Additionally, there was an attempt to provide a data exchange format that would also be useful for collection, storage and retrieval of these data.

Objectives

The reasons for establishing protocols and collecting a large data base can be summarized:

1. To improve existing and define new electrocardiographic criteria
2. To provide support for better standardization of criteria and terminology
3. To improve communication and teaching of physicians and allied health personnel
4. To enhance present and future programming efforts to develop standards for computer electrocardiographic program testing and validation
5. To promote collaborative clinical research among institutions by employing compatible techniques in data collection

To meet these needs the design features of the data base should be specific enough to provide a means to test, validate and improve electrocardiographic diagnostic programs and yet be general enough to encourage basic and clinical electrocardiographic research.

This Task Force has identified several methodologies that may be used to conduct comparative evaluation of electrocardiographic programs and has taken the position that program evaluation should be delayed until methods of evaluation are better defined and agreed upon. To accomplish these goals it is important to establish clinical protocols to improve electrocardiogram-independent criteria.

This task force also divided electrocardiographic interpretations into three different categories:

A. Statements documented by electrocardiogram-independent data (hypertrophy and infarction, for example)

B. Statements based upon electrocardiogram-dependent criteria (arrhythmias and conduction disturbances, for example)

C. Purely descriptive statements that do not imply a specific diagnosis (axis deviation and certain repolarization abnormalities, for example)

The development of a data base for electrocardiographic use should be oriented initially to provide improved criteria for statements that the Task Force, considering the role of computers, has included in Category A.

General Guidelines for Data Base

The establishment of specific protocols for electrocardiogram-independent data should be structured to encourage collaboration among several institutions. Our purpose is to define the data for collection but not to identify the computer file structure or retrieval methods

to be employed. *General features of the data base should include:*

1. Common means of coding, identifying, and selecting patients
2. Machine readable and readily retrievable data that are interchangeable among institutions
3. Well defined objective quantitative data measurements and recording
4. Minimizing of investigation and variability by limiting subjective impressions
5. Mechanisms for quality control and periodic data review for accuracy and completeness
6. Techniques that assure patient privacy
7. Data collection techniques that interface with other ongoing studies whenever possible

Identification and Justification for Electrocardiogram-Independent Data

There is general agreement that the data base should include, but not necessarily be limited to, information of three basic types:

I. Historical data
II. Clinical measurements
   A. Coronary care unit
   B. Laboratory
   C. Echocardiography
   D. Cardiac Catheterization
III. Autopsy data

These specific categories were selected for the data base because they are commonly available, are meaningfully correlated with electrocardiographic abnormalities, can be best quantitated and reproduced and represent information most likely to reflect specific cardiac pathology.

Summary of Data Base Format

To determine the content necessary for an electrocardiogram-independent data base the Task Force examined several data collection forms from on-going collaborative studies in the United States and Canada. The design of each section within the protocol reflects the specific information considered important for the shared data base although each collaborative institution may use any format desired for its own data collection and storage. The data base protocol is assembled into three general categories: (I) historical data; (II) clinical measurements; and (III) autopsy data. The data sources included in the clinical measurements are limited to four: (A) coronary care unit; (B) laboratory; (C) echocardiography; and (D) cardiac catheterization.

The information requested in the history section is quite broad. However, it is considered important because of the potential influence upon a given electrocardiographic interpretation. The details included in the coronary care unit and laboratory sections are essential to confirm or exclude certain specific cardiac diagnoses. The measurements in each of the other sections—echocardiography, cardiac catheterization and autopsy—are sufficiently detailed and quantitative to provide in-depth information. The autopsy measurements have been selected to be most appropriate in relation to the clinical variables recorded in the other categories.

Conclusions and Recommendations

This task force makes the following conclusions and recommendations:

1. It is necessary to establish more objective electrocardiographic criteria for cardiac pathology. For basic and clinical research in electrocardiography to provide improved interpretations, comparison of electrocardiogram-independent data with electrocardiographic diagnoses is necessary.
2. An electrocardiogram-independent data base from several collaborating institutions should be encouraged. The Bethesda Conference in conjunction with the electrocardiographic Committee of the American Heart Association should recommend funding to support such a national data base collection.
3. It is necessary to review periodically the electrocardiogram-independent data base necessary for electrocardiographic evaluation and validation.

It is recommended that an ad hoc committee of the American College of Cardiology and the American Heart Association be established to encourage data base studies (and funding for such studies) and to review periodically the data base requirements for electrocardiographic research. This ad hoc committee should coordinate the implementation and ongoing effort of data collection.

Task Force II: Quality of Electrocardiographic Records

L. THOMAS SHEFFIELD, MD, FACC (CHAIRMAN), RONALD PRINEAS, MB, PhD, FACC, HOWARD C. COHEN, MD, FACC, ANDREW SCHOENBERG, PhD, VICTOR FROELICHER, MD, FACC

In dealing with the quality of electrocardiographic records, we have attempted to identify and recommend the best accepted practices without making cost-effectiveness comparisons. Electrocardiographic quality begins with the skill of the recording technician, and we have examined means of developing this skill. It is dependent upon the fidelity of the recording and transmitting hardware, which we have evaluated. The efficiency and accuracy with which the electrocardiogram can be put to clinical use is dependent upon recording and ancillary data format. Storage and retrieval of electrocardiograms and ancillary data are required to

provide continuity of quality electrocardiography. The culmination of the electrocardiographic process is the clinical interpretation of the tracing. The medical and legal responsibilities of those concerned with electrocardiographic interpretation were explored.

In recommending any practice or process, we have sought the best recognizable state of the art consistent with established reliability. Where available evidence reveals no clear method of choice, we have attempted only to report this fact, sometimes with comment.

The quality of electrocardiograms and of their interpretations in daily practice is a representation of the extent to which theoretical electrocardiographic understanding and contemporary technology have been applied to clinical medicine.

Technician Training

An essential step in good electrocardiography requires that proper technique be consistently employed by technicians. Although newer electrocardiographs are more able to compensate for poor technique, technicians need some skill.

Prior Experience

An electrocardiographic technician need not have had prior professional experience. Any person of average intelligence can be taught to record high quality elective electrocardiograms during rest. We recognize that there are different levels of requirement, from technicians with minimal skill in exercise electrocardiography to experienced technicians in cardiac laboratories who, besides recording electrocardiograms at rest and during exercise, interpret Holter monitoring data and record other noninvasive cardiac performance measurements. On-site training in these laboratories is probably the most efficient way of producing electrocardiographic technicians of high caliber.

Training Requirements

As a minimal requisite, all electrocardiographic technicians should have a core training instruction that includes knowledge of the following:

1. Artifacts due to (a) improper electrode application; (b) powerline interference; (c) muscle tremor; and (d) peculiarities of the specific electrocardiograph in use.
2. Proper format of recording.
3. Recognition of patterns that require additional electrocardiographic recording.
4. Basic tests of performance of the electrocardiograph to include a check on proper paper speed and calibration pulse.

Electrode application: Instruction in electrode application should include knowledge of:

1. The proper position for standard 12 lead recording and optional lead systems (see record format). The use of devices for proper location of chest leads[1] is encouraged.
2. Proper skin preparation.
3. Recognition of artifacts due to lead reversal, loose electrodes or improper lead cable attachment.

Powerline and other types of artifact: Electrocardiographic technicians should learn to recognize alternating current interference. They should also be taught the common causes of such artifacts and methods for correcting them.

The causes of muscle tremor and ways of recognizing artifacts due to such tremor and of correcting them should be taught. Other causes of electrocardiographic artifact (coughing, respiratory variation, and so forth) should be illustrated during training of technicians.

Operation of specific electrocardiographs: Technicians should use manufacturers' instruction booklets for use and maintenance of specific machines. These instructions should be carefully explained by the training staff.

Recording format: The particular recording format in use should be explained to technicians, with provision of a checklist to ensure correct reading of *all* data.

Electrocardiographic interpretation: It is desirable that technicians have a summary understanding of the genesis of electrocardiographic waves so as to recognize arrhythmias requiring extra recording and the presence of lead switch applications and "alert" situations for an electrocardiographer.

Test of performance of the electrocardiograph: Technicians should be taught to recognize overdamping, underdamping, sensitivity setting and decay rate acceptability. They should be able to recognize signals indicating that manufacturer maintenance checks need to be carried out.

Form of Training

Training should be on-site for most purposes. In research studies, specific group instruction is mandatory for uniformity. Training manuals[2] have been published and also are produced by some manufacturers.

Examples of poor quality tracings, with their cause and correction, should be available. Electrocardiographic technicians' societies should be encouraged to provide such examples. Minimal acceptable limits (as described under "Record Format") should be adhered to.

Before commencing routine electrocardiograms, technicians should submit 5 to 10 tracings recorded by themselves to be "certified" by the local electrocardiographer.

Continuing quality control: Continued production of good electrocardiograms is best achieved by immediate feedback from electrocardiographers who have to interpret the tracings. As to the use of computer-read electrocardiograms, programs to detect records of unacceptable quality can be used to relay the same information. Apart from immediate feedback, a periodic summary stating the proportion of poor-quality tracings can be used to determine whether retraining is necessary. For such feedback, therefore, each technician should write his or her identification number on each record.

Record Format

Number of electrocardiographic channels: The single channel electrocardiograph has the lowest purchase price and smallest size; for these reasons, it is usually preferable for portable use and for use in physicians' offices and small hospitals.

Three simultaneous electrocardiographic channels allow superior interval measurements as well as time-coherent measurement of wave form vectors. Standard instrumentation exists for transmitting three simultaneous channels by telephone and radio; this number of channels may be simultaneously recorded on the most modestly priced instrumentation tape recorders. Existing three channel electrocardiographic recording facilitates visual interpretation of the tracing by the use of automatically formated records. Therefore, automatic three channel recorders will be preferred by most users who record a sufficient volume of electrocardiograms to justify the higher purchase cost of three channel equipment.

TABLE I

Lead Nomenclature

Electrode	Location of Attachment[8]
Right arm (R)	Right wrist
Left arm (L)	Left wrist
Left foot (F)	Left ankle
Right foot (G)	Right ankle
V_1	Right sternal margin, 4th intercostal space
V_2	Left sternal margin, 4th intercostal space
V_3	Midway between V_2 and V_4
V_4	Left midclavicular line, 5th intercostal space
V_5	Left anterior axillary line, V_4 level
V_6	Left midaxillary line, V_4 and V_5 level
V_7 and V_8*	Left posterior axillary line and left midscapular line, V_6 level
Leads* recorded on right side of thorax, such as	V_4R-right midclavicular line, 5th intercostal space

* Optional leads.

Number of leads recorded for resting electrocardiograms: A standard resting electrocardiogram should contain a minimum of the 12 conventional leads (3 Einthoven limb leads,[3] 3 augmented unipolar limb leads and 6 Wilson chest leads).[4] The additional recording of the Frank orthogonal leads[5] or some other combination of leads is optional.

Sequence of lead recording: Einthoven limb leads should come first, in numerical order, followed by augmented unipolar limb leads (aVR, aVL, aVF sequence), followed by the precordial leads in numerical sequence. These should be followed by the optional leads. When lead V_4R[6] is recorded, it may be inserted wherever desired in the sequence; however, it must be appropriately marked. For strictly practical considerations,* we recommend that lead V_4R be located in the position usually occupied by lead V_4 when automatic three channel electrocardiographs are used.

Nomenclature: The lead nomenclature recommended by the American Heart Association[7] is used to identify each lead: I, II, III, aVR, aVL, aVF, V_1 to V_6 and V_4R.

Location of electrodes: The electrodes for recording the standard resting 12 lead electrocardiogram are located according to Table I.[8] The precordial (V) electrodes (but not the limb electrodes) are located as shown in Figure 1. Location of electrodes for stress testing are described in Table II.

When it is impractical to attach electrodes on one or both wrists or ankles, this fact should be noted on the record and the electrode or electrodes attached more proximally on the limbs as necessary. If it is impractical to attach chest electrodes at their exact locations but it is possible to attach them within one interspace width of the correct location, this is permissible provided the details of the translocation are furnished with the tracing. Otherwise the affected electrodes are not attached and the reason therefore recorded and furnished with the tracing.

Length of leads recorded: 1. *For wave form interpretation,* a minimum of 2.5 seconds of recording is required, provided satisfactory technical quality of recording prevails.

* By displacing only one electrode instead of four, the likelihood of error in electrode positioning is minimized. That situation applies when the lead V_4 electrode is simply put on the right side of the chest contrasted with the situation required if all four electrodes, V_1 through V_4, are specially positioned to accommodate lead V_4R.

TABLE II

Some Bipolar Leads Used in Conjunction With Stress Testing

Lead	Positive Electrode Location	Negative Electrode Location	Comments
CM_5*	V_5 position	Manubrium	One of the most sensitive bipolar leads for detecting S-T changes
CH_5	V_5 position	Forehead	Favored in Sweden, especially for bicycle tests
CS_5	V_5 position	Right infraclavicular fossa	Detects somewhat more muscle artifact than lead CM_5
CC_5	V_5 position	V_6R position	Bears a closer resemblance to lead V_5 than most bipolar leads
CB_5	V_5 position	Low right scapula	Closely resembles lead V_5 but has more muscle artifact than most other bipolar leads
CR_5	V_5 position	Right arm	Used in northern Europe and USSR for pre- and postexercise records, usually with 4 to 6 chest lead positions. High muscle artifact level during exercise

* The number 5 refers to the position on the chest of a corresponding V lead such as V_5. Thus the positive electrode could be located in any numbered V lead position.

TABLE III

Electrode Locations for Exercise

Electrode Designations	Location on Body
	Frank Lead System, Exercise Modification*
A	Left midaxillary line, level of 5th interspace at the left sternal border
C	"45 point," level of 5th interspace at the left sternal border
E	Center of breastbone (sternum), level of 5th interspace at the left sternal border
F	Left lower abdomen (near anterior superior iliac spine)
G†	Right lower abdomen (near anterior superior iliac spine)
H	head (forehead); located near one side of the forehead near hairline
I	Right midaxillary line, level of 5th interspace at the left sternal border
M	Middle of back, level of 5th interspace at the left sternal border
	12 Lead Electrocardiogram, Exercise Modification
F	Left lower abdomen (near anterior superior iliac spine)
L	(Left arm), lateral aspect of left infraclavicular fossa
R	(Right arm), lateral aspect right infraclavicular fossa
V_1	Fourth interspace, right sternal border
V_2	Fourth interspace, left sternal border
V_3	Midway between lead V_2 and V_4
V_4	"45 point," level of 4th interspace at the midclavicular line
V_5	Midway between lead V_6 and V_4
V_6	Left midaxillary line, same horizontal level as lead V_4

* We recommend the modification employed by the Lipid Research Clinic Project, using the Frank electrodes designated A, C, E, I, M, H and F

† Patient ground.

2. *For rhythm interpretation,* a minimal continuous recording of 6 seconds is required.[9] This will permit recognition of the vast majority of cardiac rhythms, but in special instances, and particularly for the less commonly recognized arrhythmias, much longer records will be elected.

3. *For computer interpretation,* the length of record will be specified by the particular computer program used. To collect records for future computer analysis and to assure compatibility with all systems in current use, a minimum of 10 seconds of recording of each lead group is required, because current interpretive program requirements range from slightly more than 2 seconds to 10 seconds per lead group.[10]

Standardization: A 1 mv calibration pulse should be inserted at the beginning or at the end of the conventional 12-lead sequence. If the entire electrocardiogram is not recorded at the same deflection sensitivity, the exact sensitivity of each portion of the recording should be indicated appropriately.

Tracing quality: This includes the correctness of the identification data and of the clinical information furnished with the request for an electrocardiogram, as well as the date and time of recording. This also includes correctness of electrode application, baseline stability, baseline "jiggle," muscle artifact and powerline artifact (see Appendix I). Also affecting tracing quality are the qualities of the electrocardiograph (dealt with elsewhere), especially the fidelity of chart paper transport speed, stylus deflection accuracy and linearity, overall frequency response and common-mode rejection.

Ancillary patient data: It is recommended that ancillary patient data accompanying the electrocardiogram include the name of the subject, age, sex, race, drugs being taken, electrolyte status if known, height, weight and clinical diagnoses. These items constitute prior probability patient data that may enhance interpretation of the electrocardiogram both by certain computer programs and by human electrocardiographers, and therefore these data should be supplied with the request for the electrocardiogram.

Exercise Test Records

Preexercise Records

The resting control electrocardiogram should be recorded immediately before exercise and interpreted before proceeding with the test. It should be recorded at least 2 hours after eating, drinking or smoking, except under special test circumstances, and should include at least 12 conventional leads, optionally the Frank leads, and whichever lead pattern will be used for recording during and after exercise. The resting control electrocardiogram is recorded with the patient in the recumbent position, the standing position and in the position (such as sitting) used during the postexercise period. The mimimal time for recording the exercise electrocardiographic pattern is 5 seconds for each record. This shall not be construed to place any special limits on the record length requirements of computer analytical systems for the exercise electrocardiograms.

Exercise Records

The exercise lead pattern should consist of at least two simultaneous leads and preferably three leads. There is not sufficient information available to make a definitive requirement concerning the number of leads to be recorded during and after exercise, although persuasive data indicate that the more leads recorded, the greater the resulting test sensitivity.[11,12] Conventional Wilson V leads are preferred, but if bipolar leads are used, at least one should be lead CM_5, and no other leads should share the CM_5 precordial electrode. This procedure is used to ensure the maximal amount of diagnostic data acquisition from the exercise test, but also as a fail-safe technique to avoid loss of both electrocardiographic leads during the exercise test as the result of a single electrode failure.

Electrode locations: The locations of electrodes for some commonly used electrographic lead systems[13] are shown in Table II and Figure 1. The Frank lead system is described in Table III.

Hyperventilation electrocardiogram: This is strictly an optional record, but if used it should consist of at least a 5 second record of the electrocardiogram before and after the hyperventilation maneuver.[14] Be-

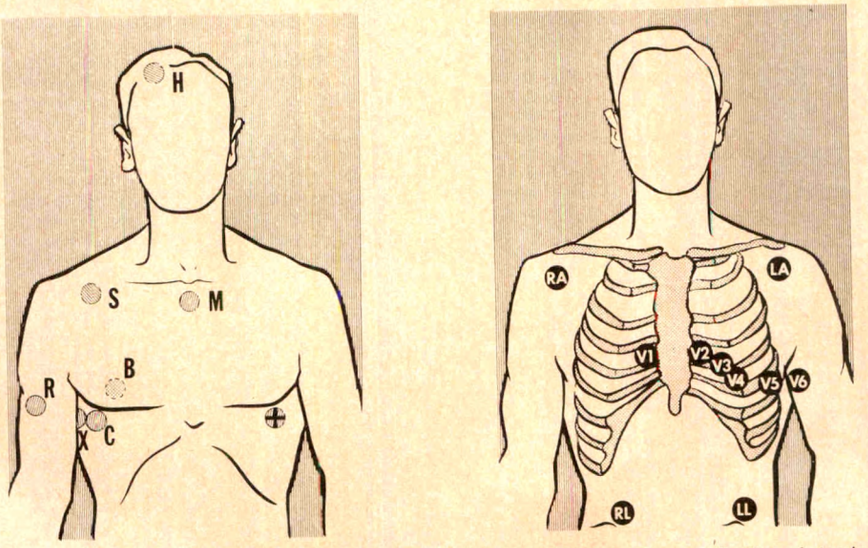

FIGURE 1. Electrode locations. **Left,** for bipolar precordial leads. **Right,** for the Mason-Likar exercise modification of standard electrocardiographic leads. B = back over low right scapula; C = V_5 position on right side of chest; H = head; LA = left arm; LL = left leg; M = manubrium; R and RA = right arm; RL = right leg; S = right infraclavicular fossa; + = V_5 position.

TABLE IV

Electrocardiographic Storage Media

Electrocardiographic paper
Wax-treated paper requiring a hot stylus recorder
Thermochemical-treated paper requiring a hot stylus recorder
Permeable ceramic-coated paper requiring direct contact with ink jets under high pressure
Untreated paper requiring ink jet or carbon-transfer recorders
Xerographic paper reduction of the electrocardiogram
Microfilming
35 mm on aperture cards
16 mm film in rolls or in microfiche jackets
Analog
Reel-to-reel tape
Cassettes
1/2 inch (1.27 cm) tape on Hollerith cards
Digital
Digital tape system
Floppy disc
Disc pack
Bubble memory (for the future)

fore studies proceed, these two records should be interpreted and any changes resulting from hyperventilation should be allowed to subside before exercise is continued.

Electrocardiographic recording during exercise: A continuous display of two or more leads by means of cathode ray oscilloscope should be displayed throughout exercise. Hard copy of recordings of at least 5 seconds' duration should be made every 3 minutes during exercise, with every change of work load, upon the appearance of any significant subjective or objective change in the test subject and upon the appearance of any significant change in rhythm or QRS-T contour during exercise, whichever occurs first, and at the end of exercise.

Postexercise electrocardiogram: A conventional 12 lead electrocardiogram should be recorded immediately after exercise with the patient in the same body attitude as for the preexercise control record. If the full 12 leads were not those chosen for in-exercise monitoring, then it will not have been necessary to use extensive skin preparation for all the involved electrodes, as is required for those electrodes generating the in-exercise electrocardiograms. This 12 lead electrocardiogram and the exercise monitoring leads, if different, should be repeated between 2 and 3 minutes after exercise and between 4 and 6 minutes after exercise. Electrocardiograms may be recorded more frequently if desired. The time of recording with respect to termination of exercise should be written on each record.

Postexercise recordings typically cease 6 minutes after exercise, but should extend until the electrocardiogram has stabilized for up to 10 minutes if significant changes occurred.

This Task Force believes that there is an excessive number of variations in the way exercise electrocardiographic testing is carried out. These include variations in the leads chosen for recording during and after exercise, in the mode of exercise used, in the protocol used to adjust work loads and time individual work loads, in the indications for terminating the exercise stress (and, consequently, in what constitutes an adequately diagnostic exercise test procedure) and, finally, in the interpretation of the resulting electrocardiograms because of variations in both the criteria used and the rigor with which electrocardiographic changes are measured.[7] These variations should not be discouraged in clinical investigations aimed at establishing which methods of stress testing are superior for application to a particular problem, but the wide variation found in the clinical practice of exercise testing has unnecessarily restricted the diagnostic potential of the test method. This Task Force urges that a scientific basis be developed for standardizing methodology of the exercise electrocardiogram. When rigorous comparisons demonstrate clear superiority of a particular technique, this technique should be recommended for general adoption except when investigational aims call for variations.

Other Forms of Electrocardiographic Recording

In addition to rest and exercise electrocardiography, many other clinical uses are made of the electrocardiogram. Long-term ambulatory electrocardiographic monitoring, intensive care unit and operating room electrocardiographic monitoring and supplementary electrocardiographic recording on phonocardiograms, echocardiograms and cardiac catheterization records of pressures and electrograms are the most common additional uses. We recognize the importance of all of these uses but do not believe that sufficient experience has been accumulated to make standardization of their format necessary or desirable.

Storage of Records

Duration of Storage

Because of the importance of serial electrocardiographic changes, an electrocardiogram should be kept for at least 5 years and representative tracings for as long as possible thereafter. We recommend that every electrocardiographic interpretation be kept indefinitely. Storage and retrieval capabilities should be maintained so that copies of electrocardiograms or their interpretations can be forwarded to other medical facilities, with the patient's consent. In conjunction with any storage technique, a clinical interpretive code with diagnostic criteria is advisable, such as that developed at the University of Utrecht.[15] When electrocardiograms are stored for future retrieval, distortion and the effects of aging should be avoided or minimized in whatever storage medium is used. The available storage media are listed in Table IV.

Electrocardiographic Storage on Paper

Since cutting and mounting can be avoided by the use of three channel electrocardiographs, it is often now economical and advantageous to obtain two or more 12 lead tracings 8 by 10 1/2 inches (20 × 27 cm) at the bedside and to use one for filing and another for the patient's record. The longest experience has been with wax-treated paper, which is known to retain an electrocardiographic image for 20 years or longer. However, it is pressure-sensitive and easily marred. This can be alleviated somewhat by covering the paper with plastic tape, but this adds to expense and technician time. The thermochemical-treated paper is newer, sturdy and not easily marred. There are many different types of thermochemical paper, and consequently data are not available regarding the

life expectancy of electrocardiographic images on it. The ceramic-coated paper is very sturdy and comparable in price. It has a hard ceramic finish with a high contrast, which makes it durable and easy to interpret. The untreated paper is the cheapest, but the ink-jet and carbon-transfer technique record characteristically "fuzzy" electrocardiographic images. The ink-jet[16] and carbon-transfer recorders are available with up to eight channels and are expensive; however, they have an excellent upper frequency response for phonocardiography and are very popular in Europe.

Blues and reds are poorly copied by some xerographic reproduction machines. Also, the symmetrical grid of the electrocardiographic paper can be distorted. Nonetheless, with proper equipment, long-lasting file copies of electrocardiograms of excellent quality and their interpretations can be quickly and economically made.

Electrocardiographic Storage on Microfilm

Microfilming is a good primary storage medium or a parallel technique to use with computerized storage.[17] Because it is impractical to transform paper-recorded electrocardiograms into an analog or digital format, microfilming will continue to be a valuable storage technique. There are many choices in microfilming methodology, but the best and cheapest technique has not been established. With available equipment, 35 mm reproductions can be copied, developed and mounted on aperture cards in 1 minute by untrained personnel. These Hollerith cards with a 35 mm aperture for the 35 mm film can be keypunched with identification information and sorted. The 16 mm reproductions must be filmed in rolls for economical development and take at least 2 days. They usually require cutting and insertion into microfiche jackets or expensive equipment so that particular electrocardiograms may be located in the microfilm roll cassettes. Microfiche jackets have many advantages, including retention of up to 60 records, inexpensive duplication, easy scanning, and at least a 24 to 1 reduction in storage volume. Many medical data bases are being maintained in this medium, and it appears to be inexpensive and convenient. Additional rolls of microfilm are easily and economically established for security. With any microfilming technique, care must be taken to see that archival capabilities are maintained by removing less critical data achieving the proper density, and caring for the film properly. Microfilming techniques require microfilm readers and copies in strategic, convenient locations. Currently, the 8 by 10 1/2 inch paper reproductions of microfilm images are expensive and of poor quality.

Magnetic Storage of Electrocardiographic Records

Compression schemes[18] for analog or digital electrocardiographic storage must be extensively verified by independent institutions or organizations before they are accepted. These compression techniques are necessary for economical storage but can result in unacceptable distortion of the primary electrocardiographic wave form. Reconstruction of the 12 lead electrocardiogram from the vectorcardiogram is probably not valid because coefficients for reconstruction are unique for each individual.[19] Analog and digital storage is extremely dependent upon instrumentation, and scientifically sound guidelines should be followed.

The Canadian colloquium on computer-assisted interpretation of electrocardiograms[20,21] and the American Heart Association Committee on Electrocardiography[8] have outlined state of the art specifications for equipment. The Hollerith cards with 1/2 inch (1.27 cm) analog tape mounted on them can be keypunched with patient information, diagnostic codes and other miscellaneous information[23]; this permits storage of all of a person's electrocardiograms in a series of cards filed together. A special playback unit is required, but all other analog techniques require time-consuming search to identify previous records. Digital storage techniques are desirable and are rapidly becoming available because of technologic advances. Digital storage requires expensive electronic equipment, computer and a computer programs along with unproved compression schemes. Proper techniques for analog to digital conversion are important.[24] However, in conjunction with a computerized registry, a disc pack costing several hundred dollars probably will be able to store up to 100,000 electrocardiograms. Whatever storage medium is used, its limitations should be recognized so that an attempt is not made to do things with the stored data that are technically impossible, such as high frequency electrocardiographic analysis from analog tape data.

Storage of Other Records

The same quality for storage of records as previously indicated for the resting electrocardiogram is necessary for Holter monitoring and exercise test electrocardiographic recordings. When computer techniques are applied to these diagnostic procedures and an interpretation or "compressed" record is generated, it is advisable that these techniques be verified before their results become the only data stored. Signal averaging can lead to distortion,[25,26] and even computer measurements can be in obvious error since they are dependent upon imperfect algorithms. Enough of the actual recording should be made available to justify the diagnostic interpretation of appropriate portions of these tests.

Review and Recommendations on Electrocardiographic Instrumentation

Introduction

Optimal quality of electrocardiographic records cannot be achieved without accurate instrumentation for amplifying, transmitting, storing and displaying the electrocardiogram. The importance of using recorders that meet minimal performance standards has been frequently stressed by those who developed the empiric electrocardiographic diagnostic criteria.[27–29] The American Heart Association has published recommendations for standardization of leads and specifications for instruments in electrocardiography and vectorcardiography for many years.[22,30] More recently, as a result of medical device legislation,[31] the Food and Drug Administration (FDA), by contract with Utah Biomedical Test Laboratory (UBTL),[32] has drafted a performance standard for electrocardiographic devices.[35] In Europe, the International Electrotechnical Commission (IEC) has been formulating a similar standard.[34] Various Canadian groups have been concerned for several years about developing instrumentation standards[20] and evaluation criteria[35] for computer-assisted electrocardiographic processing. An instrumentation subcommittee of the joint advisory committee for the Canadian Cardiovascular Society and the Canadian Heart Foundation has recently published such a paper.[21] There are two de facto commercially used standards in regard to telephone transmission of the 12 lead electrocardiographic signals and patient identification information.[36,37]

Purpose of Standards

The purposes of these standards vary greatly. The FDA and IEC standards are intended to be enforceable standards that impose minimal safety and performance requirements. Their requirements are generally stated as "shall," and test methods for measuring compliance with the standard are carefully defined. The requirements of the American Heart Association and Association for the Advancement of Medical Instrumentation and Canadian standards, developed by voluntary consensus user groups, usually use the word "should" for requirements. They are generally intended only as guidelines and recommendations, and do not have to be met by every electrocardiographic recorder sold on the market. Lastly, there are the manufacturers' design specifications[36,37] for patient identification and 12 lead telephone transmission. These are essential for the designer of automated computer electrocardiographic acquisition and interpretation.

Scope of Electrocardiographic Instrumentation Standards

A brief review of what is covered in the various standards should help to focus attention on problem areas in electrocardiographic instrumentation and to establish a basis of the Task Force II recommendations. Requirements for 12 lead and vectorcardiographic instrumentation in general have been well defined by existing standards.[8,33,34] This is not the case for newer electrocardiographic diagnostic methods such as exercise testing, Holter monitoring and esophageal, endocardial and bundle of His recordings. Requirements for magnetic and paper recorder accuracies for rhythm strip in intensive and coronary care units are covered to a limited extent.[33,38]

The latest American Heart Association recommendations[8] cover the broadest range as regards diagnostic quality electrocardiographs including analog to digital conversion, tape recording of electrocardiograms, amplifier characteristics, auxilliary outputs and lead nomenclature and placement. The lead nomenclature and placement for endocardial and esophageal leads are proposed in detail. However, instrumentation requirements for this type of recording are not defined.[8] The FDA-UBTL standard in its coverage of electrocardiographic monitors encompasses requirements for specialized equipment such as Holter, stress test and rhythm strip recorders, but the detailed record format and accuracy requirement for these applications are not covered by any of the standards. The proposed Canadian standard[21] specifies in great detail electrocardiographic amplifier and telephone transmission characteristics for applications of computer processing. The two industrial standards[36,37] specify lead sequencing and timing, the frequency modulation, multiplexing of three channel signal and the transmission of patient identification information. Recommendations for functional requirements and tentative performance specifications for automated exercise electrocardiographic systems have been drawn up by Rautaharju et al.[39]

Comparison of Instrumentation Requirements

The performance requirements for single channel and multichannel electrocardiographic recorders are comprehensively covered by the American Heart Association, FDA-UBTL and IEC standards.[33,34] Table V summarizes the variables specified in these standards. The FDA-UBTL fourth-draft requirements have been harmonized with the IEC standards to such an extent as to require only one column in the table. The FDA-UBTL standards as well as the American Heart Association standard recommendation contain extensive rationale to justify these requirements.

The American Heart Association requirements are, with only a few exceptions, more exacting than the FDA standard. This is particularly true of the overall accuracy, common mode rejection, drift rate, standardization voltage accuracy and noise. There is little question that most recorders should not only meet the American Heart Association requirements when new, but should be maintained at that performance level when in clinical use. It is realized, however, that a total system amplitude error of less than ±5 percent and the 100 hertz frequency response can be achieved only with careful periodic maintenance and if technicians are trained to recognize abnormal performance in frequency response, trace hysteresis and paper speed.

As mentioned previously, the FDA and IEC standards are minimal enforceable performance standards that should eventually be met by all 12 lead and vectorcardiographic recorders. The FDA standard does not impose requirements on recorders already in clinics and hospitals. This is an area where the recommendation of the American College of Cardiology and the Task Force can play an important role in improving and maintaining high quality electrocardiographic recorders.

Pacemaker recording requirements, as well as ability to withstand defibrillator overloads, are covered in the FDA standard and are not specified by the American Heart Association. It is recommended that the FDA requirements be accepted in these areas.

As regards the safety requirements of patients, isolation and leakage current, the American Heart Association recommendations now exceed those being contemplated by other organizations such as the Association for the Advancement of Medical Instrumentation, Underwriters Laboratory and National Fire Protection Association. The leakage current standard[42] of the Association for the Advancement of Medical Instrumentation is undergoing balloting at the American National Standards Institute to determine whether it should be adopted as a standard approved by the Institute. If such is the result, the FDA is most likely going to adopt it as an FDA baseline standard. The problem with accepting the more exacting American Heart Association recommendations is that several of the leakage currents, that from chassis to ground and that resulting when 120 volts are applied to the leads, cannot be met by many manufacturers without redesign and certainly not by older equipment still in use in hospitals.[32]

Computer Communications and Electrocardiographic Transmission

Several standards are in use or have been proposed in the area of transmission of electrocardiographic signals over telephone lines and telecommunications facilities.[8,21,36,37,41]

TABLE V

Functional Performance Requirements of the Food and Drug Administration (FDA) and American Heart Association (AHA) for Direct Writing Electrocardiographs

Requirement Description	Minimal or Maximal	Units	Minimal or Maximal Value of Performance Variables	
			FDA Type I	AHA
Range of linear operations of input signal	Minimal	mv	±5	±7
Skew rate range	Minimal	mv/sec	320	400
Direct current offset voltage range	Minimal	mv	±300.0	±200
Allowed variation of amplitude with direct current offset	Maximal	%	±5	±5
Gain control chart recorder	Minimal	mm/mv	10 and 5	20,10,5
Gain drift rate				
After first minute	Maximal	%/min	±0.33	NS
Total drift in 1 hour	Maximal	%	±5	±2
Speed selection	Minimal	mm/sec	25 and 50	25 and 50
Speed error				
For 0.20 to 2 second recording	Maximal	%	±5	±5
Recordings greater than 5 seconds	Maximal	%	NS	±2
Width of display	Minimal	cm	4	5
Divisions on preruled paper	Minimal	div/cm	10	10
Error of rulings	Maximal	%	±2	±2
Trace width	Maximal	mm	1	1
Reading visibility	Minimal	mm/sec	1600	2000
Time marker error	Maximal	%	±5	±2
Allowable error for ±5 mv signals	Maximal	%	±10	±5
	or			
	Maximal	μv	50	25
Upper cutoff frequency (3 DB)	Minimal	Hz	100	100
Allowable overshoot to step response	Maximal	μv	100	NS
Decay time constant after step input	Minimal	sec	3	3.2
Error in electrode weighing factors	Maximal	%	5–10	±7
Hysteresis	Maximal	μv	50	20
Standardization nominal value	. . .	mv	1.0	1.0
Allowable deviation from value obtained with 1 mv at leads	Maximal	%	±5	±2
Input impedance any lead at 10 Hz—variable with frequency	Minimal	MΩ	2.5	2.5
Direct current any lead	Maximal	μA	0.1	1.0
Common mode rejection-allowable noise				
With 28 v, 60 Hz and ±300 mv DC and 5 kΩ imbalance	Maximal	μA	100	NS
With 336 v, 60 Hz applied through 22 pF capacitor and 100 kΩ imbalance	Maximal	μv	NS	2000
Noise internal RTI—p-p	Maximal	v	40	28
Multichannel cross talk	Maximal	%	2	1
After reset by automatic or manual means, return time to within linear recording range	Maximal	sec	3	NS
To within 1 mm of center	Maximal	sec	NS	0.5
To within 3 mm of baseline after lead switching	Maximal	sec	1	NS
Baseline drift rate RTI	Maximal	μv/sec	10	NS
Total drift RTI	Maximal	μv in min	500 in 2	50 in 50
No damage differential voltage 60 Hz				
Applied for 10 seconds	Minimal	v p-p	1.0	NS
Applied for 5 seconds through 100 pF capacitor	Minimal	v p-p	NS	336
Defibrillator protection			Yes	Yes
Overvoltage (applied to 100 ohm load and electrodes)	Maximal	v	5000	336
Energy (applied to 100 ohm load and electrodes)	Maximal	J	400	NS
Pacemaker display capability pulse	Maximal	mv	500	NS
Duration		msec	1	NS
Leakage current for isolated leads	Maximal	μA	20	10
Chassis	Maximal	μA	100	10
With 120 v applied to electrodes	Maximal	μA	20	6

NS = not significant; RTI = electrocardiographic amplifier input.

TABLE VI

Instrumentation Standards for Electrocardiographic Transmission and Computer Acquisition

Variables	Units	Canadian[21] 1976	AHA[8] 1975	Commercial Type 1[37]	Commercial Type 2[36]	Emergency Telemetry[41]
Dynamic range						
Maximal signal	mv	±5	±7	±5.0	±5	±5
Minimal DC offset	mv	ns	±200	±200	±400	ns
Frequency response						
Upper 3 db	Hz	125	100	100	100	40
Lower 3 db	Hz	0.05	—05	dc	dc	0.01
FM transmission						
FM carrier ch 1	Hz	1075	1075	1075	1075	1400
FM carrier ch 2	Hz	1935	1935	1935	1935	na
FM carrier ch 3	Hz	2365	2365	2365	2364	na
Sensitivity	Hz/mv	50,25	ns	50,25	−40,−20	30 to 50
Maximal signal	mv	±2.5,±5	ns	2.5,±5	±2.5,±5	±50
Patient identification code		TT	TT	TT	ASCII	Voice
Allowable error (1 mv)	%	±3	±5	±5	±2	ns
Allowable noise rms	μv	<5	<10	<5	<20	<10
Computer sampling						
Resolution ECG	μv	10	10	1.25	5	na
Resolution A/D	bits	10	10	12	10	na
Minimal sampling rate (samples/sec)		500	500	250	250	na
Maximal skew between channels	μsec	100	1000	1300*	2000‡	na

A/D = analog to digital; AHA = American Heart Association; ch = channel; DC = direct current; ECG = electrocardiogram; FM = frequency modulation; na = not applicable; ns = not specified; rms = samples/sec; TT = touch tone.
* Skew due to the A/D conversion process only.
‡ Total recording system skew.

All of the proposed standards, except for emergency telecommunications,[41] are concerned with transmitting three channel electrocardiographic signals of full diagnostic quality.

Table VI is a summary of proposed design standards. Note that there is substantial agreement in terms of dynamic range, frequency response and frequency modulation characteristics. The center frequencies for the three channel electrocardiographic transmission—1,075, 1,935 and 2,365—are standardized bases on the Bell 604 data sets. The allowed deviation of frequency around these center frequencies varies considerably in that the Canadians recommend no more than ±125 hertz (Hz); one commercial type no more than ±100 Hz; and the other ±125, but allows ±175 Hz to extend the dynamic range. Note that in all cases except for emergency transmission, the standard gain of 1,000 can be used only for up to a signal of ±2.5 mv. This corresponds to a ±2.5 cm deflection of the chart recorder at a gain of ±10 mm/mv. An incompatibility in frequency modulation gain exists between the type 2 commercial system (−40 Hz/mv) and that used by others (+50 Hz/mv). This incompatibility is extended in that the Canadian and the commercial type 1 standards use the touch tone coding for transmitting lead identification and patient information, while the commercial type 2 transmits frequency-modulated ASCII code at 110 band rate. The ASCII system had the advantage of direct compatibility with many computer languages using ASCII code, the flexibility of both alphabetic and numeric transmission and ability to sense errors by using a parity bit transmission. The touch tone system is simpler and more compatible with the standard telephone lines. The disadvantage of having two systems is that electrocardiographic transmission cart and computer interface hardware and input and output software cannot easily be made compatible. It is in the public interest if the users of telephone transmission are not restricted in their options of computer use by incompatible services of two systems.

The Task Force concurs with the recommendation of the American Heart Association and the Canadian group of sampling each channel at 500 samples/sec, in particular where data bases for empiric diagnostic criteria are being collected. The Task Force realized that most electrocardiographic computer analysis programs use the 250 sample/sec rate,[10] and this is acceptable where the makeup and diagnostic accuracy of the program justify it.

It is of paramount importance that the total recording, transmission and sampling system be such as to preserve the fidelity of the expected range of electrocardiographic signals. At a minimum, this means that the dynamic range of the total system be as good as that of the direct writer. Any signal recorded on the chart paper should be capable of being modulated and demodulated with minimal distortion in time and amplitude and without amplitude clipping. The analog to digital converter input voltage range should coincide with or exceed the voltage range produced by the demodulator. Finally, electrocardiographic signals in the range between +5 and −5 mv should be capable of being reproduced at the end of the transmission system with no visible difference from that recorded directly from the patient.

Instrumentation for exercise testing includes both a monitor scope and a direct writer. Since S-T segment change is the main variable to be measured, fidelity of the signal recording, particularly in the low frequency range, is essential. It has been suggested that exercise testing instruments conform to the fidelity recommendations of the American Heart Association for 12 lead electrocardiographs and vectorcardiographs.[39] This Task Force agrees with this recommendation and urges that unless justified by the need of experiment, a frequency response range of 0.05 to 100 hertz or greater be used for exercise testing.

Legal Implications

Objectives

The ultimate objective of a legal system, as it applies to medicine, is to prevent harm to the patient. The legal system includes (1) an appraisal to determine whether or not injury has been sustained, (2) a determination of whether or not the injury has been caused by failure of a legally applied standard of care, and (3) legal redress to ameliorate unnecessarily sustained injury. Moral and ethical awareness, together with the recognition of the potential use of the legal apparatus, provides the incentive for a medical system to know and abide by its legal responsibilities.

The two main areas of potential liability associated with an electrocardiographic system are civil (for malpractice or negligence) and criminal (for unauthorized practice of medicine).

Sources of Liability

Any one of the several components of an electrocardiographic system may cause data to be erroneous or lacking, or to be interpreted incorrectly, thus causing the generation of an incorrect diagnosis. Certain components may cause the system to be unsafe. Thus the participants of an electrocardiographic system must be alert to civil or criminal liability.

An electrocardiographic system may include: (1) patient electrodes; (2) technicians; (3) the recorder; (4) the electrocardiographer; (5) generation, reproduction and distribution of the electrocardiogram and its report; (6) storage of the electrocardiogram and its report; (7) telephonic or radio wave transmission of the electrocardiogram; (8) computer analysis of the electrocardiogram; (9) short-term electronic and longer-term magnetic storage of the electrocardiogram and its report; (10) magnetic accumulation of many hours of electrocardiographic data (Holter monitor recording or a compressed data system); (11) a rapid scanner; (12) electrocardiographic monitoring equipment; (13) an arrhythmia alarm system; (14) computer arrhythmia analysis; (15) trend analysis and trend plot generators; (16) exercise stress testing equipment; and (17) fetal electrocardiographic monitors among others. Thus, even in its simplest form, an electrocardiographic system is complicated, and an enormous effort may be required to ensure that such a system operates within the law, that is, that (1) there is no unauthorized practice of medicine, (2) safety standards set by law are followed, (3) the standards of quality set by law are met, and (4) quality control of the electrocardiographic system and its products prevents negligence, including malpractice.

Many safety and quality standards are included in the most recent FDA draft on minimal performance standards for electrocardiographic recording devices. Legislation allowing the FDA to set such standards has already been passed. Thus, these standards will have the force of law. However, the FDA standards may not cover some components of electrocardiographic systems, such as patient electrodes, technician competence, quality of telephonic or radio wave transmission, quality of computer analysis, quality of electronic and magnetic storage, quality of electrocardiographer interpretation, quality and efficiency of reproduction and distribution systems. Some established, some untested and certain theoretical legal implications exist for substandard quality of some of these components.

Liability for Electrocardiographic Interpretations

Cardiologists have been sued for incorrect or inappropriate electrocardiographic interpretations. However, the question has never been answered as to whether the remote cardiologist, by virtue of the analysis of the electrocardiogram, is practicing medicine. "[One does not hold himself] out to the public as being engaged in the diagnosis or treatment of ailments of human beings . . unless assertive conduct is directed toward the public with a view to establishing a physician-patient relationship."[42] Furthermore, this principle is more strongly stated in a Maryland case. Maryland apparently specifically exempts from the unauthorized practice statute consultations by an out of state physician with an in-state licensed practitioner.[43]

Computer programs: Institutions have been brought into court because of an erroneous computer analysis of an electrocardiogram. However, the Department of Registration and Education of Illinois has indicated that an institution is not practicing medicine by providing computer analysis of electrocardiograms for physicians. If a court test were to uphold such an opinion, then an institution providing such a service might be held only to negligence standards, or possibly to malpractice standards, but would be under no criminal liability for unauthorized practice of medicine.

The need for, and the importance of, computer application to medical and hospital practice is increasingly recognized by the legal community.[44] Computer programs for electrocardiographic analysis have improved greatly over the last several years, so that wave form recognition and implementation of recent criteria for electrocardiographic abnormalities are of reasonably high quality. These programs also perform some quality control analyses such as tests for frequency response, differentiation among various types of artifact including 60 cycle interference, muscle tremor, telephone line noise and limb lead placement errors. This type of quality control may not be included in the final draft of the recent FDA standards, but such standards may follow in the future and, like the recent ones, may carry the force of law. These standards and those that might be related to storage and retrieval should be developed by groups (including institutions and commercial enterprises) that have had the most experience in this area. Certain limited standards for transmission and processing of electrocardiographic data have already been suggested by the American Heart Association. Institutions are civilly responsible for the quality of these automatic electrocardiographic systems whether or not such a system consists of the practice of medicine, in the same way that an unlicensed practitioner is required to exercise the same professional standards of skill and care that prevail among licensed practitioners.[45] Thus, quality control is the best protection against civil liability because the question of whether the

practice of medicine is involved may not even be pertinent. "The mere want of a license does not raise any inference of negligence and if an unlicensed practitioner exercises the requisite skill and care in administering treatment to a patient he is not liable in damages from injury to the patient from such treatments, merely because of this want of license."[45]

Criteria for diagnosis and competence: One of the most difficult questions is whether or not there are legal ramifications related to criteria for diagnosis and recognition of competence to read electrocardiograms. Certain obvious abnormalities should be recognized and similarly interpreted by all physicians who read tracings, as well as by all computer analysis programs, and this expectation is most likely to be upheld by the courts. It would seem to be proper for this Task Force on quality of the electrocardiogram to urge that certain obvious criteria generate the appropriate diagnosis because of the probable legal obligation to do so. However, a great many criteria, perhaps most, are in a state of flux. Suggesting that standardization of criteria is equivalent to high quality interpretation may be incorrect and may inhibit further development of good criteria. It should be understood that although publication of a single set of "recognized" electrocardiographic criteria would be useful to many physicians these criteria might become the standard upon which the courts would rely. The use of newly developed criteria, such as those that might be available from the huge data banks of electrocardiographic computer analysis systems, would be discouraged because of inevitable delay involved in changing the single published set of recognized criteria.

The problem of evaluating the electrocardiographic reader is in some ways similar to the problem of evaluating the criteria, because the reader and the tester must depend upon these criteria. The difficulty lies in the state of flux of many diagnostic criteria.

An additional problem involves patients' right to privacy. The patient data transmitted to an electrocardiographic laboratory, especially a distant one, must be used with discretion to avoid invasion of privacy.

Legal Aspects: Summary and Recommendations

This Task Force therefore makes the following points and recommendations:

1. We point out that minimal standards for certain components of electrocardiographic systems have been developed by the FDA and will carry the force of law.

2. Additional standards for some of the remaining components of electrocardiographic systems will probably follow, and possibly will carry the force of law. These should be developed by cooperation among medical centers, commercial enterprises and other institutions that have had the most experience in the areas in question.

3. We urge that computer analysis of electrocardiograms not be considered the practice of medicine, whether distribution of the analysis is within the state or into another state, so that physicians are not unduly restricted from receiving such service, nor institutions with computer resources restricted from providing it. However, it is premature to propose that any computer electrocardiographic service is so well accepted that its availability is mandatory in the absence of a competent local electrocardiographer.

4. Similarly, we urge that, although the interpretation of a tracing by a physician electrocardiographer in one state *might* be considered the practice of medicine in that state, the distribution of that interpretation to a second state not be considered the practice of medicine in the second state.

5. We suggest that standardization of certain criteria may improve the quality of electrocardiographic systems; however, before a compendium of electrocardiographic criteria is developed, the effects of the legal implications upon the users of criteria subsequently formulated should be considered.

6. We point out that patient data transmitted to an electrocardiographic laboratory increase the reliability of the interpretation, but that such data are private and must be used with discretion so as not to violate the right to privacy of the patients involved.

APPENDIX I

Technical Tracing Quality Criteria*

1. Baseline quality. The minimal slope of the baseline in any electrocardiographic sample will be reported as follows:
   - 4 = 0 − <0.1 mv/sec (1 mm in 25 mm at slow speed)
   - 3 = 0.1 − <0.4 mv/sec
   - 2 = 0.4 − <1.0 mv/sec
   - 1 = 1.0 mv/sec but has at least 3 QRS complexes in a straight line
   - 0 = not having any 3 consecutive QRS complexes in a straight line
2. Powerline artifact, 50 or 60 hertz. This will be measured from peak to peak where the artifact is the most obvious:
   - 4 = no visible artifact
   - 3 = 0 − <0.1 mv artifact
   - 2 = 0.1 − <0.2 mv artifact
   - 1 = 0.2 − <0.3 mv artifact
   - 0 = ≥0.3 mv artifact
3. Muscle tremor artifact and intermediate frequency artifact ("baseline jiggle"). This will be measured from peak to peak in the highest quality part of any individual lead group sample:
   - 4 = no visible artifact
   - 3 = 0 − <0.1 mv artifact
   - 2 = 0.1 <0.2 mv artifact
   - 1 = 0.2 − <0.3 mv artifact
   - 0 = ≥0.3 mv artifact
4. Clipping or lost electrode. This evaluation is performed on the portion of the tracing having best technical quality:
   - 4 = no clipping or lost electrode
   - 2 = clipping which does not involve the ST-T waves
   - 0 = clipping which does involve the ST-T waves or 0 represents also a lost electrode in that lead group
5. Limb lead reversal. This evaluation is performed on the worst example of the tracing, that is, if it occurs any point in the electrocardiographic set the coding is performed.
   - 4 = no limb lead reversal anywhere in the test
   - 0 = limb lead reversal occurring somewhere in the test

* These criteria, employed by the Lipid Research Clinics Project (LRCP) Central Electrocardiographic Laboratory, are recommended for general use, and a "Class I" record is considered satisfactory for unrestricted interpretation. This is defined as a mean score of 3.00 or more using the scoring schedule found in the LRCP Mini-Memo 4(10), September 1976.

Task Force III: Computers in Diagnostic Electrocardiography

P. M. RAUTAHARJU (CHAIRMAN), MARIO ARIET (CO-CHAIRMAN), T. ALLAN PRYOR (CO-CHAIRMAN), ROBERT C. ARZBAECHER, JAMES J. BAILEY, RAYMOND BONNER, CHARLES R. GOETOWSKI, JAMES K. HOOPER, VIRGINIA KLEIN, C. KAY MILLAR, JOHN A. MILLIKEN, DAVID W. MORTARA, HUBERT V. PIPBERGER, LEON PORDY, RUSSELL L. SANDBERG, ROGER L. SIMMONS AND HERMAN K. WOLF

This Task Force was commissioned to examine the role of computers in optimal electrocardiography. The broad terms of reference assigned to the Task Force cover various aspects of computer applications in clinical electrocardiography with specific objectives to examine the present state of the art of computer-aided interpretation of electrocardiograms and to identify optimal features in programs and processing systems.

Some consideration was initially given to documenting comparative performance data on computer electrocardiographic programs on the basis of already published evaluations. After considerable deliberation, the consensus of the Task Force was that the methodology for computer program evaluation has to be first clearly delineated and specified before various programs can be compared. Furthermore, the majority of the Task Force favored comparative program evaluation using well defined test libraries, with appropriate clinical documentation and specific selection criteria for each test group. It was believed that documentation of actual comparative program evaluation results should be delayed until the evaluation methods are defined and until protocols and case selection criteria are agreed upon. Progress in these aspects is reported by Task Force IA of this Conference on Development of a Data Base for Electrocardiographic Use. This Task Force on Computers thus assigned a high priority to efforts to specify methodology of electrocardiographic program evaluation.

Excluded from the scope of this report are applications of computers in interpretation of exercise electrocardiograms, monitoring of critically ill patients, ambulatory monitoring and associated arrhythmia analysis, interpretation of fetal electrocardiograms and use in epidemiologic studies. Several monographs and reviews have been published on computer analysis of electrocardiograms.[1–26] The reader is advised to consult particularly References 1, 3 and 6.

Description of Computer Electrocardiographic Processing Systems

General Overview

Computer systems for the analysis of electrocardiograms have as their main component a program that performs measurements, interprets the clinical significance of the measurements and possibly compares the interpretation and measurements with those derived from the patient's previous tracings. These computer systems usually perform additional functions, such as storing the electrocardiograms for future reference. The electrocardiographer may use the systems for writing his reports by simply editing the computer interpretations. One key feature of an electrocardiographic processing system is that the reviewing physician, as well as the recording technician, can have access to it from almost any telephone set.

Computer Electrocardiographic Programs

A program may have four basic components:

1. *A measurement program,* which extracts from the electrocardiogram a set of measurements. This is further subdivided into an automatic wave form recognition section and a measurement section, which then extracts from the wave forms, a set of values and contours for interpretation.
2. *An interpretation program,* which generates the final statements to be reported by the program.
3. *A rhythm program,* for identification of the cardiac rhythm.
4. *A comparative analysis program,* which compares serial electrocardiograms and notes significant changes between successive tracings.

Statements of interpretation: Detailed descriptions of the characteristics of these components and the differences between various program designs are covered in Appendix I. The key feature of the programs with respect to their clinical utility is the set of statements used for reporting the interpretation. According to the way in which optimal disease or condition-related electrocardiographic criteria can be established and evaluated, one may distinguish three types of statements (Table I).

1. *Type A statements* define a degree of likelihood for the presence of a specific disease or clinical condition. Their accuracy can be determined on a statistical basis using information independent of the electrocardiogram.
2. *Type B statements* identify electrophysiologic conditions defined and detected primarily by the electrocardiogram itself. In some instances the condition can be confirmed by invasive electric probes. Thus, the accuracy of type B statements is determined by the quality of the program's wave recognition and measurement modules.
3. *Type C statements* describe features in the electrocardiogram that may or may not be related to anatomic lesions or the physiologic state. Although they may have importance in the context of other clinical information, taken by themselves their specificity is low or unknown (for example, nonspecific ST-T changes).

TABLE I

Three Categories of Electrocardiographic Statements Amenable to Different Types of Evaluation

I. Documentable by nonelectrocardiographic means
Infarction/injury
Hypertrophy/enlargement/overload
Pulmonary disease
Metabolic/digitalis effect
Ischemia (possibly documentable)
II. Detectable primarily by electrocardiography
Rhythm disturbances
Atrioventricular blocks
Pacemaker rhythms
Pacemaker artifacts
Bundle branch blocks
Fascicular blocks
Preexcitation (Wolff-Parkinson-White)
III. Purely morphologic descriptors
Axis deviations
Low QRS voltage
Increased QRS voltage
Nonspecific ST-T abnormalities
Strain
Large T waves

TABLE II

Utilization of Computer Electrocardiographic Programs in 1976[18]

	Annual Volume*	Key References†
Proprietary Programs		
IBM	1,400,000	1, 3, 12
TELEMED	1,400,000	3

* Annual volume is given for programs for which the reported volume exceeds 10,000 electrocardiograms.

† See list of references at end of text. Several other programs are described in references 1 and 3, including the TNO modular program of van Bemmel et al. and the Lyon program of Arnauld and Rubel.

Other Systems Features

Although the accuracy and reliability of the computer electrocardiographic program are important characteristics of an interpretation system, the program's utility in a clinical environment is significantly influenced by several other factors: (a) the method of electrocardiographic transmission and entry into the system; (b) permanent storage of electrocardiograms; (c) format and style of the report; (d) the method of physician review and generation of the final report; (e) other management aids such as quality data on technicians' performance, equipment quality control, etc.; and (f) flexibility for system modifications. A detailed description and critical reviews of features of available systems are presented in Appendix II. The identification of optimal features of a system is dependent on the particular environment in which the system operates. This fact will have an important effect on the comparative evaluation of systems.

The system features discussed in this section involve to some extent subjective criteria, which make the results "soft" but by no means useless. Comparative results can be obtained even by these categories if standardized methods of evaluation are used (for details see Appendix III).

Present State of Computer Interpretation of Electrocardiograms

Level of Utilization

On the basis of the Arthur D. Little report,[2] it can be estimated that in 1976 about 10 percent of the electrocardiograms recorded in hospitals and less than 2 percent of those taken in physicians' offices were processed by computer. Table II indicates the reported utilization in 1976 of electrocardiographic programs developed in private and public sectors. Growth indicators suggest that we are at the beginning of a period of rapid expansion of interpretation by computer. It was not always possible to verify the utilization figures at the source for the data given in Table II. Reservations are expressed about growth patterns predicted in various industrial forecast reports.

Analysis of the patterns of diffusion of computer-aided electrocardiographic interpretation into patient care suggests that the initial level of user acceptance is determined by a variety of factors in addition to the actual diagnostic accuracy of the program. Although diagnostic accuracy plays the main role, efficiency and convenience of physicians' review procedures, measurement reliability, reporting style and format and customer support may significantly influence the acceptance of any given electrocardiographic program or processing system. The history of many early failures and a few recent successes indicates that under rigorous automatic quality control, and by providing the physician-reviewer with a convenient, efficient schema for error detection and correction, the total electrocardiographic processing system can function despite deficiencies in the computer measurement and interpretation program.

Advantages of Computer-Assisted Electrocardiographic Interpretation

Electrocardiographic processing by a computer (Table II) offers several advantages. Some of the advantages should be considered primarily subjective impressions rather than documented facts because of the lack of objective systematic comparative analyses of the relative merits of manual and automated processing. There is a need for additional systematic evaluation, particularly regarding cost comparisons.[2]

Computer-aided electrocardiographic processing *enhances the capacity* of handling high volumes of

electrocardiograms. This benefit is particularly evident in large hospitals or groups of hospitals that have pooled their services. Although cost reduction through automation or semiautomation of electrocardiographic processing has not been clearly demonstrated or achieved on a large scale, it is reasonable to expect that *cost containment* can be achieved by increasing the capacity of the system to handle an increasing electrocardiographic volume without a proportionate increase in medical personnel and space required for the service.

The benefit of *improved turnaround* and *distribution* of the service is particularly important to small hospitals[2] and physicians' offices. Rigorous *quality control,* particularly in a real time electrocardiographic processing system, can substantially enhance record quality and thus the reliability of interpretation. Recent advances in mass storage technology result in substantial improvement in the *efficiency of record storage and retrieval.* This will greatly facilitate implementation of comparative electrocardiographic programs.

Computer-aided electrocardiographic interpretation may improve the quality of interpretation service by providing a *uniform standard of* interpretation for the group of physicians in charge of reviewing computer interpretations.

Computer analysis of electrocardiograms has had a substantial impact on *basic research in electrocardiography,* and has increased the feasibility of and capacity to carry out heart disease prevention programs and cardiovascular epidemiologic studies.

Since the objective of computer electrocardiography is to improve the quality and delivery of patient care, the users most likely to benefit from the *availability* of computer-aided electrocardiographic interpretation service are physicians' offices and hospitals with few cardiology consultants.

The impact of computer-aided interpretation may be particularly important for *emergency electrocardiographic services* in situations where a cardiologist is not continuously available. Increased coverage can thus be provided, with improved availability of electrocardiographic reports and physician review or cardiologic consultation, or both.

The introduction of computer-aided interpretation in larger regional hospitals with an adequate cardiology staff may be less pressing and beneficial than elsewhere. The utility and acceptance of computer-aided electrocardiographic interpretation may largely depend on the objectives and priorities of the cardiology department and the professional qualifications of the cardiology staff. Improved *efficiency* of electrocardiographic reporting regarding the time spent by the professional and clerical staff may become the key determinant leading to the decision to implement computer-aided processing systems in larger hospitals to meet the increased work load.

Problem Areas and Disadvantages of Electrocardiographic Interpretation by Computer

As with any other laboratory test or diagnostic procedure, computer analysis of electrocardiograms can be abused. Relevant medical-legal and economic issues are discussed in the reports of other Task Forces of this conference. The following possible disadvantages are of particular concern.

Increasing uncritical reliance on computer interpretation: This may result in deterioration in the quality of teaching electrocardiography. On the other hand, with appropriate planning and use, a semiautomated interpretation system should become an efficient and reliable teaching tool because many electrocardiographic interpretation programs provide with the report the exact criteria for the given interpretation. Equally important for efficient teaching is easy access to already validated reports. Electrocardiographic test libraries, which provide additional electrocardiogram-independent clinical information, should add another dimension for in-depth learning of computer-aided interpretation.

Easy availability of electrocardiographic interpretation: This can possibly lead to an unwarranted increase in utilization of the service. Although an improvement in the availability of the service may initially lead to an increase in volume of electrocardiograms, this increase soon levels off.[2] The increase may reflect correction of underutilization that existed before a computer-based service was introduced.

Mass applications of computer interpretations: With easy and increasing availability of computer-aided electrocardiographic interpretation, there is considerable pressure to provide large-scale interpretation service in mass applications, such as periodic health check-ups, clearance for physical fitness programs, screening of selected populations at the community level or groups of employees in industry and screening of life insurance applicants. These areas require study when one judges the utility of computer processing of electrocardiograms in terms of costs and benefits and the potential impact on the ultimate consumer, the patient. Perhaps the crucial question to be answered by those who advocate mass application of computer-aided interpretation is, "which electrocardiographic findings should be reported?" And perhaps the most prudent answer is that only those findings should be reported that are sufficiently important for medical management of the person concerned, or that have adequately proved significant predictive value in conditions in which an appropriate medical intervention can retard or stop the progression of the underlying disease.

Lack of independent objective standard: The key problem in the assessment of the present state of the art of computer electrocardiographic interpretation is the lack of an independent objective standard in most past evaluation attempts. Pipberger and Cornfield[8] noted that most of the published evaluations are inadequate and often misleading because they have not tested diagnostic accuracy against electrocardiogram-independent evidence: "Investigations which lack an objective reference standard will never provide us with an answer. In the interest of better patient care, answers need to be obtained soon." [8]

Inadequate standardization of definitions and measurement rules: Computer programs, although by

no means immune to noise and artifacts, have produced a significant improvement in the consistency of measurement and interpretation in comparison with visual procedures. The consistency of measurement is of particular importance in comparing serial tracings. The magnitude of this problem in electrocardiographic classification was pointed out by Prineas and Blackburn,[9] who observed that more than one of four cases of reported events (significant "worsening") coded as new infarctions was due to visual coding inconsistencies in spite of triplicate reading and arbitration of disagreements. Measurement and interpretation of the same set of electrocardiograms by *different* computer programs will produce a considerable number of disagreements. The primary source for these differences is inadequate standardization of definitions and measurement rules. It should be recognized that current visual measurement rules[10] are inappropriate for direct implementation in a computer program.

Classification and coding schemes: Several groups of electrocardiographers have proposed electrocardiographic criteria or coding schemes that have been or could be considered for computer implementation. From these classification schemes the Minnesota Code[11] has been widely used in epidemiologic studies. A severe limitation in the clinical use of these codes is the lack of separation between diagnostic classification criteria and criteria for classification of purely descriptive morphologic electrocardiographic features. This problem will be further considered in Appendix III.

Future electrocardiographic classification schemes and program development efforts are likely to rely heavily on clinically well documented data banks for both development and testing. Several such data banks are now being developed. The effort involved in these undertakings can be substantial, especially in the collection and documentation of data banks for serial comparison programs.

Computer analysis of pediatric electrocardiograms: This subject has until recently received a low priority among program designers and users. Special problems exist in this area because of considerable differences in signal characteristics in comparison with adult electrocardiograms and because of the fast, profound evolution of electrocardiographic patterns from birth to adolescence. In view of the age-dependent "normal" standards in infants and children and the concomitant difficulties in differential diagnosis between normal and abnormal conditions, it is reasonable to expect that computer analysis should significantly facilitate the interpretation of pediatric electrocardiograms. Systematic cooperative research and development efforts in this field should be encouraged by the establishment of suitable clinical data bases for program development and testing.

Relative merits and deficiencies of existing programs: Past reports on acceptance by and experience of users of computer programs have focused mainly on systems that have been successful. The Task Force recognizes the bias possibly introduced by this factor in this and other reports and suggests that future evaluative reports on the state of the art of computer-aided electrocardiographic interpretation pay more attention to the opinions of important sectors of "nonusers" and the experience of former users of programs and systems that have not been successful.

This report is deficient and incomplete in several aspects. Although desirable and optimal features of electrocardiographic programs and processing systems are discussed in general terms and guidelines provided for program evaluation, no attempt is made actually to identify and compare the relative merits and deficiencies of existing programs and systems. Continuing long-term efforts on comparative program evaluation need to be made by parties as free as possible from conflict of interest.

Evaluation Methodology

Accuracy, acceptability, utility and reproducibility: Evaluation procedures must take into consideration the user's specific environment; this will determine the importance of the various system features. A complete method for evaluating computer electrocardiographic programs and systems involves four different aspects: accuracy, acceptability, utility and reproducibility. *Accuracy* is defined as the sensitivity and specificity for type A statements; it is evaluated by using a library of cases for which the diagnosis is determined or excluded by nonelectrocardiographic means. Certain interpretive statements (type B and some type C) can only be evaluated against the standard of a given set of electrocardiographic measurements or criteria established prior to evaluation. *Acceptability* of any electrocardiographic interpretive statement is determined by the reviewing physician and is the only method for evaluation of statements (type C) for which the above methods cannot be applied. *Utility* involves the evaluation of convenience, time-saving, cost-saving and usefulness of the system. *Reproducibility* is a test of a system's stability in the presence of noise, such as powerline interference and patient artifacts. The method for evaluating each of these four aspects is given in detail in Appendix III.

Conclusions and Recommendations.

1. Computerized electrocardiography is being effectively utilized today in many medical institutions. The electrocardiographic analysis programs and the related computer technology in general are still undergoing rapid evolution to meet the specific, widely varying needs and requirements for electrocardiographic processing in any given clinical environment. Growth indicators suggest the beginning of a period of rapid expansion of electrocardiographic processing by computers, resulting in substantial changes in the practice of electrocardiography. During this rapid evolution, all those involved in health care delivery should carefully monitor the medical, educational and economic implications of utilizing this new technology.

Some factors to be evaluated are: (1) verification of the improvement in the quality of electrocardiographic reading when an electrocardiographer uses a supplementary computer interpretation; (2) the impact of electrocardiographic reading quality on the use of

computer service in areas without an electrocardiographer; and (3) the need for new professional education programs to train electrocardiographers to make efficient use of computer-aided interpretation.

2. Electrocardiographic interpretation by a computer is a laboratory test that may lead to a medical diagnosis, once reviewed by a qualified physician.

Diagnostic electrocardiographic interpretation by a computer or a physician reviewer should be subjected to the same kind of rigorous evaluation as any other laboratory test or diagnostic procedure.

3. Lack of an objective reference standard in the majority of past reports on the performance of electrocardiographic programs inhibits analysis of relative merits and shortcomings of various programs. The Task Force strongly supports cooperative efforts for the establishment of test libraries for electrocardiographic program evaluation.

It is recommended that the performance of various electrocardiographic programs be established using such test libraries and evaluation procedures specified in this report. Detailed test results of program evaluation should be made available to program users. The test and development library should be administered by a party free of conflict of interest. In the interim before the test libraries are available, developers of computer programs should provide documentation of the diagnostic criteria used and evidence to support their rationale.

4. Implementation of electrocardiographic analysis programs on computer systems or operating environments that are different from those for which the program was originally designed may significantly alter the program's performance. Considerable problems exist in verifying that a "transported" program is a reasonably close reproduction of the authentic source.

It is recommended that comprehensive test methods be developed to verify that translated or transported electrocardiographic programs perform in all functional aspects identically to the original version. It is further recommended that translators provide accumulation of their efforts to verify the accuracy of their translations.

5. Substantial differences exist between electrocardiographic programs regarding measurement definitions and classification terminology. While recognizing the importance of diversity for innovation, the Task Force considers the lack of standardization of terminology and definitions a substantial impediment to progress. It is recognized that the currently used visual measurement rules and definitions of electrocardiographic "waves" and intervals are too ambiguous to permit a reasonably uniform implementation in computer programs.

Systematic efforts aimed at more consistent and precise electrocardiographic measurement rules, definitions and terminology are strongly encouraged.

6. The scope of the present report excludes several important areas of electrocardiology, that is, exercise electrocardiograms, monitoring and associated arrhythmia analysis, interpretation of fetal electrocardiograms and applications of computers in epidemiologic studies.

In view of the rapidly growing application of computers in these areas, it is recommended that the American College of Cardiology or some other appropriate organization establish task forces to evaluate critically the current state of the art.

APPENDIX I

ELECTROCARDIOGRAPHIC PROGRAM DESCRIPTION

There now exists throughout the world a large number of computer programs that have been specifically designed to analyze electrocardiograms and report the clinical interpretations. In comparing these programs, it is evident that although there are many concepts common to all of the programs, each differs from the others in many ways. Differences are found in both the technique of electrocardiographic classification and measurement of wave forms. The programs generally perform four basic functions, which are independent of each other. Comparison of programs therefore requires comparison of each of the functions separately, namely, measurement, interpretation, rhythm and serial comparison.

Differences in the design of each of these four functions contribute to the reliability and accuracy of a particular electrocardiographic program. To present the state of the art of existing programs, this section outlines some of the differences in the available clinical programs.

Electrocardiographic Measurement Programs

Lead systems: The most notable difference in the programs is the choice of lead systems used for the analysis. Programs use either the standard 12 lead system or an orthogonal X, Y, Z system. The developers of 12 lead programs have primarily restricted their classification strategies to criteria that could be implemented in either an automated or manual system. Thus, most measurements made by 12 lead programs correspond to those that can be used manually by a cardiologist in reading electrocardiograms. Developers of three lead programs, however, have frequently used measurements other than those required for manual reading. Such measurements might include areas, slopes and curvatures.

Location of fiducial measurement points: Single versus multiple channel transmission: The main task in the measurement program is the location of these fiducial points (for example, the onset and the end of the QRS complex). Strategies for location of these fiducial points depend upon transmission to the computer either of simultaneously recorded multiple leads or of a single lead. Location of fiducial points with simultaneously recorded leads is in general easier and produces greater measurement reliability. The extent of improved measurement reliability with simultaneously recorded leads is not precisely known. Therefore, some developers have continued to use single channel transmission systems because single channel computer electrocardiographic carts cost less. Multiple lead transmission, however, is used in both 3 lead and 12 lead analysis programs. With 12 lead systems, the leads are transmitted in four sets of 3 leads each. In searching for the fiducial points on simultaneously recorded leads, the most common technique is to calculate from the sampled leads the instantaneous spatial velocity at each point in time. This transforms the three leads into a single signal, which accen-

tuates the distinguishing feature of the electrocardiogram, that is, the presence of electrical activity during the generation of a complex. The algorithm then uses absolute or relative velocity characteristics of the signal to detect the onset and the end of the various wave forms.

Statistical correlation techniques for fiducial point system: A second method of fiducial point location, which on many occasions is used as a refinement after location by spatial velocity, is the use of statistical correlation techniques. In using correlation, a standard template is somehow defined by the program developer. The template is then correlated against the signal being processed to determine the point of highest correlation. Given the point of highest correlation with the template, the program locates the fiducial point of interest. Even though these techniques are the most prevalent for location of fiducial points, other empirical search algorithms have been defined by various program developers.

Techniques to optimize accuracy of measurements: All of the programs attempt to make use of the redundancy of complexes available in the sampled electrocardiogram to optimize the accuracy of measurements extracted from the tracing. Three techniques are currently in use. The first locates the "best complex" for analysis. To find the "best complex," all of the complexes of a given lead set are located. The program then chooses one of them for analysis. One criterion for the complex selection is generally a function of noise measured on the complex. The second technique locates all of the complexes within the lead set and averages them. This procedure reduces the random noise on the signal. The measurements are then extracted from that average complex. The third technique extracts measurements from every complex located on the lead set and subsequently averages the measurements. It should be noted that in these last two averaging techniques, morphologically different complexes are used neither in averaging nor in measuring. Only those complexes having similarity are used in either averaging the measurements or computing a final "averaged complex."

Because many of the errors attributed to electrocardiographic programs result from measurement errors, evaluation of this function is crucial in determining overall program performance. One difficulty in constructing a measurement program has been the need to define quantitatively qualitative parameters (e.g., S-T shape).

Interpretation

Criteria classification: Classification strategies used by program developers are divided into two major techniques. The first and most widely used is a deterministic approach, that is, the use of Boolean logic statements combined with a decision tree. In this approach, the program follows a logical decision path to ultimately arrive at a set of nonconflicting statements about the electrocardiogram. The second strategy uses maximal likelihood statistics to calculate probability of a particular classification. This technique uses general statistical properties of the measurements with underlying statistical models to develop a better technique for classification of the electrocardiogram. Even in this method, decision trees and some Boolean logic are also invoked before final application of the Bayesian statistics.

Criteria versus measurements errors: The programs using only decision trees and Boolean logic differ from one another primarily in methodology of implementation; that is, it is theoretically feasible to take the logic from any one of these programs and implement it in another program by changing the methodology of implementation to correspond to the second program. Therefore, in evaluating the deterministic programs, it is much easier to differentiate errors in criteria from errors in measurement.

Rhythm Analysis

Rhythm strip analysis: Different rhythm analysis programs are most distinguishable by the amount of data and continuity of those data used by the program. The amount of data analyzed by the programs ranges from 8 second to 60 second strips. In some programs, the rhythm strip is a continuous rhythm strip from a single lead set; in others, the rhythm strip consists of short strips from various lead sets joined together to form a single continuous strip. The latter is used by most of the 12 lead systems; that is, the rhythm strip is constructed from the four lead sets transmitted to the computer, with each lead set being sampled for approximately 5 seconds, giving a total of 20 seconds of rhythm data. With the three lead systems, an 8 to 30 second continuous lead strip is analyzed. Programs using a switched lead rhythm strip have had to devise an algorithm that is independent of the data recorded during the switching intervals. If the data recorded during the switching intervals are not constructed, the difficulty in developing an adequate rhythm analysis program increases as the time of each lead set decreases. A lower limit of 5 seconds per lead set is recommended for such programs. The basic wave form location techniques in the rhythm module are similar to those that are used in the measurement module, with new variables being added to aid in rhythm determination.

Three questions to be resolved by any rhythm analysis program designer are:

1. What is the definition of R-to-R irregularity?
2. How is it possible to search for P waves and over what area?
3. What criteria are available for detection of premature ventricular complexes?

Whereas measurement and classification sections of computer programs have many similarities, with rhythm analysis there is a much greater degree of individuality in the programs. The methods used to answer the preceding questions vary widely among the programs. For example, regularity might represent percentage deviation from the mean R-R interval in one program and be defined as the width of a histogram of R-R intervals in another. Even greater differences characterize the P wave searches devised by the program developers. The differences in approach result primarily from the qualitative nature of the definition of the concepts. Each program must therefore be evaluated separately respecting the effectiveness of its techniques for rhythm determination.

Serial Comparison

Comparative programs: Development of programs for comparative analysis of serial electrocardiograms is still new. The majority of programs available do not yet have a comparative analysis module. The principal difficulty to be resolved by comparative programs is the inconsistencies resulting from measurement changes and statement variations between the two electrocardiograms being analyzed. In deterministic programs it is quite possible to see rather significant differences in the statements reported on serial electrocardiograms, whereas in fact the measurements determined by the program in each of the electrocardiograms do not differ significantly because of the thresholding nature of the decision strategy. As measurements fluctuate about the threshold, statements change. Thus, the program developer is faced with a dilemma of how best to report this information to the user. Each of the programs available with comparative

modules has attempted to handle this problem, with the developers basing their criteria for significant changes in measured variables on their experience and data available to them. These programs are in their infancy, and important changes can be expected during the next few years.

Other General Considerations

Several program characteristics that differentiate electrocardiographic programs do not conveniently fit into one of the preceding modules. These include the amount of analog or digital filtering (or both), sampling rate and precision of digital values. Each of these factors affects the performance of a program and its ability to measure various components of the electrocardiogram. Another consideration is the performance of the program in the presence of noise in the electrocardiogram. The noise rejection criteria of these programs differ significantly and will affect the overall performance of such programs.

A final difference is the use and effect of other clinical data on the outcome of the program. The amount and use of clinical data vary with the clinical status. It is expected that future program development will place increased reliance on clinical data.

APPENDIX II

SYSTEMS AND HARDWARE CONSIDERATIONS

The hardware and software components and the several functions involved in computer analysis of electrocardiograms are illustrated in Figure 1. The reader is referred to the A. D. Little report[2] for a general description of these functions. The following discussion will concentrate on a "typical" system, recognizing that numerous options are available at every electrocardiographic processing step. Deviations from the "typical" system will be pointed out and desirable enhancements to present systems indicated.

Record Identification

Usually, identification information is transmitted over telephone lines from the remote location to the central computer. Two exceptions should be noted: (1) off-line acquisition, where the identification and the electrocardiographic signals are recorded on magnetic tapes or cassettes built into the cart, and later batch-processed by computer; and (2) processing of identification and electrocardiographic signals in a computer and generation of a report on a printer, both of which are built into the cart. The second, a radically different approach, lacks some of the editing, reviewing, storage, retrieval, billing and other desirable features discussed later. But the sharp decrease in the cost of micropressors and other electronic components may make this approach economically attractive in the future.

Identification data to be transmitted: The telephone connection may be achieved through manual dialing or automatic dialing performed by the cart; once established, the identification information is transmitted digitally to the computer. This information may have been present in the cart prior to the telephone call and then transmitted automatically or it may be entered during transmission. It is usually required that a patient identification number be provided as well as a hospital (or department) identification number so that the computer will know where to send the report. It is very useful to include a cart identification number and a technician identification number to aid in isolating problems. Some of

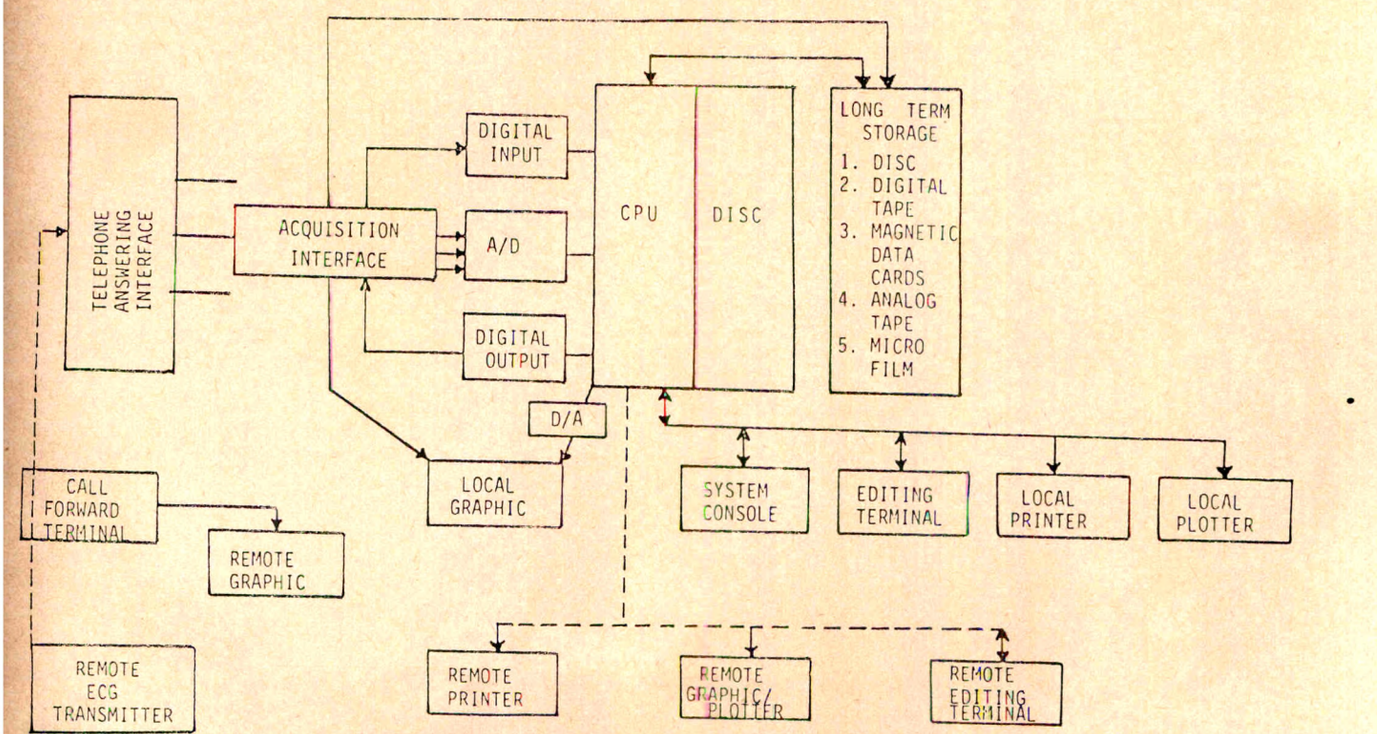

FIGURE 1. Schematic diagram of computerized electrocardiographic analysis system. A = analog; CPU = computation unit; D = digital; ECG = electrocardiographic.

these numbers may be built into the cart so that they don't have to be reset from patient to patient.

There is no consensus on the additional data that should be transmitted as part of the identification sequence. Some of the most popular entries are age, coded medication and diagnosis, height and weight or coded body build, and blood pressure. In off-line systems, the time and date of the electrocardiogram are also very desirable, whereas in on-line systems they are supplied automatically by the computer. If the system has the capability of transmitting letters as well as numbers, the name of the patient, a desirable component of the final report, can be transmitted as well. Because of the lack of consensus the system should be flexible.

Error checking and correction: Because storage and retrieval systems are very dependent on the accuracy of the identification information for ensuring that a series of electrocardiograms belong to the same patient, error checking, and to some extent error correction algorithms, are very desirable. Some examples would be (1) limit checking on variables such as sex, age, blood pressure; (2) the transmission of a check digit at the end of the digit string to serve a function analogous to the parity check bit; and (3) the checking of the patient's age and sex or possible name if there is a minor difference in the identification number relative to a previously stored electrocardiogram.

As errors are detected, the technician should be informed by a signal to the cart and a correction requested. The systems that attempt to improve the quality of the identification information and reduce the price of the transmitter cart by providing voice communication between the electrocardiographic technician and an operator at the computer site will increase the labor and telecommunication costs. Provision should also be made for error detection when the system is in "back-up" mode.

Acquisition and Transmission of Electrocardiograms

In almost all systems, the transmission of the electrocardiographic signals follows after the identification information phase. The signals from the electrodes that had previously been attached to the patient are amplified and combined in the cart to generate scalar leads, and are transmitted automatically, three simultaneous leads at a time, although some systems transmit one lead at a time. These analog signals are modulated for transmission over the telephone lines. (Detailed transmission characteristics, frequency response, and other data are discussed in the report by Task Force II on Quality of Electrocardiographic Records.)

Transmission systems: Some manufacturers convert the signals from analog to digital in the cart before digital transmission, thus eliminating modulation, demodulation and transmission distortions but requiring a buffer in the cart or special telephone lines and modems or data compression schemes. The transmission method affects the flexibility, availability, and cost of access to the central system, and voice grade telephone lines will, in many cases, be most desirable. Analog vs. digital (and, by implication three channel versus single channel) transmission should be analyzed in this context.

The computer receives the analog signals through an interface system, which demodulates and digitizes them (usually at a sampling rate of 250 to 500 samples per channel per second with an 8 to 12 bit resolution). A calibration signal transmitted prior to or after the electrocardiographic signals is used to calibrate the signals and to examine their overall quality. Different systems provide other checks on the signals, such as the length of time each lead set is transmitted; these checks should be easily changed because of the differing requirements of analysis programs.

Signal preprocessing and manipulations: Identification and possible improvement or correction of electrocardiographic signal quality in terms of noise, flat leads, baseline wandering and other artifacts have a major impact on the diagnostic accuracy of analysis programs. The boundary between these signal preprocessing functions and signal manipulation within the analysis program itself is not clear in present programs; however, this is crucial, because the system should decide before disconnecting the telephone whether the electrocardiogram should be accepted. In systems with report printers in the electrocardiographic cart, the cart may remain connected by telephone until an analysis is transmitted back and the technician can then decide whether to retransmit, but in systems where communication is terminated at the end of the transmission, an on-line quality control program should inform the technician through a visual or audible signal that the electrocardiogram was acceptable so that the patient may be disconnected with the assurance that an analysis will be generated.

Report

The electrocardiographic interpretation provided by the computer in the form of a report is usually transmitted by telephone to a remote printer or printed at the computer or review site. In some cases, the report is hand-carried or mailed to the remote site. The report contains the patient number and other identification information from the cart as well as a diagnostic interpretation and selected electrocardiographic measurements. It may also contain a graphic presentation of the complete electrocardiogram or selected portions of it or vector loops.

The report may be generated at the remote site very shortly after transmission or after it has been reviewed by a physician (this activity will be discussed in the next section). Although usually a hard copy report is needed for inclusion on the patient's medical record, under some circumstances, particularly in hospitals having their own computer systems, it may be advantageous for a defined group of users to have access to reports through video terminals.

Unit record: It would be very desirable to have a "unit record," that is, a piece of paper containing all information relevant to the electrocardiogram, rather than the inconvenient package produced by the present systems and caused by the manual matching of the tracing to the interpretation report. If the name of the patient also needs to be typed on the report, additional clerical procedures and delays are created. The machine in which this unit record is generated needs to be able to type and plot with acceptable accuracy and speed while receiving its information from the computer over telephone lines. However, the main difficulty in the compression of information is the length of paper generated by programs, some of which require 30 seconds of electrocardiographic data. The solution is to (1) present it in more than one sheet or in one larger sheet, (2) reduce the scale of the tracing, or (3) present less than the complete tracing by selecting one complex from each lead, or half of each lead. In this case, a continuous strip would need to be presented to illustrate arrhythmias.

Data Management

To facilitate the peripheral activities related to electrocardiographic interpretation, a central computer system should generate a number of reports in addition to the expected interpretation report.

Report on status of different computer tasks: The first of these should be a report that can provide for the central facility, for each remote user of the central system, for each department in a large hospital, for a particular patient or specific electrocardiogram, the status of the different tasks that have been completed for each electrocardiogram, the time at which they were completed and the ones remaining to be completed. Some important questions would be the time the electrocardiogram was received, the time it was analyzed, whether an unconfirmed report was transmitted, whether it was reviewed, whether an edited report was transmitted, and so forth. A natural consequence of this capability is to produce a count for each user of the services performed in a given period of time to serve the billing function. This program can also produce utilization reports of the central facility and provide peak load indications (in time of the day or specific days) when the frequency of electrocardiograms transmitted increases beyond acceptable limits and causes conflicts or an increase in turn-around time.

Report on number of rejected electrocardiograms and corrected interpretations: Another type of report should analyze the number of electrocardiograms rejected from each location and the cause of rejection. If individual carts and technicians are identified in each transmission, specific problem areas can be pinpointed and resolved by correcting telephone line problems, repairing faulty equipment or retraining personnel. A quantitative estimate of the program/physician agreement could be obtained by recording the number of electrocardiograms in which diagnostic statements or measurements are corrected by the reviewing physicians. Information on the type of diagnostic abnormality, the specific measurement and the physician making the correction can be accumulated to point out areas of weakness in the program or possibly differences in clinical criteria between the program developers and the clinical users.

Storage and Retrieval

The storage and retrieval systems provide an extremely valuable resource for research in electrocardiography. A search program should be capable of selecting from the files interpretation reports, tracings or wave forms of electrocardiograms having a particular diagnostic abnormality, belonging to patients using a specific drug or in a given group, and so forth.

Storage techniques: Various storage techniques have been available for some time, such as microfilming of tracings and reports, storage of tracings on analog or digital tape and of reports on digital tape, and the storage of electrocardiographic signals on cards that contain a strip of analog tape. Most of these techniques are limited, either because the stored record is not readable by the computer or because there is significant difficulty in retrieving a desired record. Although they have many advantages, particularly space reduction, over paper systems, they have not been adequate as a basis for automated storage and retrieval systems.

Serial analysis programs: Recent developments in disc storage technology and the availability of computer programs to perform the serial comparison of electrocardiograms promise to provide a new dimension in computerized electrocardiography as well as cost reduction. Very little experience has been gained yet on the utilization and effectiveness of on-line computerized storage and retrieval systems with or without serial analysis programs to formulate a judgment, but many users agree that it has great potential.

The storage needs for human performance of serial analysis are probably different from those of computer programs. Human readers probably require previous computer tracings or at least a single complex per lead plus a rhythm strip, whereas the computer program may require only a "measurement matrix" plus a list of the "diagnostic statements."

Considerations of how much data to store per electrocardiogram are still relevant, and data compression techniques are discussed as ways of optimizing on-line access to a reasonable number of records. The rapidly changing technology may obviate these considerations by providing bigger, faster and cheaper mass storage units in the future.

Physician Review

The computer-generated report can be annotated and edited with the assistance of the computer to improve the final report. This improvement might consist of the inclusion of the patient's name or a verification of the patient's sex, age, medication, or other data. But the most important editing function is that of reviewing, which consists of correction by an electrocardiographer of errors in the computer interpretation of the electrocardiogram.

Reviewer editing of tracing and interpretation: To perform this function, the reviewer needs a complete or a partial tracing, the computer interpretation and possibly other clinical information. If the reviewer is located at the computer site, these are easy to obtain, although in many systems tracings are not routinely generated on all electrocardiograms, so that some action needs to be taken to generate a tracing for editing. If the reviewer is located away from the central computer and away from the transmitting carts, some systems provide a call-forward interface, which receives a call from the transmitting cart and reroutes the call to the central computer, but generates a tracing while the electrocardiogram is transmitted from the remote hospital through it to the central computer. An alternative in this case would be for the remote hospital to transmit the electrocardiogram to the central computer, and for the computer to transmit both a tracing and an interpretation to the remote reviewer. This alternative allows the reviewer to monitor the quality of the signals received by the computer. The reviewer can then compare the tracing to the computer interpretation and (1) enter corrections and additional annotations through a remote editing terminal and request that the edited report be transmitted to the hospital from which the electrocardiogram was transmitted, or (2) call the physician at the transmitting location directly. The task of editing should be made easy, because it requires interaction between the computer and people who do not regularly use computers.

Flexibility and Reliability

Flexibility: Flexibility is needed because no system will satisfy all needs. Some users prefer one analysis program to another; therefore different quantities or types of data may be required, resulting in different transmission requirements (for example, not all transmitting carts are compatible with the same central facilities).

Even within a system that provides a specific analysis program, users have different needs; some users may require editing of all electrocardiograms, but others may require no editing or editing only of electrocardiograms with certain abnormalities. Similarly, some users require additional tracings, vector loops or reports including measurement matrices. Some want individual reports back immediately; others prefer to have them transmitted back as a group. Users also have differing preferences as to the type and amount of data to be kept in a storage and retrieval system for various types of

patients or electrocardiographic abnormalities. A system should satisfy as many of these requirements as possible without having to do major reprogramming of its software.

Reliability: The most important measure of reliability is the percent of time that the central facility is available to the user. This availability requires first, that the central facility be "up," and second, that enough incoming telephone lines be available so that the user can enter the system when necessary. Only the large analysis centers have been able to afford computer redundancy to achieve reliability, but because of cost reductions in computer hardware, a system containing multiple central processing units, discs, acquisition interfaces and other modules may be economically feasible in the future. On the other hand, as more regional centers become operational, it becomes desirable for centers to agree to process electrocardiograms sent from users of another center having hardware problems. Problems would then arise from centers having slightly different versions of the analysis program or from a center not having previous electrocardiograms from the other center to perform serial analysis. Short periods of computer unavailability can be easily resolved by analog recording of the incoming electrocardiograms followed by a batch processing after recovery. There should be a provision to at least acknowledge and record transmitted electrocardiograms in the event of failure of crucial system components.

Power and cart failures: Computer systems should be equipped with automatic hardware and software capability for restarting after power fluctuations or failures, with only the electrocardiogram being received at the time of the failure being lost. The technician sending the electrocardiogram would either be notified that retransmission was necessary or, in the case of total system failure, would be alerted by failure to receive the normal acknowledgement. In addition, the system should be structured so that vital functions can be maintained even when part of the system fails.

Another aspect of system reliability is illustrated by failures of the transmitting cart. In many small hospitals, only one cart is available, and this failure causes total unavailability of the analysis service. Immediate repair or installation of a functioning cart is essential to maintain the confidence of the clinical staff in the computerized system.

APPENDIX III
SYSTEM EVALUATION METHODS

Methodology of Program Evaluation

Evaluation of electrocardiographic programs should be considered in light of the goals of the evaluation. Two primary goals have been identified. The first is measurement of program's diagnostic accuracy (that is, ability to identify properly patient condition). The second goal is to measure the usefulness of the program in a specific environment.

Recently a host of invasive and noninvasive procedures have become available, which allow more extensive documentation and validation of electrocardiographic interpretation than has been possible in the past. As part of this development, there has been a trend in the last 20 years to use the electrocardiogram in more quantitative terms rather than for purely qualitative and descriptive cardiac evaluations. The widespread use of statistical techniques in modern medicine has reinforced this trend toward quantitation, and diagnostic criteria are now being judged by their sensitivity and specificity rather than by strictly empirical subjective clinical experience. This holds true also for the evaluation of interpretation programs.

Methods of Evaluation of Program Accuracy

Three basic methods are here identified for measurement of program accuracy. Method I attempts to determine the sensitivity and specificity of diagnostic classification by a computer using as a standard the electrocardiogram-independent evidence (such as autopsy documentation of left ventricular hypertrophy). This method inherently minimizes observer bias and evaluates the program's true ability to diagnose properly a given set of conditions. *Method II* accepts as a standard a constrained human observer, the constraint being a given set of measurements or criteria agreed upon before the evaluation (for example, conduction defects or arrhythmias).

Method III is similar to Method II, but the constraint is less rigorous. The evaluation in this instance is between the program and the observer, or the majority opinion of a group of observers.

This kind of evaluation should be performed only for descriptive statements, the meaning of which cannot be precisely defined (for example, flat T waves, left ventricular strain). Although it is not possible to use Method I for all measures of program performance, new evaluations should increasingly rely upon it. Similarly, Method II should replace Method III if meaningful comparisons of programs are to be made. It should also be recognized that these same concepts hold true in evaluating physician performance.

Measurement of a computer's electrocardiographic interpretive accuracy in light of these methods results in three types of statements that can be made by human readers or computer programs. The first type (A) comprises statements that refer to the diagnosis of an anatomic lesion or pathophysiologic state and that can be determined from nonelectrocardiographic evidence such as cardiac catheterization studies, serum enzyme levels, ventriculograms, echocardiograms, scintigrams and autopsy findings. The second type (B) covers statements that refer to the diagnosis of an electrophysiologic state and therefore are primarily detected by the electrocardiogram itself. Such diagnoses can at present be confirmed beyond the surface electrocardiographic data only through the use of multiple invasive electrical probes. Statements of Type B, therefore, should lend themselves to evaluation by Method I or II. Statements of Type C are purely descriptive statements of electrocardiographic features, which may or may not be related to anatomic lesions or physiologic disturbances.

Measurements of Accuracy of Type A Statements

Library of cases: To test the sensitivity and specificity of Type A statements, a library of cases must be selected for which the condition has been determined or excluded by nonelectrocardiographic means. Such conditions may be present singly or in combinations. In general, the test library has to have a balanced representation of electrocardiograms from different age groups, races and sexes. Also, the different diseases should be represented in their full spectrum of de-

velopment, starting from the barely identifiable to the extreme cases. All electrocardiograms in the library have to meet minimal quality standards and have to be recorded with equipment meeting minimal technical specifications, for example, those suggested by Wolf et al.[25] Because of their clinical importance, the following diagnostic categories have to be contained in the library: (1) infarction/injury; (2) hypertrophy/enlargement/overload; (3) chronic pulmonary disease; (4) "probably normal," defined as asymptomatic and not positive by nonelectrocardiographic tests for any of the above categories.

Uniformity of criteria and statements: To obtain meaningful results, the testing has to be performed in a multigroup environment. For each of the diagnostic categories the test shall produce results regarding both the sensitivity and the specificity of the criteria. For uniformity, it is recommended that the levels of grading for both the abnormality itself and the electrocardiographic statements be limited to the following terminology (see the report of Task Force I on Terminology and Criteria for definitions):

Normal = definitely, probably

Abnormality = definite, probable, consider

The sensitivity and specificity of each level should be measured in the library.

The robustness of a diagnostic algorithm is measured by (1) its ability to separate a given abnormality from normal, and (2) and its ability to separate a given abnormality from other abnormalities.

It should also be recognized that if a program fails to recognize a documented abnormality, it may be a result of limited information in the electrocardiographic signal itself, not a fault of the program. Further, the signal itself may suggest an abnormality that cannot be documented by nonelectrocardiographic means.

Measurements of Accuracy of Type B Statements

Arrhythmias: *Sufficient numbers of the following rhythm classes should be included:*

1. Sinus rhythm, including tachycardia, bradycardia, and sinus arrhythmia
2. Atrial flutter/fibrillation
3. Premature complexes (atrial or ventricular, single or multiple)
4. Other supraventricular arrhythmias
5. Other ventricular arrhythmias
6. Other less frequent arrhythmias
7. First, second and third degree A-V block

Electrocardiograms for this part of the library should be selected and classified either on the basis of consensus among several electrocardiographers or on the basis of other electrophysiologic studies. In general, performance will be measured by determining the sensitivity and specificity. An exception to this rule is the detection of events that occur rarely because specificity then has only a limited meaning. We suggest an additional measure, the error ratio:

Error ratio = (falsely detected events
+ missed events)/correctly identified events

The output statement "undetermined rhythm" seems to require special treatment. Its frequency of occurrence would be established in each of the preceding rhythm classes, as well as in the total population.

Conduction defects: These are another group of electrophysiologic phenomena for which the surface electrocardiogram is the usual means of diagnosis. In this area, it is sometimes difficult to agree upon predetermined criteria for classification, and further documentation by invasive electrophysiologic studies is rarely available. Sufficient numbers of the following classes of conduction defects should be included in a test library:

1. Bundle branch block (complete, incomplete)
2. Unifascicular and multifascicular blocks
3. Other intraventricular conduction defects
4. Pacemaker rhythm
5. "Normal" as defined in category (vii) for Type A statements by Task Force I on Terminology.

These classifications, even with consensus, may overlap; therefore, it is recommended that testing be limited to measuring the frequency of agreements, partial agreements, disagreements and the frequency of any false calls in the "normal" population.

Measurement of Accuracy of Type C Statements

Type C statements, which describe electrocardiographic features, represent a difficult area for evaluation because they may or may not be related to documentable disease. The differences of opinion may depend largely on local customs and particularly on the place of medical training of the electrocardiographer. When a Type C statement occurs in conjunction with a Type A statement or as a supporting reason for making the Type A statement, it would seem reasonable to regard the Type C statement as part of the Type A statement and not to evaluate that Type C statement separately. However, when an isolated Type C statement occurs, a number of methods for handling it may be considered. Some Type C statements are intended by the program developer to suggest specific diagnostic entities. For example, "increased QRS voltage" may be the developer's way of suggesting hypertrophy. "Left axis deviation from later forces" may be intended to suggest left anterior fascicular block. In such cases, the substitution of a semantic equivalent such as "consider left ventricular hypertrophy" or "consider left anterior fascicular block" should be discussed with the program's developer and treated as Type A and Type B statements. Another approach might be to measure the frequency of the occurrence of such statements in the Type A and Type B libraries, which might suggest where semantic equivalencies might be established.

Test of statements by submission to other electrocardiographers: In the absence of semantic equivalencies or some similar measure of relevence, one could test the acceptability of such statements by submitting a large collection of electrocardiograms, preferably from Type A and Type B libraries, to a large group of electrocardiographers from many different medical centers. Thus one could measure the frequency of occurrence of a given Type C statement (isolated) and the percent of times the expert electrocardiographers agreed with the statement. An isolated Type C statement that had a high frequency but a low percent agreement might adversely affect user acceptance of the program. Similarly, an isolated Type C statement that most electrocardiographers made and for which the program had a low frequency (even though the percent agreement was very high) might also affect user acceptance.

In such a test, it would be useful to supply the human reader with the criteria required by the isolated Type C statement so that he can manually verify from the electrocardiogram that those criteria are, indeed, fulfilled by the tracing. If this manual verification is not feasible or possible, evaluation should consist of enumeration of how many nonverifiable statements the program contains and how often they occur.

It should be acknowledged that such a test is not meaningful when a 3 lead program is compared with statements based on

a 12 lead electrocardiographic program (and vice versa). It is this kind of difficulty that the evaluation methods of Type A and Type B statements are designed to circumvent.

Systems Evaluation

Repeatibility or Reproducibility

Reproducibility and noise factors: Repeatibility or reproducibility of both program measurements and statements is a test of the program's stability in the presence of noise. Commonly encountered types of noise in electrocardiographic records are (1) powerline interference; (2) skeletal muscle noise (electromyogram); (3) baseline wander; (4) telephone transmission noise; (5) digitization noise; (6) other system noise (wow, flutter, amplifier, drift); and (7) patient factors (lead position, for example).

Travis[19] recorded electrocardiograms on magnetic tape and played them back several times. This tests the stability of a program to system noise factors such as wow and flutter. Bailey et al.[20] tested reproducibility by using alternate samples from an electrocardiogram converted from analog to digital representation at a rate twice the nominal rate. A third method, already introduced in 1967[21] and more recently used by Helppi et al.[22] for program testing, superimposes known amounts of random noise on a clean electrocardiogram. This method tests a noise effect somewhat like skeletal muscle noise. A fourth method[23] uses complete repeat recordings from the same patient. This method tests the reproducibility of the program in the presence of all noise factors. The difficulty with this method is that all noise factors, including patient factors, are combined in an uncontrolled way; therefore, one cannot isolate the factor that caused the program to fail.

Some of these difficulties could be avoided if one used very clean electrocardiograms and added controlled amounts of alternating current interference, skeletal muscle noise and baseline wander to the electrocardiographic signal. Since it has been shown by Wolf et al.[24] that different electrocardiographic patterns show different noise sensitivities, the tests described should be performed using noise-free records carefully selected from the different electrocardiographic classifications.

A global figure of merit may be established for comparative purposes for a given clinical environment characterized by the comparative frequency of the different noise types and levels and by the distribution of different electrocardiographic classifications. The program should detect nonelectrocardiographic signal, burst noise, missing leads and inconsistencies in information derived from different lead sets.

Verification of "Translated" Programs

Several electrocardiographic programs have been implemented on computer systems or operating environments that are different from the one for which the program was originally designed. These changes have a distinct possibility of producing program results deviating from the original program developer's intention. Further, systematic differences might even be introduced by different signal preprocessing environments such as signal filtering or characteristics of the analog-digital converters. Users who make such an environmental change should conduct detailed tests to verify the system performance in the altered environment. Documentation of tests and results should be made available.

Evaluation of Other Systems Features

Although the electrocardiographic program determines the clinical utility of a computer interpretation system, other systems features establish the operational utility of the system. Aspects of human engineering will determine the attitude of users toward the new technology. More important still, most of these systems features have a direct bearing on the costs of recording, interpreting and storing of electrocardiograms, and will in a crucial way influence the acceptability of the system.

So far only a few reports are available on the systematic evaluation of total electrocardiographic processing systems,[26] and the methodology for assessing the various features—often of a subjective nature—requires substantial refinement. Methods presented here are therefore of only a preliminary nature.

Operational systems features can be grouped into two categories: (1) Features affecting the convenience of using the system. They are judged by the degree of acceptability by the user. (2) Features influencing the economical aspects of the system. They will be evaluated primarily on the basis of their cost-effectiveness. Items falling under category 1 are acceptance by electrocardiographic technician, acceptance by physician-reviewer, and acceptance by physicians who receive the verified electrocardiographic report.

It is preferable to determine acceptability by all three of these groups after a sufficient period of exposure and familiarization with the system (for example, 2 months). Care has to be taken to not extend the familiarization period too much to prevent possible dissatisfaction from turning into resignation, which might give misleading results.

The evaluation of user acceptance may take two forms, one based on a questionnaire and a second using indirect but measurable quantities. For each of the three groups, the following indirect measures are suggested:

1. **Technician:** The time needed to record an electrocardiogram and perform all the preparatory and clerical functions the system requires is a reasonable measure of the utility of the system. Because this time is also influenced by the degree of the technician's frustration with the system, it provides a measure inversely related to acceptability.

2. **Reviewing physician:** The reviewing physician's role in the system is to edit computer electrocardiographic interpretation so that the result is equivalent to a report he would otherwise produce himself. His system acceptability is influenced by the ease with which he can perform the editing function and by the amount of editing he has to perform. These quantities can be measured in terms of editing time per electrocardiogram and frequency of changes, respectively. The latter quantity should be established separately for the different types and subgroups of statements (such as, Type A, subgroup infarction). It is advisable to perform the acceptance testing separately for individual reviewers, to obtain a measure of variance among the reviewers. No attempts should be made to arbitrate physician reviews to obtain a majority agreement because arbitration will not take place under normal operating conditions. It is emphasized that an acceptance test only evaluates agreement and does not imply accuracy on the part of either the physician or the computer. Even in cases of complete agreement the electrocardiographic interpretation may be incorrect.

3. **Other physicians:** The acceptability of the system by other physicians will be determined primarily by the degree to which the electrocardiographic report facilitates patient management. A second consideration may be the reduction of clerical functions or the addition of special services provided by the system. As an indirect measure of acceptability of the report, one can use the number of consultations with the reviewing physician on patient management. Another, although negative, measure for acceptability is given by the number of inquiries requesting clarification of phrases used in the electrocardiographic report, but this measure can be used only during the very initial phase of the system use.

The evaluation of systems features under category 2 can be performed using standard cost-effectiveness methods. Items in this category include:

1. Elimination of clerical functions
2. Elimination of hard-copy storage
3. Availability of 24 hour service
4. Reduction in paper costs for the several hard copies generally used in interpretation
5. On-line quality control (which reduces number of patient recalls for repeat tracings)
6. Provision of billing services and financial control

A systems evaluation will have to consider all these points and weigh them according to the specific requirements of each installation for a total evaluation of cost-effectiveness.

Task Force IV: Use of Electrocardiograms in Practice

LEON RESNEKOV, MD, CHAIRMAN, SAMUEL FOX, MD, CO-CHAIRMAN, ARTHUR SELZER, MD, CO-CHAIRMAN, RICHARD CAMPBELL, MD, RORY CHILDERS, SAMUEL KAPLAN, MD, ALAN LINDSAY, MD, PAUL McHENRY, MD, ROBERT SCHLANT, MD and RONALD SYLVESTER, MD

Guidelines for Utilization of Electrocardiograms

In addressing the question of utilization of electrocardiograms, continuous ambulatory monitoring and exercise tests, the Task Force considered (1) over- and underutilization, (2) safety, (3) cost, and (4) contribution to diagnosis and patient management. Appropriately supervised, these tests can be performed at an acceptably low risk to the patient. Continuous ambulatory monitoring and exercise testing are expensive, and overutilization may contribute significantly to an excessive economic burden.

A particular concern was that overutilization of these tests may lead to overreaction in the form of unwar-

ranted diagnostic and therapeutic interventions. The Task Force was particularly concerned with inappropriate interpretation of these tests. The tests cannot be interpreted in a vaccuum. They must be correlated with the clinical setting and integrated with the patient's history, physical findings and other laboratory results.

Adult 12 Lead Electrocardiogram: Indications

1. Electrocardiograms are indicated in patients who have clinically suspected heart disease or who are at high risk of having heart disease. Subsequent electrocardiograms may be indicated to evaluate a change in symptoms or clinical status or to evaluate therapy. It is uncertain how often follow-up electrocardiograms are indicated in patients with heart disease whose condition is stable. The Task Force recognized that in some patients periodic electrocardiograms are helpful and that this decision should be left to the judgment of the physician.

2. *Should every adult have a baseline electrocardiogram?* Data are not adequate to establish an age at which electrocardiograms are justified for asymptomatic persons. Cost factors and the problems of unwarranted anxiety produced by misinterpretation must be considered in light of the value of a baseline tracing for comparison with an electrocardiogram taken upon the appearance of symptoms. Nevertheless, the Task Force recommended that a baseline electrocardiogram be obtained in all adults.

3. *Routine annual electrocardiograms*[1] *after a baseline tracing* has been obtained are not indicated unless clinical changes suggest heart disease or the patient is in a high risk group. Routine annual electrocardiograms may be indicated in patients at high risk of having heart disease. In others, periodic electrocardiograms every 5 years may be desirable although there are no hard data to support this recommendation.

4. *In preoperative patients* the Task Force recommended that routine electrocardiograms be obtained in all adults to provide a recent baseline record to help manage surgical complications (for example, cardiac or pulmonary complications, electrolyte imbalance).

5. *In patients with acute myocardial infarction,* daily or several daily 12 lead electrocardiograms are recommended until the condition is stable. In patients with uncomplicated acute myocardial infarction, it is not necessary to obtain daily electrocardiograms after stabilization. It was recommended that an electrocardiogram be obtained shortly before the patient's discharge from the hospital, at his first follow-up visit and before he returns to work or to his previous level of activity.

6. *For patients after cardiac surgery,* guidelines similar to those outlined in the preceding paragraph should apply.

7. *With respect to electrocardiograms in the emergency room,* the Task Force was concerned about overutilization. It was emphasized that electrocardiograms in the emergency room should be indicated medically and should be obtained in conjunction with a careful clinical evaluation that suggests heart disease. When electrocardiograms are performed in the emergency room, a competent electrocardiographer should be quickly available. Comparison with previous electrocardiograms should be encouraged. A tracing taken in the emergency room should be processed and interpreted in the same way as other electrocardiograms taken in the hospital. It should be emphasized that a normal electrocardiogram does not exclude an acute myocardial infarction or any other acute cardiovascular catastrophe.

Electrocardiograms should be obtained in all patients with either penetrating or nonpenetrating chest trauma.

Continuous Ambulatory Monitoring in Adults[2,3]

The clinical significance of much of the data derived from continuous ambulatory monitoring is still unclear and should be considered a focus for additional research. Such recordings are subject to a host of artifacts, many of which may simulate cardiac arrhythmias and ischemia.[4] There is a significant risk of overutilization of such data in the clinical management of patients. Continuous ambulatory monitoring should not be performed without obtaining a 12 lead electrocardiogram.

Indications: Continuous ambulatory monitoring is important in assessing the efficacy of treatment in selected patients with symptomatic arrhythmias or conduction disturbances. The method is also useful to evaluate patients with daily or frequent, rather than occasional, symptoms and to identify possible occult arrhythmias or conduction defects. This should be done in association with a careful clinical evaluation for noncardiac causes of these symptoms. Continuous ambulatory monitoring information should be correlated whenever possible with a diary of the patient's symptoms.

2. Continuous ambulatory monitoring may be useful to evaluate patients who have premature ventricular complexes or ventricular tachyarrhythmias, or both, after a myocardial infarction. The procedure may identify patients with increased risk, but it is not known whether therapy will alter the prognosis of these patients.[5]

3. *The role of continuous ambulatory monitoring to evaluate asymptomatic patients for conduction defects* (for example, atrioventricular or bifascicular block and other intraventricular conduction disturbances, and in follow-up of patients being maintained with pacemakers) is unclear because the value of therapeutic intervention in such patients remains uncertain. This role of continuous ambulatory monitoring needs further research.

4. *Continuous ambulatory monitoring should not be used for routine evaluation of patients with chest pain or discomfort* because ST-T changes observed during continuous ambulatory monitoring are unreliable indicators of myocardial ischemia. Such changes may be observed in many subjects who do not have heart disease.[4,6–11] Continuous ambulatory monitoring is not a substitute for exercise testing.[6–11]

5. *The optimal lead placement* for continuous ambulatory monitoring and the justification for multiple channel continuous ambulatory monitoring require further study.

Exercise Testing in the Adult

The Task Force believed that results of exercise testing may be overinterpreted, leading to unwarranted invasive and therapeutic interventions. An abnormal exercise response alone, without other clinical indications should not be considered a circumstance requiring selective coronary arteriography. Similarly, other costly or formidable procedures should not be considered automatically indicated in asymptomatic subjects

Indications: 1. *In asymptomatic patients,* exercise tests usually do not need to be performed or repeated if there are no clinical indications for the tests including the development of circumstances implying increased risk of significant disease. The Task Force emphasized the difference between exercise electrocardiography and exercise function or tolerance testing. Much information is obtained by the latter, which includes not only the exercise electrocardiogram but also the comprehensive monitoring of symptoms, signs and circulatory responses.[12,13]

2. *To clarify a diagnosis of coronary heart disease,* the patient's clinical status should be carefully assessed before he is subjected to exercise testing. The test may be contraindicated in some patients, such as those with unstable angina; it is also contraindicated within 10 days of acute myocardial infarction.[12,14] Low level exercise tolerance evaluation may help to define exertional constraints for the patient upon discharge from the hospital.

3. *In patients with an abnormal baseline electrocardiogram,* the exercise electrocardiogram has a decreased reliability.[12,14] This applies to patients with ST-T changes on standing, patients with hyperventilation and patients taking drugs (such as digitalis preparations) that may modify the ST-T response to exercise. Patients with electrolyte or metabolic abnormalities may also have ST-T changes during exercise that are difficult to interpret.

4. *After cardiac surgery,* exercise testing is useful to measure the patient's effort tolerance and to evaluate his or her cardiac function. In such postoperative patients, the ST-T changes during exercise testing are less reliable than the assessment of functional and circulatory responses.

5. *Exercise testing may also be useful in following up the status of patients with documented heart disease of many types,* especially after recovery from myocardial infarction. Exercise testing is useful to evaluate the efficacy of treatment in selected patients with cardiac arrhythmias and may complement continuous ambulatory monitoring.[6–11]

6. *Exercise testing is useful to identify some patients with coronary heart disease who are at unusually high risk of having an acute event.*[15] During low levels of exercise, such patients may show marked and early onset S-T segment depression, a decrease in blood pressure, serious ventricular arrhythmias or prolonged postexercise S-T segment depression.

7. *The value of exercise testing in asymptomatic subjects* requires further study. Such testing may be indicated to evaluate subjects (airline pilots, for example) who present an increased community or occupational hazard.[16] Exercise testing is also useful in middle-aged persons before they undertake high level exercise training programs.[17,18]

The Task Force emphasized that exercise tests should be conducted in accordance with safety standards as recommended by the American Heart Association Committee on Exercise. The Task Force recommended progressive multistage exercise testing and recognized the need for further studies concerning optimal lead systems, protocols and computer assistance in interpretation of data.

Pediatric Electrocardiography

Leads: In addition to the usual 12 leads, lead V_4R or V_3R should be recorded routinely. When dextrocardia (cardiac malposition) is present, equivalent right chest leads should be taken. Multiple chest leads (V_4R or V_3R, V_1 to V_6) may not be practical in small babies because of the size of the chest. In these instances, at least the following leads should be obtained: I, II, III, aVR, aVL, aVF and V_4R or V_3R, V_1, V_3 and V_6.

Although much information is available concerning the normal limits of the infant's and child's electrocardiogram in relation to age, sex and race, this is an area for further study.[19,20] A baseline electrocardiogram is not considered necessary in normal children. Routine preoperative electrocardiograms are not indicated.

Indications for electrocardiography in children: These include clinical suspicion of heart disease, chronic anemia, neuromuscular disorders, metabolic disorders, chronic pulmonary diseases and electrolyte imbalance.

The electrocardiogram is also used to monitor possible cardiotoxic effects of antineoplastic drugs and to assess siblings of patients with idiopathic hypertrophic subaortic stenosis (hypertrophic obstructive cardiomyopathy) and other familial heart diseases as well as siblings of patients with a prolonged Q-T interval of unknown cause and children with congenital deafness.

Interpretation: The electrocardiogram in teenagers must be interpreted with caution[21] because even in the absence of recognized heart disease the records frequently show (1) large QRS voltages that can be misinterpreted as evidence for left ventricular hypertrophy, (2) early repolarization with S-T segment elevation that could be misinterpreted as pericarditis or myocardial ischemia, or (3) T wave inversion in leads V_1 to V_3. Accordingly, electrocardiograms in otherwise healthy teenagers with atypical chest pain may be of limited value.

Continuous Ambulatory Monitoring in Children and Adolescents

These tests may be used to unmask conduction defects and ventricular tachyarrhythmias in patients with

cardiac symptoms including syncope and to evaluate atrial or ventricular tachyarrhythmias during physical activity, supraventricular arrhythmias in children who have had extensive intraatrial surgery, sinus bradycardia in the symptomatic child, the therapy of arrhythmias, and children with heart block or with pacemakers. Further study of the value of continuous ambulatory monitoring in children is needed.

Exercise Testing in Children and Adolescents

The same precautions, indications and contraindications should be used as in exercise testing in adults.

Indications: Exercise testing may be used to assess the progression of severity of left ventricular outflow obstruction,[22] including subvalvular, valvular and supravalvular aortic stenosis, coarctation of the aorta and idiopathic hypertrophic subaortic stenosis; to unmask arrhythmias or conduction defects in specific high risk symptomatic patients[23] after ventriculotomy; to detect persistent arrhythmias after extensive intraatrial surgery and to unmask arrhythmias in symptomatic patients.

Comments: It is probable that exercise testing is underutilized in children and adolescents. There is great need for further study to establish indications and normal limits.

The value of the test should be established in children and adolescents with (1) a strong family history of early death from coronary heart disease, (2) hyperlipoproteinemia, (3) hypertension, (4) syncope or near syncope, (5) chest discomfort or pain, (6) asymptomatic arrhythmias, (7) chronic anemia, or (8) mitral valve prolapse.

The value of exercise testing before participation in competitive sports is unknown.

Assessing Competence and Education in Electrocardiography

Electrocardiographer's Competence

The definitive interpretation of the electrocardiogram should be made by a physician (MD or DO).

Electrocardiographers' activities involve three levels: physicians recording and interpreting tracings of their own patients; physicians "reading" electrocardiograms for hospitals, clinics or other physicians, thus acting as consultants, and physicians whose chief interest is in electrocardiography and who act as teachers, investigators and experts in electrocardiography. The great majority of electrocardiograms are being interpreted by the "electrocardiographic reader" working under a contract or agreement with a hospital or clinic. The reader's other role is analogous to that of the hospital pathologist or radiologist for whom there are well defined qualifications (certification by respective specialty boards) necessary for the contractual agreement between the hospital and the radiologist or pathologist. Qualifications for electrocardiographers have never been defined. Thus it is imperative that quality control is maintained by requiring evidence of the electrocardiographer's competence. The Task Force recognized the impact of the change in standards for competence in electrocardiographic interpretation and recommended that this change take place expeditiously for 3 to 5 years and without interrupting services that are currently available.

Electrocardiographer's Qualifications

Certification by the Subspecialty Board in Cardiovascular Diseases of the American Board of Internal Medicine (or American Board of Pediatrics for the childhood population) cannot be required for all electrocardiographers. It is important, however, that those who do not have such certification show evidence of competence in the interpretation of electrocardiograms. This evidence requires documentation of formal training (such as rotation through a cardiology service during residency with adequate training in electrocardiography) and continuing experience and learning in this field. Physicians now engaged in electrocardiographic reading may demonstrate the equivalent of formal training by long experience in the interpretation of electrocardiograms or adequate postgraduate education. It is expected, however, that within 5 years all readers will have demonstrated their competence by passing a qualifying examination (to include pediatric cardiology) in electrocardiography. Inasmuch as the subspecialty boards currently do not provide testing and certification in a limited area of their subspecialty, the qualifying test in electrocardiography should be organized by cardiologic educational organizations, such as the American College of Cardiology and the Council for Clinical Cardiology of the American Heart Association. The test should emphasize the interpretation of electrocardiograms together with basic theoretical knowledge.

Because of rapid changes in the field of electrocardiography, the knowledge and competence of all electrocardiographers should also be updated every 5 years after completion of formal residency training. Physicians who complete their residency training and who have adequate training in electrocardiography will be expected to pass the qualifying examination in electrocardiography (or the examination of the subspecialty board in cardiovascular diseases) within 2 years after completion of their formal training.

Criteria for competence of electrocardiographers can best be defined by delineating the essential recommended knowledge and skills. Such an enumeration, undertaken by an ad hoc committee of the American College of Cardiology with input from 20 well known electrocardiographic authorities, was prepared for the Electrocardiography Core Curriculum and Self-Assessment Program of the College.[24] The list of recommended skills and knowledge is divided into two categories: (1) those for electrocardiographic readers (147 items), and (2) those for the advanced electrocardiographer and teacher (174 additional items).

Electrocardiographic Interpretation in Acute Care Hospitals

Electrocardiography is a laboratory procedure that must be applied and interpreted in the context of the clinical problem. In this respect, it is akin to radiology,

in which the reader acts as a consultant who may interpret the same change differently according to the available clinical information. Electrocardiographic interpretation provided with the knowledge of the clinical problem is superior to and more likely to be correct than that provided on the basis of the tracing alone. Thus, in an acute care hospital it is highly desirable to have available fully trained electrocardiographic readers. However, if electrocardiographers of demonstrated competence are not available, present technology permits telephone transmission of electrocardiograms for interpretation in a distant organized electrocardiographic facility. This system is preferable to having electrocardiograms interpreted by readers who cannot meet standards of competence. Some of these electrocardiographic referral centers or systems are equipped to provide immediate reader interpretation or computer interpretation with overreading.

The Task Force recognizes the considerable potential error in computer interpretation of electrocardiograms and recommends that all computer interpretations, including those read as normal, be verified by a qualified reader. Furthermore, capabilities for comparison of tracings must be available.

Training in Electrocardiography

Training in electrocardiography should include in-depth experience with a wide variety of records and should be based on material from acute care hospitals, in which there is an ample variety of tracings from acute cardiac disorders (myocardial infarction, arrhythmias). It is recommended that all training programs for all physicians performing primary care (in fields such as internal medicine, pediatrics, emergency medicine and family practice) include a formal rotation through electrocardiographic units that provide trainees the learning experience of supervised interpretation of at least 2,000 tracings. Such training, followed by continuing exposure to postgraduate courses and practical experience in electrocardiography, could afford those with outstanding interest in this diagnostic procedure sufficient competence to pass the proposed test.

Periodic continuing education courses should be made available to electrocardiographic readers. The purpose of such courses would be to update electrocardiographic knowledge and review previous knowledge. The postgraduate course or workshop should have specific objectives and a well defined curriculum encompassing the essential knowledge and skills required by the electrocardiographer. The format of continuing education instruction should vary: The programs might be organized, for example, as a concentrated 3 to 5 day course or as a series of sessions held once a week.

Conclusions

Guidelines for the utilization of electrocardiograms in the pediatric and adult age groups interpreted by physicians or by computer programs were defined. Similar guidelines were defined for the use and interpretation of continuous ambulatory monitoring of the electrocardiogram and of exercise testing.

Recommendations were made for a core curriculum in electrocardiography, certification of competence in the interpretation of adult and pediatric electrocardiograms and reassessment of competence at appropriate intervals.

In certain areas it was recognized that no definite recommendations could be made at this time and that additional study was needed.

Task Force V: Cost Effectiveness of the Electrocardiogram

JORGE RIOS, MD (Chairman), FRED SANDQUIST (Co-Chairman), CAPT DOUGLAS RAMSETH, MSC, USA, ROBERT STRATBUCKER, ERICA DRAZEN AND JEAN HANMER

This report was designed to survey the available body of knowledge concerning the cost of electrocardiograms and indicate areas in need of further study. The need to establish a reasonable cost is accentuated by the present climate of concern about the cost of health care on the part of the Congress, the legislatures and the public. National expenditures for health care have tripled since 1965.[1] The availability of hard data will allow judgments of reasonable, justifiable charges by administrators, physicians and consumers.

This type of data will be scrutinized carefully in coming years. The passage of the Health Policy, Planning and Resources Development Act of 1974 (P.L. 93-641) and the subsequent designation of health planning agencies throughout the country are an example of establishing agencies to review new and existing health services, to determine if the cost is reasonable and the services necessary.

The establishment of a standardized cost-accounting method for electrocardiograms and cost-effectiveness determinations for various methods of their acquisition will expedite and simplify the procedures for charge justifications. Further, many employers and health insurers, as well as unions, are questioning the high cost of health insurance and pressuring providers to lower costs or provide alternative service delivery methods.

A search of published data reveals that information concerning the cost of electrocardiography is sparse. Those reports that do exist are fragmented, and the populations studied are small or in unusual circumstances. It is vital that the facts about the expenses involved in electrocardiography be established.

Cost-benefit decisions carry the potential trade-off between lower cost and higher quality. These decisions need physician input if they are going to be reliable, safe for patients and accepted by the medical community.

Definitions of Users

The costs of obtaining and interpreting electrocardiograms are dependent upon several factors—volume, rate of normal and abnormal tracings, hours of service and type of equipment used. Table I summarizes some characteristics of various users that influence the costs of electrocardiograms. Users are categorized into three groups: primary, secondary and tertiary care providers.

Data acquisition and processing methods relate to the type of service required. Although a single practitioner performing an average of eight electrocardiograms a day can work efficiently with a single channel recorder, a 1,000-bed tertiary care facility taking 4,000 records a month might justify a dedicated computerized elec-

TABLE I

User Characteristics—Influence on Electrocardiogram

Facility	Type of Patient	Type of ECG (Pathology)	Results Sensitivity/Specificity	Volume per Year	Equipment
Primary Office (private) Group	Outpatient	High number of normal tracings	High sensitivity	100–1,000/year* 2,000–40,000	1 channel 3 channel
Secondary	Inpatient	Balanced Normal vs. abnormal	High sensitivity High specificity balanced	Low–2 per bed/month† High–4 per bed/month 2,500–15,000	74% 1 channel‡ 19% 3 channel 7% 3 channel automated

trocardiographic system on grounds of economic feasibility.

Primary care providers usually see a high number of normal screening electrocardiograms; they are not cardiologists and may have limited access to their services. Screening clinics for industry or government process a high proportion of normal electrocardiograms for employment or other special purposes.

Secondary care facilities treat inpatients, most of whom have relatively uncomplicated medical or surgical problems. The size of these institutions ranges from 30 to 600 beds. Because their population consists of inpatients, the ratio of normal to abnormal electrocardiograms is more balanced.

Tertiary care facilities handle complex cases on a regional basis and frequently perform teaching functions as well. They usually have a staff of cardiologists and a larger number of abnormal electrocardiograms for interpretation.

The distinction between secondary and tertiary care facilities is becoming blurred because of trends toward specialization and the displacement of specialists toward secondary care facilities providing a full range of services.

Method for Electrocardiographic Recording

Electrocardiographic recorders: The elements influencing the cost of electrocardiographic production and processing are listed in Table II. In the United States electrocardiograms are recorded with single or three channel machines. Although six channel recorders are available, they are not yet in wide enough use to ascertain true costs.

The operation of single channel recorders is essentially manual. Several manufacturers provide an automatic lead switch for a predetermined recording duration. Although their performance and reliability are accepted and have been proved over the years, these recorders require more technician time to record and process each tracing than do three channel recorders.

Three channel recorders demonstrate useful and increased productivity, although they cost six times as much as single channel carts. The actual recording time does not differ significantly but the three channel electrocardiographic cart has a distinct advantage in productivity per technician. A technician with a single channel recorder can process 360 tracings a month (computer-assisted practice of cardiology report—CAPOC[2]). The same technician can handle 760 elec-

TABLE III

Comparison between Single Channel and Three Channel Recorders*

Volume of ECG (no)	Single Channel		Three Channel	
	Absolute Cost per ECG ($)	No. of Carts Necessary to Handle ECG Volume	Absolute Cost per ECG ($)	No. of Carts Necessary to Handle ECG Volume

3000	5.51	10	4.25	5

* Data obtained from the CAPOC report.[2] Data represent total direct costs for manual processing. Differences in cost are due solely to differences in type of cart used. All other cost factors are held constant for this simulation.
ECG = electrocardiogram.

trocardiograms a month with a three channel recorder. Three channel carts are being increasingly used in institutions that may or may not also use computer processing.

Volume: The impact of this efficiency factor as it relates to electrocardiographic volume is displayed in Table III. Since the various cost elements are comparable and derive from the same source (CAPOC report),[2] it seems clear that three channel recorders are most efficient for large institutions. Table III shows that the cost per electrocardiogram is significantly affected when volume requires purchase of an additional unit. This phenomenon is less noticeable when volume is large. Hard data to support this analysis for smaller volumes are not available to this Task Force. The dollar figures used in the CAPOC report are derived from government sources and thus are not necessarily comparable with private sector costs. They are shown strictly for comparison purposes.

Computer-assisted costs: An additional point for consideration is the cost of transmission of electrocardiograms from recording site to processing site. Several options are now available: (1) generation of hard electrocardiographic copy to be manually transported to the site or mailed in batches; (2) on-line transmission through conventional telephone lines with storage at the processing site on tape for subsequent batch processing either manually or by computer; (c) recording in magnetic output for subsequent batch processing by direct transmission to the processing site; and (d) on-line transmission and computer analysis.

The cost-effectiveness of three channel recorders, combined with on-line transmission through conventional telephone lines and permanent magnetic storage, is shown in Table IV. Such systems shorten clerical time and report generation if a dedicated minicomputer is used to generate the full diagnostic statements. It can be seen that a 4:1 improvement in average handling time is obtained by changing from 3.67 hours/electrocardiogram to 0.97 hours electrocardiogram. However, this improved efficiency does not result immediately in decreased production costs because a minimal number of technician hours are needed to provide an adequate hospital staffing pattern.

Technician costs: With increasing personnel costs in recent years, this difference in costs may be more impressive. Future studies should document when and whether decreased technician time becomes an important cost consideration. Technicians are still needed, but they can also perform other tasks in their newly freed time. The improved efficiency can be translated into expansion of services, such as provision of more hours of coverage per working day. This improvement in the quality of service can be accomplished with no additional costs. Table V illustrates the impact of semiautomation on cost per electrocardiogram for a 450 bed university hospital (1973 dollars).

Cost Breakdowns for Manual Electrocardiographic Operation

This section analyzes what little cost information is available and indicates areas in which information is inadequate. To determine the actual cost per record, more than the obvious cost of carts and electrocardiographic paper must be acquired. Items such as overhead, space and fringe benefits for personnel are also factors to be considered.

A cost analysis of manual electrocardiographic processing appears in Table VI. Total production costs for varying institutional characteristics are compared. This presents difficulties simply because the cost factors could not be standardized. Furthermore, accounting practices vary among institutions, and it is difficult to establish an absolutely comparable breakdown of cost elements. A study in which comparable costs could be identified would be useful. We did not have the resources to undertake such a task.

We defined three basic cost categories: personnel (technical and supervisory, not interpretive fee), direct expenses (suppliers, equipment maintenance and equipment depreciation) and indirect expenses (space rent, plant operation and overhead).

The cost of an electrocardiogram varies because of factors other than the type of chart or number of technicians available. For example, tracings acquired from groups of ambulatory patients reporting to a central location are less expensive than the same number of

ECG = electrocardiogram.

tracings taken by a technician in individual hospital rooms. When these scattered orders constitute the bulk of the institution's electrocardiographic caseload, the type of cart, the institution's layout and other factors play an increasingly important role in cost determination.

Analysis of Manual Interpretation

Determining the actual cost of electrocardiographic interpretation is difficult because allocation of the cost of the physician's interpretation can be done in several ways. The type of institution, the interpreter's level of skill, the degree of abnormality of the tracings and the nature of the patient population all influence the time necessary to interpret the electrocardiogram. The cost associated with interpretation by an expert electrocardiographer is higher than that associated with interpretation by a generalist. Adjusting for the cost of such expertise in providing interpretation of complex time-consuming electrocardiograms belongs in a more extensive but necessary study.

Physician costs: The best available method is to assess the potential cost of a physician's providing the necessary electrocardiographic analysis. The data presented here are derived from several sources. The report "Automated Electrocardiography in the United States"[3] indicates that the average reading time for a cardiologist is 97 seconds per electrocardiogram and the range is from 60 to 180 seconds.[3] This means that on the average a cardiologist can process between 30 and 40 electrocardiograms an hour.

The value of the physician's time for interpretation of electrocardiograms can be calculated in terms of his total gross annual earnings or in terms of the fee he charges for each interpretation. Because the fee for service compensation systems are more widely used, it is probably more realistic to calculate costs using these figures.

According to a study of electrocardiographic costs by Arthur D. Little, Inc., fee schedules represent the market price for the cardiologist's time and also indicate a value placed on his responsibility for the interpretation. Annual income figures can be used to calculate the value of the time saved by computerizing electrocardiographic interpretation. However, both methods of calculating costs are very imprecise.

Teaching time: One of the numerous elements in evaluating physician cost is the teaching conducted in most tertiary hospitals or institutions affiliated with medical schools where graduate and postgraduate education is conducted. A study conducted in the Electrocardiographic Laboratory at the George Washington University Medical Center in 1974 estimated that during a 3 month observation period, 48 percent of a cardiologist's reading time was spent in teaching. In other words, when electrocardiograms were read in conjunction with trainees and medical students, the efficiency factor of the cardiologist decreased by approximately 50 percent.

TABLE VII

Range of Internists' Fees for Electrocardiogram With Interpretation and Report*

Fee ($)†	% of Internists Charging It
≥25	17
20	35
16–19	11
15	30
11–14	3
≤10	4
Median fee $20	

* The costs covered include not only those of acquiring, mounting and storing the electrocardiogram, but also the physician's fee for interpreting the record and processing his findings (report). The distinction is important because interpretation costs are sometimes shown separately.
† Fees are those most frequently charged by office-based MDs in the spring of 1975. Fees are shown as single figures instead of as ranges where few if any doctors charge amounts in between; in these cases variations have been lumped with the lower figure. From **Owens A:** At last: hard figures on how fast fees have been climbing. Medical Economics, October 13, 1975, p 109.

TABLE VIII

Cost of Implementation of In-House Computer ECG System

	Cost ($)
Computer systems	
Basic system	100,000–140,000
includes all hardware and software for in-house application	
Approximate monthly rental with maintenance	3,000/month
Yearly maintenance	7,000/year
Typical system	120,000–150,000
(includes basic system plus ability to provide service to remote hospitals)	
Approximate monthly rental with maintenance	3,500/month
Yearly maintenance if purchased	8,600/year
Analysis and storage system	200,000–225,000
(includes typical system plus ability to store 150,000–200,000 ECGs)	
Approximate monthly rental with maintenance	6,000/month
Yearly maintenance if purchased	14,000/year
Program rental fee	400–600/month
Computer-compatible ECG carts	
1-channel writer, 3-channel transmission	5,000
Approximate monthly rental with maintenance	145/month
Yearly maintenance if purchased	400/year
3-channel writer, 3-channel transmission	7,400–9,000
Approximate monthly rental with maintenance	225/month
Yearly maintenance if purchased	700/year
Other equipment	
Remote teleprinter	2,500–3,000
Approximate monthly rental with maintenance	80/month
Yearly maintenance if purchased	250/year
First year of maintenance	Usually covered under warranty

Ratio between normal and abnormal records: The volume of the operation and the ratio between normal and abnormal tracings help to define the most effective method for electrocardiographic analysis. Trained technicians can perform routine measurements and preprocess electrocardiograms with a coding system to facilitate physician work and enhance performance. This approach may prove extremely useful for those institutions not large enough to justify a computer system.

Table VII shows the range of internists' fees for interpretation of electrocardiograms. The figures from a study prepared by the Department of Defense evaluating the Naval Regional Medical Center in San Diego indicate that it takes 2 minutes to interpret a normal electrocardiogram and up to 6 minutes to interpret an abnormal one. Assuming 50 percent abnormal tracings, these data indicate that 50 hours of cardiologist reading time are required per 1,000 electrocardiograms.[3]

Computerized Electrocardiography

Computerized In-House Electrocardiographic Systems

Cost analysis of computerized electrocardiographic processing requires separation of acquisition and processing costs. In general, the implementation of computerized interpretation for hospital use is associated with the use of three channel carts. Additional costs are incurred when remote facilities perform analysis of data because the total charges associated with long-distance telephone calls must be incorporated into the total unit cost.

The cost of a computer system (central processing unit) and related peripheral equipment, currently used for electrocardiographic processing is shown in Table VIII. An expense that in-house computer processing would add is installation of telephone jacks at the patient's bedside to permit on-line transmission, a cost that usually is no more than $20 per installation with no monthly additional charge and a dedicated business line. Any study of cost effectiveness of computer processing requires a clear correlation with electrocardiographic volume (Table IX).

Service Bureau Processing

Commercial service bureaus provide computer-assisted electrocardiographic interpretation for customers

TABLE IX

Monthly Cost of Computerization With In-House System*

	Assuming 5-Year Equipment Amortization	Assuming 10-Year Equipment Amortization

ranging from physicians in private offices to the staffs of clinics, hospitals and screening centers. We considered three representative service bureaus whose basic service charges are shown in Table X. As indicated, charges are volume-dependent, with defined break points resulting in user discounts for higher volumes.

Basic charges are based upon a graduated monthly electrocardiographic volume, but differences in what is included as part of this charge make absolute comparison difficult. For example, one service bureau includes either a specialized transmitting device or a single channel tracing recorder with transmitting capability at no charge, but it requires a minimal monthly volume (6 and 15 electrocardiograms a month, respectively). Another vendor can provide graduated schedules including either a three channel cart and a teleprinter or one covering only the analysis service.

Several service bureaus include telephone charges for data transmission to their facilities and for return of the analysis reports. Some require an additional $1 per electrocardiogram to telephone results back to the user. (Their basic charge includes mailing the analysis report to the user.)

TABLE X

Representative 1976 Service Bureau Costs

addition to the basic monthly service charges. In essence, when a user is considering a contact with a service bureau, it is imperative to define explicitly what type of service is required, what is included in the service bureau's basic charges, what options are required and what it is the user's responsibility to provide.

Electrocardiographic Charges for Manual and Computer-Assisted Electrocardiographic Processing

Precise information on electrocardiographic cost could not be ascertained. Accordingly, an attempt was made to evaluate the question indirectly by examining charges as reported by major insurance carriers for various states.

Tables XII to XV depict the geographic distribution of electrocardiographic charges for two major providers. Variations are readily apparent for various states with no clear relation to regional area. Charges do not seem to differ significantly between manual and computer-assisted electrocardiographic processing (Table XVI). Similarly, the average charges vary only slightly regardless of the medical environment providing the service. Information concerning charges in relation to the expertise of the interpreter cannot be determined, and it appears that a major cost factor is what the local communities consider customary and reasonable for the procedure, as well as the allowable charge by the largest providers.

Facilities

Space and related facilities needed for the adequate function of a heart station are a direct consequence of the characteristics of the institution and the volume of electrocardiograms processed. The electrocardiographic laboratory should be integrated with the other cost centers involved in noninvasive cardiologic diagnostic procedures if they are available.

Space specifically allocated to electrocardiography is determined by the volume of records processed and the type of processing utilized. Minimal requirements include a comfortable well lighted reading room, office space for the laboratory supervisor, ample storage space for the last 5 years of recordings, appropriate space for the preparation of reports and other administrative support functions (such as billing and preparation of insurance forms) and space for specific

* Telemed is a commercial service bureau.
ECG = electrocardiogram.

technical work such as mounting and cutting. Standard safety precautions should be ensured for equipment, fire protection, ventilation and air conditioning. If a magnetic storage medium is used, environmental conditions should be controlled and monitored. Similarly, all necessary electrical installations needed for the support of data processing equipment should meet industry standards and accepted safety practices.

Facilities for recording of electrocardiograms for inpatient and outpatient populations should meet standards for electrical insulation and other safety aspects. Proximity of electrocardiology facilities to the laboratory and the radiology department expedites patient processing, particularly new admissions, with a minimum of patient transportation.

In a single practitioner's office, electrocardiograms can be readily taken in an examining room. Group practitioners performing more than 12 electrocardiograms a day find it convenient to set aside a special area for electrocardiographic recording and processing. This minimizes equipment transfer with attendant damage and allows centralized billing.

Personnel

The method used for electrocardiographic processing plays an important role in determining the personnel requirements. The architectural design of an institution influences the time necessary for an electrocardiographic technician to travel between nursing units.

Ideally, technical and clerical functions should be separate. The extent of technician coverage is, again, a function of electrocardiographic volume and the primary goals of the institution. If an institution uses a three channel recorder,

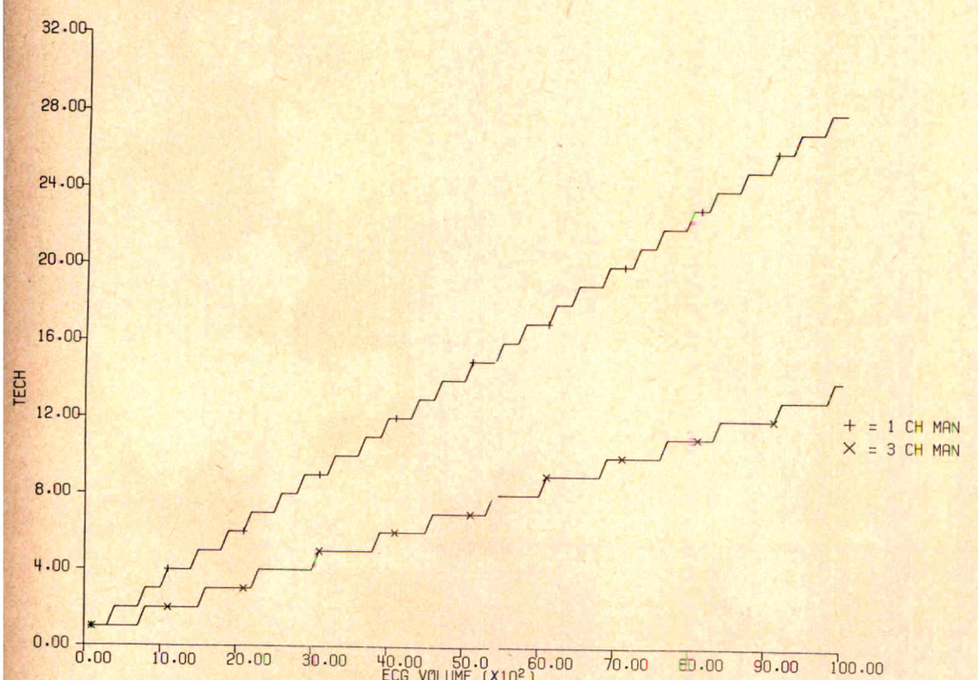

FIGURE 1. Graph showing effects of single and three channel electrocardiographic machines on productivity of technicians. It can be seen that three channel machines consistently save technician time and thus lower costs for personnel. These savings are particularly significant as the volume of electrocardiograms increases. CH = channel; ECG = electrocardiographic; MAN = manual; TECH = technicians.

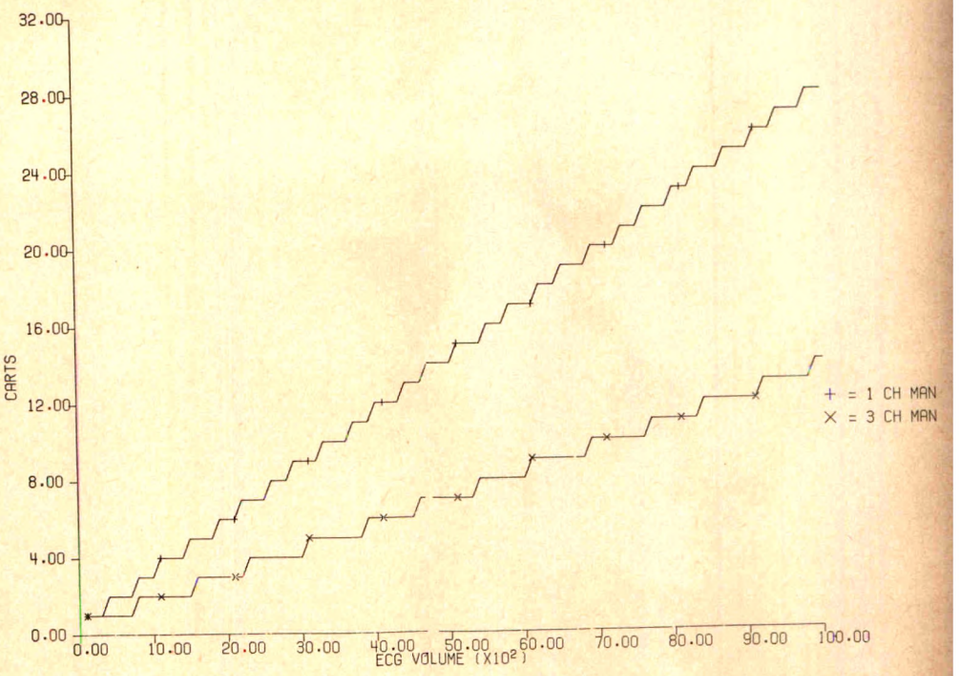

FIGURE 2. Graph showing the number of single channel manual electrocardiographic carts needed to produce tracings at specific volumes versus three channel manual electrocardiographic carts. The use of three channel carts reduces the number of carts needed per 1,000 electrocardiograms. However, three channel carts currently cost six times as much as single channel carts.

trained personnel are needed at all times because the chances of technical errors and equipment breakdown are greater when the equipment is operated by untrained personnel. On the other hand, for institutions using single channel carts, trained nurses, paramedical personnel or house officers may provide adequate service.

It is difficult to determine rigid operational guidelines for electrocardiographic data acquisition because manpower requirements are determined by volume as well as equipment characteristics.

Equipment

For a detailed discussion of the costs and benefits of single channel versus three channel electrocardiographic recorders in various settings, the reader is referred to the "Method for Electrocardiographic Recording" section.

Simulation of Costs

To determine which methods of electrocardiographic acquisition are likely to be cost-effective for a given institution, a computerized simulation can be used. Presented here is information about a simulation program developed by one member of this Task Force (D.R.) to measure alternatives such as single channel versus three channel carts per volume of electrocardiograms to show cost-benefit break points.

The computerized simulation uses cost data obtained from salary and equipment cost records and productivity data obtained from measured performance in situations similar to that of the method to be simulated.

To simulate alternatives properly, two types of items were identified. First, a variable function item has a volume-dependent cost function, which is linear over fixed regions of volume and may have discrete steps associated with particular volumes called break points. An example is an electrocardiographic service bureau with an initial fixed charge, no incremental costs and decreased costs at greater volumes.

The second type is a fixed productivity, fixed cost item. Once the fixed productivity of this item is exceeded, it is assumed that another must be acquired to handle the increased volume. Electrocardiographic carts fall into this category.

Examples of output from the simulation program are given in Table XVII and Figures 1 and 2. These tables compare six alternative methods of providing electrocardiographic support at three selected volume levels and show the calculation of the costs associated with these methods.

Conclusions

1. On the basis of the limited data available to this Task Force, some guidelines for evaluation of costs and cost-effectiveness were developed. However, a more comprehensive study of costs is needed before any firm conclusions on cost-effectiveness can be reached because of hidden costs and other elements that must be identified.

2. Before a new processing system is installed, cost analysis of all available options should be conducted to assure that the new process is the least costly approach to providing the desired service. Costs for each system must be determined individually to take into account institutional and geographic factors.

3. Cost is not the only factor to be considered. Less tangible benefits of computerization may also prove to be determinants.

Body Surface Mapping

Purpose: Isopotential body surface maps are used to provide a complete picture of the body surface effects of the currents from the heart. The potential distributions are represented by contour lines of equal potential, and each distribution is displayed instant by instant throughout activation or recovery, or both. Body surface maps do not require the assumption of an equivalent dipole or any other equivalent generator model.

At present, body surface maps provide a standard for testing and comparing lead systems in regard to their ability to reproduce accurately all available body surface electrocardiographic information. Another use is the evaluation of conditions that produce localized changes in the ventricle (ischemia), conditions with the simultaneous presence of prominent repolarization and depolarization potentials (ventricular extrasystoles) and conditions with anomalous sites of excitation (Wolff-Parkinson-White syndrome).

Current status: In 1889 Augustus Waller[1] recorded 10 to 20 electrocardiograms from the surface of the human body and plotted the amplitude on a representation of the human chest. Thereby, body surface mapping was historically the first method used in human electrocardiography. The potential distribution he showed appeared as if a dipole had been located in the chest. Thus, the dipole model of cardiac electrical activity as interpreted from body surface recordings had a major influence on electrocardiographic recording and interpretation for more than 50 years. Since the equivalent dipole can be represented by a vector, three leads are sufficient to define the "heart vector" so as to represent the *equivalent* effect of all the heart currents at any instant of time. However, it was shown[2] that when potential distributions were recorded over extensive areas of the chest, results could not be accounted for on an equivalent dipole basis. In 1963 Taccardi[3] described the sequence of body surface potential distributions during ventricular excitation in normal human subjects and interpreted them physiologically to indicate that a more complex electrical model of the heart was required to account for body surface potential patterns. Since then, extensive studies have confirmed and extended the application of body surface maps in patients. These studies have shown that at some instants the body surface distributions are simple and at other times complex, during both activation and repolarization. Thus, isopotential body surface mapping has provided a stimulus to extend the interpretation of electrocardiograms to one of predicting selective electrical events within the heart, rather than considering only overall equivalent effects.

The technique usually consists of recording in excess of 100 electrocardiographic leads distributed over the entire chest.[4] Recording and data processing are done with the aid of computers, and the entire procedure can be carried out by trained technicians.

The analysis of maps at present is primarily descriptive, as with most conventional electrocardiographic and vectorcardiographic methods. However, quantitative comparisons have been made between normal patients and patients with inferior infarction.[5] Estimates have been made of left ventricular muscle mass and compared with angiographic estimates.[6]

Detailed analysis of maps recorded with more than 100 electrocardiographic leads has shown that for most conditions approximately 24 to 32 leads should provide excellent coverage of the total body surface.[7] This represents a modest increase as compared with the number of leads used to record conventional electrocardiograms and vectorcardiograms but not so many as to be excessively cumbersome. The use of this type of "limited lead" recording system involves the initial recording from approximately 30 leads, and the potentials for all body surface positions are derived from the originally recorded waveforms.

Body surface maps have been used primarily for research purposes; however, there has been preliminary clinical application in the following areas: localization and sizing of myocardial infarcts, detection of areas of ischemia (especially those apparent only with exercise), localization of ectopic foci, and differentiation of aberrant supraventricular conduction from ventricular origin.

Future development: *The principal needs are to* (1) refine the recording and data processing techniques, (2) extend the qualitative interpretation criteria, and (3) develop quantitative models for representing cardiac electric activity from body surface maps. Refinement of the recording techniques to the best number of leads, rapid data processing procedures with small computers, and display of the potential distribution on movie film are needed to make the maps readily available and easily viewed by the physician. The techniques for data presentation to facilitate the review of maps will be important. Especially promising is the use of QRS, T and QRS-T iso-area body surface maps, as proposed by Abildskov et al.[8]

The clinical use of body surface maps is limited at present to qualitative interpretation, which is basically the responsibility of the physician. This will be the main

approach required for some time. Ideally, the physician would be able to interpret events in the heart physiologically, in terms of the heart itself. Consequently, the use of body surface maps has highlighted the importance of developing a generally accepted representation or model of the electric activity of the total heart. At present the isochrome has been used for activation.[9,10] However, this representation cannot be used for the S-T segment and T wave, and other representations must be developed.[11] The representation of cardiac electric activity, as derived from body surface maps, should provide an important clinical tool for extending conventional electrocardiography for the goals noted. In essence, the recording of body surface maps will provide the basis for future research on the "inverse" electrocardiographic problem.[12]

An important immediate application is the use of limited lead systems to record body surface maps during ischemia induced by exercise or pacing. It is already apparent that body surface maps may provide an important way to correlate localized cardiac ischemia with the results of other techniques, such as myocardial imaging and echocardiography. Diagnosis of myocardial infarction that is equivocal or not apparent in conventional electrocardiograms can be facilitated with body surface maps.

Body surface maps should be useful in the study of repolarization to determine the genesis of the normal T wave, to explore further the complex repolarization potential distributions in some abnormal conditions, and to determine the patterns that allow differentiation of minor S-T segment elevations in normal patients from such elevations in patients with ischemic disease.

Body surface maps should provide an improved way to localize more accurately the origin of anomalous sites of excitation such as those that occur in Wolff-Parkinson-White syndrome, extrasystoles and ventricular tachycardia.

Direct Cardiac Mapping—Recording of Potentials Directly From the Heart

Purpose: Cardiac mapping is a method whereby potentials recorded directly from the heart are spatially depicted as a function of time in an integrated manner. The location of recording electrodes (epicardial, intramural or endocardial) and the recording mode used (unipolar versus bipolar), as well as the method of display (isopotential versus isochrone maps), depend upon the problem under consideration.

Current status: Accepted clinical applications have empirically resulted in the almost exclusive use of isochrone maps to depict sequences of activation. The surface activation of the human heart was first reported by Barker et al.[13] in 1930 using the technique of epicardial mapping reported earlier by Lewis and Rothschild.[14] The most elaborate studies were obtained by Durrer et al.[10] and Brusca and Rosettan[15] with in vitro methods using revived human hearts in the adult and the fetus, respectively.

The most successful application of direct cardiac mapping has been in the localization of accessory pathways associated with the Wolff-Parkinson-White syndrome, as first demonstrated by Durrer and Roos[16] in 1967. Experience to date has attested to the value of surgical interruption of the accessory pathway in managing selected patients with life-threatening or medically refractory arrhythmias associated with the preexcitation syndrome. The ability to map the sequence of atrial and ventricular activation is of pivotal significance in the new frontier of electrophysiologic surgery.[17,18]

Endocardial mapping has been used to delineate the anatomic course of the His bundle during open heart surgery to avoid injury to this structure during corrective procedures in *patients with congenital heart disease.*[19] More recently, cardiac mapping has been used to identify the site of rhythm disturbances in patients with ventricular arrhythmias refractory to medical therapy.[20] Similarly, atrial mapping has been used to define the origin of rhythm disturbances in the atria for purposes of surgical ablation.[21]

Another clinical application of cardiac mapping has been to identify areas of myocardial ischemia or infarction for purposes of revascularization or to define margins for surgical resection in the treatment of ischemic heart disease.[22,23]

Future development: *Repolarization potentials,* simultaneously acquired from many cardiac sites, can be displayed as isopotential distributions to identify and localize regions of ischemia. Problems with local injury induced by electrodes must be overcome, as well as alterations introduced by exposure to air and temperature change. Combined with recordings obtained during depolarization, this type of analysis applied to arrhythmias should advance our understanding of the underlying mechanisms and should refine the technique of localizing sites of arrhythmia for purposes of surgical ablation. This development will utilize simultaneous recording sites and on-line computer analysis. Coupled with this will be the requirement that further refinement be made in the techniques available to reproducibly precipitate arrhythmias that are not present spontaneously.

Another application of cardiac mapping will be the correlation of potentials recorded directly from the heart with body surface potentials and cardiac anatomy. Currently accepted electrocardiographic diagnoses such as hemiblock and incomplete bundle branch block are based primarily on a model of abnormality in the specialized ventricular conduction system. Data from carefully constructed activation studies obtained during surgery in such patients, correlated with the associated anatomic and pathologic features of the heart, might explain the abnormal electrocardiogram in these entities and indicate the possible role of myocardial factors.

Intracardiac Electrocardiography

Purpose: The technique of intracardiac electrocardiography involves insertion, under local anesthesia, of one or more multipolar catheter electrodes into a pe-

ripheral vein. The catheter electrode is advanced under fluoroscopic guidance to various positions in the heart. The purpose of such a procedure is to record endocardial activity generated from areas of the atria, ventricles and portions of the specialized conduction system such as the His bundle,[24] right and left bundle branches, and, possibly in the future, from the sinus and atrioventricular (A-V) nodes. In addition, several of these sites can be selectively stimulated[25] with electrical impulses delivered from the catheter electrode.

Current status: Careful assessment of the surface electrocardiogram eliminates the clinical need for intracardiac electrocardiography in many instances. *However, intracardiac electrocardiography may be clinically useful in the following situations:*

1. To measure conduction times and determine refractory periods to establish the presence of normal or abnormal electrophysiologic properties.[26] Such measurements may be useful in evaluating a patient with unexplained syncope, bradyarrhythmia or chronic A-V block to establish the presence and site of the conduction disturbance. The rationale for such an evaluation is based on the generally accepted observation that the presence of conduction delay in the His-Purkinje system carries a worse prognosis. Several points should be stressed. First, conduction disturbances may be labile, so a patient may have a normal H-V (His bundle deflection to onset of ventricular depolarization) interval and still have trifascicular disease with intermittent His-Purkinje block on other occasions.[27] Also, the clinical significance of a prolonged H-V interval has not yet been entirely established.[28]

2. Determination of sinus nodal conduction times[29] *and response to overdrive stimulation.*[30] Estimation of sinus nodal conduction time, determined by the response of the sinus node to premature atrial stimulation, assumes that the rate of sinus nodal discharge is not altered by premature stimulation, that the entire sinus node is totally discharged and "reset" by premature stimulation, and that the conduction time into the sinus node from various atrial sites equals the conduction time out of the sinus node. In fact, such assumptions are probably often incorrect, and determination of sinus nodal conduction time at present must be considered unreliable. Determination of the response of the sinus node to overdrive suppression, as a measure of sinus nodal automaticity, is plagued by a large percent of false negative responses. Patients with documented sinus nodal dysfunction may have a normal response to overdrive stimulation. However, a positive response usually indicates sinus nodal dysfunction.

3. Differentiation of aberrant supraventricular conduction from ventricular origin of the QRS complex. His bundle electrocardiography may be extremely useful for this purpose. The presence of an H-V interval equal to or longer than the H-V interval occurring normally during sinus rhythm establishes a supraventricular origin. A shortened H-V interval indicates the presence of ventricular origin[41] or conduction over an accessory pathway, bypassing normal A-V conduction.[32,33]

4. Determination of the sequence of activation to establish sites of impulse formation or pathways of conduction. Determination of the sequence of activation of the atria or ventricles may be useful in mapping the pathways involved in a tachycardia, such as those reciprocating tachycardias utilizing the accessory pathway in patients with the Wolff-Parkinson-White syndrome,[34–36] and possibly in some patients with ventricular tachycardias.

5. Determination of mechanisms of tachycardia.[37,38] The clinical determination of the mechanism of a tachycardia by the extrastimulus technique is based on the premise that a tachycardia that can be initiated or terminated by one or more premature stimuli is probably due to reentrant excitation, whereas a tachycardia that can be captured or "reset" but not initiated or terminated by pacing stimuli is very probably automatic in origin. Such an approach can be used to investigate mechanisms generating various tachycardias. However, it is important to note that under certain experimental conditions, automaticity can be triggered in isolated preparations.[39,40] This observation raises questions whether the response to premature stimulation can be used to differentiate reentry from automaticity.

6. Evaluation of the effects of drugs. The effect of various drugs can be established in patients at the time of an electrophysiologic evaluation, particularly in patients with tachycardias that can be repeatedly initiated by premature stimulation. After electrophysiologic measurements are obtained under controlled conditions, a drug can be administered to determine whether the drug prevents reinitiation of tachycardia as well as the mechanism by which this occurs. The ability or failure to initiate a tachycardia after drug administration may not necessarily correlate with the spontaneous development of tachycardia in some patients. Drugs may also help to suppress premature complexes that initiate a tachycardia, an event that may not be apparent during the limited time of an electrophysiologic evaluation.

Future development: Future applications of intracardiac electrocardiography will include refinement of its present uses. For example, newer techniques may be developed to evaluate sinus nodal function more accurately. Exploration of the left ventricular endocardium may reveal information regarding ventricular arrhythmias in addition to that obtained by exploration of the right ventricular endocardium. Specifically, areas of delayed conduction or continuous electrical activity may be found in some patients with ventricular arrhythmias.

Intracardiac electrocardiography may be combined with echocardiography or myocardial imaging to develop electroanatomic correlations. Such approaches may be useful to establish new indexes for identification of patients at high risk for sudden death due to A-V block or ventricular fibrillation. It may be that H-V prolongation correlated with one type of anatomic substrate may carry a different prognostic implication from H-V prolongation correlated with a different substrate. Electroanatomic correlations may be useful

in understanding the pathogenesis of some arrhythmias. Finally, intracardiac electrocardiography may be combined with methods for producing localized destruction of tissue permitting localized areas of automaticity or reentrant pathways to be destroyed in a manner similar to that which is done at surgery.

Continuous Electrocardiographic Monitoring

Purpose: Continuous electrocardiographic monitoring allows the detection of changes in the electrocardiogram, such as alterations in the rate and rhythm, conduction and ventricular repolarization as manifested in the ST-T waves. In the hospital this is accomplished with bedside recorders, telemetry, or portable magnetic tape recorders. Portable recorders are used for outpatients. Telemetry is used by rescue units dispatched to victims of cardiac arrest outside the hospital and in rehabilitation programs.

Current status. *In the hospital,* it is standard practice to monitor continuously the electrocardiogram of patients who have had or are at high risk for the development of arrhythmias, such as patients who have acute myocardial infarction, have undergone major surgery or have a critical illness, digitalis intoxication or conduction system disease. Continuous monitoring has been the basis for the development of coronary care units, which have probably reduced in-hospital mortality from myocardial infarction by about 50 percent.[41–43] Telemetry is used mainly in progressive care units where patients can walk. Some computer programs are available for automatic detection, diagnosis and quantification of arrhythmias, but reliance is primarily placed on human surveillance of the continuous recording and on simple alarms based on detection of rate changes. This latter approach fails to detect some transient arrhythmias.

Outpatient monitoring techniques at present allow reasonably reliable detection and categorization of disturbances in rhythm over a 24-hour period using human inspection of the graphic recordings. Detecting arrhythmias in this manner may explain the origin of symptoms, anticipate potentially fatal disorders of rhythm and guide therapy. Recent awareness of the magnitude of the problem of sudden death from arrhythmias[44] has stimulated interest in long-term monitoring to control arrhythmias and identify patients at risk from lethal arrhythmias. Present drawbacks of the techniques include limited capacity for storage of information (limited monitoring period), high cost, unreliable information related to the ST-T wave, and crude, costly and fallible methods for the retrieval and analysis of information.

Future development: *Monitoring in the hospital* could be improved by computer-assisted programs for automatic arrhythmia detection and diagnosis. Some programs have been developed but are not yet validated as to accuracy and reliability. In addition, programmed therapeutic intervention could be instituted. Also, greater capacity for receiving and storing data would allow the recording of more leads and offer some of the advantages of body surface mapping.

For monitoring of outpatients, the present clinical and investigational uses would be facilitated by technical improvements. Methods for data storage other than magnetic tape should be explored. The use of a microprocessor or other large scale integration components might allow some data reduction such as coding or simplification of the wave forms before storage or selection of data for storage. Such a method might prolong the monitoring period and reduce the size of the recorders.

It is likely that developments will enable computer technology to replace or improve current methods of data processing and analysis. It is also conceivable that technologic improvements might lead to the development of implantable permanent monitors of cardiac rhythm to be used in certain categories of patients. Such permanent monitoring would have investigational value, and might be clinically useful if combined with some form of alarm system, some method of programmed therapeutic intervention or some method of transmitting the information to a responsive medical facility.

Signal-Averaging Techniques

Purpose: Signal averaging is a method to improve signal-to-noise ratio applicable to recurrent signals if the noise is "random," that is, not synchronous with the signal. In conjunction with other methods of noise reduction, signal averaging can detect cardiac signals of a few microvolts.

Current status: With this method, potentials generated by the His bundle and bundle branches are detectable at the body surface.[45–54] The duration of the His-Purkinje wave form corresponds to the H-V interval recorded by the catheter technique.

Signal averaging has also been applied to improve resolution of potentials that are detectable by standard recording techniques. Examples of such application include the recording of fetal electrocardiograms[55] as well as of P waves[56,57] and of ST-T waves during exercise. In the last instance, the problem entails reduction of a high noise level introduced by exercise.

Future development: The main impediment to consistent reliable recording of the His-Purjinke wave form is superimposition of atrial potentials when A-V nodal conduction is relatively rapid (P-R interval near the lower limits of normal).[52] Future development will probably require a means of prolonging A-V nodal conduction during the period of recording because filtering techniques have failed to attenuate atrial potentials selectively. In some subjects, skeletal muscle potentials may interfere. Recording His-Purkinje wave forms would allow not only the temporal analysis (H-V time) now provided by the electrode catheter technique but also vectoral analysis. Abnormalities of the His-Purkinje wave form might aid in the earlier detection of conduction system disease, the anticipation of heart block and the differentiation of conduction system disease from other causes of electrocardiographic abnormalities.

The application of signal averaging to ST-T waves or the T-P segment might help to detect delayed activation of diseased ventricular myocardium. Delayed activation potentials might serve as a portent of serious ventricular arrhythmias, a guide to antiarrhythmic therapy, a diagnostic aid in detecting heart disease or a means of differentiating between reentrant and automatic ectopic beats.

The application of signal averaging to intracardiac recordings may enable direct detection of potentials from the sinus node, A-V node, bundle branches, and accessory pathways, or delayed activation potentials of diseased myocardium.[54]

Conventional Electrocardiography

Purpose: The development of conventional electrocardiography has been largely empirical. For example, "significant" Q waves in leads II, III and aVF are taken to imply inferior infarction, not because the mechanism is thoroughly understood but because a significant correlation has been established between the occurrence of Q waves before death and the presence of lesions after death.

Current status: *The specificity and sensitivity of various diagnostic criteria* as interpreted by the electrocardiographer have been extensively evaluated. These studies have shown that the electrocardiogram is diagnostically useful, but the performance is quantitatively limited. For example, a commonly used method for diagnosis of left ventricular hypertrophy has a specificity rate of 97 percent and a sensitivity rate of 60 percent.[58] On the other hand, quantitation of left ventricular mass with various electrocardiographic criteria gave large standard errors of the estimate.[59] Because conventional electrocardiographic analysis is largely empirical, or model-independent, and based upon wave form analysis the computer should be well suited for this task.

The development of computer programs to date has been largely heuristic. Electrocardiograms are classified according to the electrocardiographer's present and past ideas about the meaning of surface electrocardiographic signals. Such programs are usually an attempt to emulate the electrocardiographer. This approach has recently been reviewed by Caceres.[60] A different approach has been taken by Pipberger et al.[61] and Kornreich and Brisme,[62] who performed multivariate analysis of three orthogonal leads and an unconventional lead group, respectively. The development of these programs has been guided by the use of electrocardiogram-independent data.

Future development: *Conventional electrocardiographic studies in the immediate future should be directed toward computer processing.* It is also possible that this may improve the diagnostic performance of the electrocardiogram. Validation of computer program performance should be done using an electrocardiogram-independent objective method. This involves development of a data bank for testing programs quickly and accurately using findings obtained at autopsy and angiography, and by other means.

Magnetocardiography

Purpose: Magnetocardiography is the measurement of the weak magnetic field around the torso that is generated by the heart.[63] Recording these fields requires sophisticated equipment and is facilitated by an environment shielded from the earth's and urban electromagnetic fields

Current status and future development: Magnetocardiography seems particularly well suited to the measurements of "currents of injury," which are manifested by S-T and T-P segment shifts in the electrocardiogram. These shifts have been correlated with reduction of the resting membrane potentials and shortening of the action potential in an ischemic region.[64,65] Cohen and Kaufman[66] have recently reinforced this by measurements of direct current magnetic fields during S-T and T-P segments in experimental myocardial infarction.[67]

As pointed out by Fozzard and DasGupta,[67] this is potentially a valuable observation and is worthy of future study. The collaboration of physical and medical scientists in such studies should be fruitful.

Stress Testing

Purpose: The main purpose of stress testing is to increase myocardial oxygen requirements to unmask an impaired ability of the coronary arterial system to increase myocardial blood flow.[68–71] In most clinical situations, this test is performed to confirm or rule out the diagnosis of coronary artery disease. Stress testing is also useful to obtain an indirect assessment of myocardial function in patients with known or suspected valve or primary myocardial disease. It can also be used to detect exercise-induced supraventricular or ventricular arrhythmias and to evaluate the success of antiarrhythmic therapy in suppressing these arrhythmias.

Current status: The stress electrocardiogram can be obtained by treadmill exercise, bicycle ergometry or other exercise techniques such as the two-step test or hand grip. However, the exercise electrocardiogram is only one aspect of the overall clinical information gained from stress testing. An important aspect of stress testing is to assess the patient's exercise tolerance or overall functional capacity. This type of evaluation can be obtained only through the use of graded exercise[69]; therefore, treadmill or bicycle ergometry is the preferred instrument for the clinical stress test. The diagnostic performance of stress testing has deficiencies, in both specificity and sensitivity.[72]

Future development: *Applications of the stress test will most likely remain the same in the future,* although the broad patient information base that can be obtained from such testing will become more widely recognized. For example, the information gained concerning the patient's exercise tolerance or functional capacity may become more useful for making therapeutic decisions. The presence, magnitude and duration of S-T depression, the blood pressure and heart rate responses at the time of onset of limiting symptoms or electrocardio-

graphic abnormalities, and the presence of auscultatory abnormalities after exercise can now be used for this purpose. It is also possible that the severity of underlying coronary artery disease and myocardial dysfunction can be more closely quantified in the future by carefully evaluating these indirect indexes.

Stress testing has already been combined with myocardial imaging techniques to define better the presence and severity of myocardial ischemia and myocardial dysfunction. In the future, body surface mapping techniques, which would allow recordings during dynamic exercise, should also become available.

Overview

Future directions are predicted on the basis of new information learned in the electrophysiologic laboratories, advances in computer technology and the ability to record and process information rapidly. Much of the future work in electrocardiography will be directed toward two principal areas: (1) surface potential electrocardiography, and (2) cardiac conduction and arrhythmias.

Surface potential electrocardiography: *The conventional electrocardiogram may be used as a method for* (1) individual patient and mass screening, (2) monitoring acutely ill patients or patients with cardiac arrhythmias, and (3) long-term monitoring of rhythm disturbances.

The vectorcardiogram, based on the equivalent dipole model, is well recognized as a first approximation of the cardiac sources; it cannot account for the complete body surface potential distribution. However, to date it has been useful as an intermediate step by virtue of certain lead locations not used in scalar electrocardiograms and because of its graphic spatial-temporal display characteristics. It should be noted that the vectorcardiographic leads can also be synthesized from body surface map data.

Body surface potential distributions will be the primary direction of electrocardiography in the future. Recent work indicates that there is considerable information in the body surface potential distribution that is not adequately recorded or spatially or temporally represented in conventional electrocardiograms or vectorcardiograms. Work is in progress and should continue to define the relation between the body surface potentials, the cardiac potentials and the anatomic and functional changes in the heart that result in these potentials. The recording and analysis of multiple thoracic potentials and potential distributions follow from the relation between (1) thoracic potentials and cardiac potentials, and (2) cardiac potentials, cardiac structures and electrophysiologic function.

Basic studies relating surface potentials to cardiac potentials and anatomy will provide a foundation for future electrocardiography. Certain electrographic patterns, although secondary to one mechanism, may actually be due to another. For example, the patterns referred to as hemiblock or bundle branch block frequently represent variations in geometry, asymmetric myocardial hypertrophy, intramural discontinuities or developmental conduction system asymmetry rather than delay in the specialized ventricular conduction system. Computer simulations of cardiac anatomy and electrophysiology will be used to relate quantitatively the body surface potentials to both activation and recovery. Ultimately, inverse models will be used to predict the cardiac mechanisms of surface potentials.

The aim will be to predict a specific structural or functional state resulting in the potential distribution, or to indicate and statistically rank several possible mechanisms, including combinations of abnormalities such as hypertrophy, multisurface infarction and endocardial conduction system disease.

Arrhythmias and cardiac conduction: The mechanisms for clinical tachyarrhythmias may be diverse. Most of these mechanisms are insufficiently defined, with the possible exception of reciprocating tachyarrhythmias utilizing accessory pathways. The present clinical means for determining the electrophysiologic mechanism of arrhythmias are based on the responses of arrhythmias to electrical stimulation. Certain experimental data indicate that the responses of arrhythmias to extrastimuli may not distinguish reentrant mechanisms from certain abnormal automatic mechanisms.

Clarifying the mechanisms of clinical tachyarrhythmia will likely necessitate various means of study, including multiple simultaneous electrode mapping of activation and refractoriness. Recording the activity of critical regions of the conduction system, as well as from atrial and ventricular myocardium and recording activity from diseased regions, should provide information regarding mechanism and origin of tachycardia. Pharmacologic agents with specific effects on conduction or automaticity may be developed and used to distinguish reentrant from automatic arrhythmias. Also, further studies of programmed stimulation in arrhythmias may disclose more specific responses that will help differentiate mechanisms.

Bradyarrhythmias result from failure of pacemaking or conduction in the specialized conducting system. The present means of diagnosis rely on recording the electrocardiogram during bradyarrhythmia. However, such arrhythmias are often intermittent, so methods for assessing function of the conduction system in the interim are desirable. Such direct assessment could entail the detection of activation or recovery potentials of the specialized conducting system and the response to pharmacologic or electrical stress testing.

Many of the projections for the future cited here have been suggested as specific ways to improve the diagnostic and therapeutic usefulness of electrocardiographic recordings from the body surface and directly from the heart. However, several very important problems requiring solution, such as defining the mechanisms of the origin and maintenance of specific arrhythmias in relation to reentry versus automaticity, currently defy specific predictions for the best approach to solutions. These problems point up the need for detailed studies of ionic mechanisms, cell to cell conduction, structural details and extracellular vis à vis intracellular potentials.

27th ANNUAL SCIENTIFIC SESSION
AMERICAN COLLEGE OF CARDIOLOGY

Anaheim, California **March 6–9, 1978**

President's Page:

Cardiology 1978 at Anaheim—
Welcome to the College's 27th Annual Scientific Session

Dr. Mason

On behalf of the Officers, Membership and Staff of the College, it is my sincere pleasure and great privilege to extend a personal invitation to each of you and your families to join me, my wife Maureen and our two daughters at the world-renowned Anaheim Convention Center this forthcoming March 6–9, 1978 during the College's 27th Annual Scientific Session. The Disneyland Hotel will serve as our Headquarters Hotel. I am delighted to report that the most expansive educational program yet formulated by the College awaits you in beautiful Southern California. I am certain that you will be highly impressed by the superb quality and comprehensive extent, encompassing the spectrum of modern knowledge relating to cardiovascular diseases, of this year's program, which has been prepared in a variety of learning formats, with many innovations, by the Scientific Program Committee with Dr. Anthony N. DeMaria, Chairman, and Dr. Nemat O. Borhani, Co-Chairman. Equally stimulating are the several cultural, social and recreational activities planned by Dr. Eliot Corday, Local Arrangements Chairman, and Mrs. J. Douglas McNair, Hospitality Program Director. Considering the exciting combination of these favorable features, Anaheim 1978 promises to be a memorable event for both physician attendees and their families.

The annual meeting actually begins on March 5 with a new educational offering, a sequence of Mini-Courses on Sunday afternoon and Monday morning. These postgraduate symposia have been designed to provide a basic fund of information in certain major areas in adult and pediatric cardiovascular medicine and surgery. Organized and directed by recognized authorities, the Mini-Courses include Patient Presentations (Dr. Robert O'Rourke), Electrocardiography of Arrhythmias (Dr. Charles Fisch), Echocardiography (Dr. Harvey Feigenbaum), Exercise Testing and Cardiac Rehabilitation (Dr. Albert Kattus), Cardiac Pathology (Dr. William Roberts), Nuclear Cardiology (Dr. Daniel Berman), Hypertension (Dr. Ray Gifford), Conduction System in Children (Dr. Paul Gillette), Cardiovascular Pharmacology (Dr. William Parmley), Acute Myocardial Infarction—1978 (Dr. H. J. C. Swan), Ambulatory Monitoring (Dr. Eliot Corday) and Lipid Disorders (Dr. Robert Levy).

The Opening Plenary Address on Monday afternoon, March 6, presented by Dr. Bernard Lown, will be on "Sudden Cardiac Death—The Major Challenge Confronting Contemporary Cardiology." The Bishop Lectureship will be given by Dr. Rene Favaloro on "Direct Myocardial Revascularization—A Ten Year Journey: Myths and Realities," Tuesday afternoon, March 7. We are also honored that Mr. Norman Cousins, Editor of the *Saturday Review*, will be our Convocation Speaker on Wednesday evening, March 8.

The Core Curriculum of fundamental education in cardiovascular mechanisms, diagnosis and therapy is composed of 10 different sessions to be presented sequentially throughout the 4-day annual scientific session. The following Special Structured Sessions will focus on recent advances in cardiovascular diseases: "Vasodilator Therapy in Heart Failure," "Sudden Death," "Congenital Aortic Stenosis," "Coronary Artery Surgery," "Thrombosis," "Plasma Lipids and Atherosclerosis," "Advances in Drugs in Pediatric Cardiology," "Role of Noninvasive Techniques in Evaluation of Angina Pectoris," "Latest Observations in Cardiovascular Pathology," "Valvular Heart Disease," "Cross-Sectional Echocardiography," "The Coronary Care Unit—1978," "Advances in Cardiac Catheterization," "Nuclear Cardiology—1978," "Pacemakers—1978" and "Results of Multicenter Clinical Trials in Coronary Artery Disease Prevention."

The popular educational format of the Controversies in Cardiology is particularly enticing this year. Expert protagonists and antagonists will debate the still controversial subjects of "Intraaortic Balloon Counterpulsation," "Myocardial Revascularization and Longevity," "Exercise Training Effects on Coronary Disease," "Therapy of Chronic Ventricular Premature Beats," "Exercise Stress Testing in Coronary Disease Detection" and "Porcine Heterograft Valves Versus Mechanical Prostheses."

In addition, opportunities will be afforded for exchange of knowledge and ideas in the 36 small group Meet-The-Experts sessions as well as in the 30 evening Fireside Panels and the 40 Luncheon Panels. Dr. R. Joe Noble will direct the Self Assessment Program, which is to be principally centered on echocardiography throughout our annual scientific meeting. Also available throughout the meeting will be the Industrial Cardiovascular Instruction (ICI) area where Accel audio and video supplement tapes may be reviewed.

This year's scientific program will provide a greater opportunity than ever before for abstract presentations of original investigations in both basic and clinical aspects of cardiovascular diseases. For our 1978 meeting, we received a record number of 1,473 abstracts of

which it will be possible to present the 374 highest graded (approximately 25 percent) during our annual session. The Young Investigator's Award presentations will again be carried out on Wednesday morning, March 8.

We have given special recognition to the advent of preventive cardiology as an integral aspect of the daily activities of every physician involved in cardiovascular patient care. Thus, the theme adopted for this year's program is "Preventive Aspects of Cardiovascular Diseases." Accordingly, throughout our meeting, emphasis will be given to diagnostic and therapeutic modalities in each area of cardiovascular practice and research which are of value in the prevention of clinical heart diseases.

The Hospitality Program is unique in scope and special in unusual events designed to provide cultural experiences and necessary periods of relaxation. Two highlights are particularly noteworthy. On Sunday evening, arrangements have been made for attendees, their families and exhibitors to attend a special opening of Disneyland Park for a "Night at Disneyland." Then on Wednesday, March 8, a unique Costume Design Showing by Edith Head will be presented. In addition to these special events, Mrs. J. Douglas McNair has arranged daily visits to the Sea World in San Diego, San Juan Capistrano and Lion Country Safari, Newport and Laguana Beach Tours with Harbor Cruise, Knott's Berry Farm, Universal Studios and the Movieland Wax Museum. Also secured by Mrs. McNair are a tour of the Norton Simon Museum, a Huntington Library, Art Gallery and Botanical Gardens tour and a variety of special presentations: Transactional Analysis Women Leadership, by Sasha Sherbin; Pictographic Demonstration of Improvements in Color Photography, by Mr. Tim Taylor; Effective Reading—A Lifetime Technique, by Mrs. Carey Roberts; Precious Gems, by Lynette Barnes; and Graphology (handwriting analysis). Furthermore, on Monday and Tuesday evenings, when spouses are attending scientific Fireside Sessions, a Family Bingo program has been planned. The Hospitality Program Committee has also scheduled a Welcoming Brunch on Monday, March 6, to honor the spouses of new members of the College.

Finally, a special welcome is offered to those of you who can join us at the Post-Anaheim Symposium on Clinical Cardiology in Kauai, Hawaii, March 10–12, 1978.

Judging from the intense interest already shown and the outstanding educational and cultural experiences afforded, Anaheim 1978 promises to be the best attended of our annual meetings. I look forward to welcoming each of you to my native state of California for the College's 1978 Scientific Session.

Dean T. Mason, MD, FACC
President 1977–78

LEARNING CENTER: PROGRAM CALENDAR

The American College of Cardiology's newest department, the Learning Center, located at the College's Bethesda, Maryland headquarters, began operations last October with the offering of its first continuing medical education program for physicians with a specialty or an interest in cardiovascular medicine. The purpose of the Learning Center is to support the professional commitment to quality patient care by providing a new standard of excellence in cardiovascular continuing education.

Each continuing education program is directed toward a specific target group including: adult cardiologists (CD), internists (IM), pediatric cardiologists (PDC), and family practitioners (FP). For additional information concerning the programs listed below or for a complete schedule of programs through October 1978, contact Program Coordinator, Learning Center, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014 (301) 897-5400.

FEBRUARY THROUGH APRIL 1978

Feb. 6–8 **Pediatric Cardiology: Clinical-Pathological Correlations (PDC) (IM).** William C. Roberts, MD, FACC, director

Feb. 20–22 **Difficult to Manage Cardiovascular Problems: The Systematic Approach (FP).** Robert S. Eliot, MD, FACC, director

Feb. 27–Mar. 1 **Clinical Decision Making in Coronary Artery Disease (CD) (IM).** Arthur Selzer, MD, FACC, director

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists, educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Borys Surawicz, MD, FACC, Chairman
National Program Committee

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Extramural Programs Department, Division of Continuing Education, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

JANUARY 1978 THROUGH APRIL 1978

To be arranged individually — **Preceptorships in Cardiology.** Arthur Selzer, FACC, director, Pacific Medical Center, San Francisco, CA

JAN. 9–13 — **Ninth Annual Cardiovascular Conference in Snowmass.** John H. K. Vogel, FACC, director and James S. Forrester, FACC and Bruce C. Paton, FACC, co-directors, Snowmass Resort, Snowmass, CO

JAN. 9–13 — **Fundamentals of Echocardiographic Interpretation.** Vincent E. Friedewald, Jr., director, Kauai Surf Hotel, Kauai, HI

JAN. 20–21 — **New Developments in Stress Testing.** Myrvin H. Ellestad, FACC, William H. Allen, FACC and Robert Stuart, co-directors. Memorial Hospital Medical Center of Long Beach, Long Beach, CA

FEB. 3–5 — **Management of Cardiac Diseases—1978.** Robert J. Myerburg, FACC and Agustin Castellanos, FACC, co-directors. Omni International Hotel, Miami, FL

FEB. 23–25 — **Advances in the Diagnosis and Therapy of Cardiovascular Disease—1978.** John Ross, Jr., FACC, Joel S. Karliner, FACC, Ralph Shabetai, FACC, Kirk L. Peterson, FACC and Allen D. Johnson, FACC, co-directors. Hotel del Coronado, Coronado, CA

MAR. 3–4 — **Complex Problems in Congenital Heart Disease.** Robert M. Sade, FACC and Arno R. Hohn, FACC, co-directors. Kiawah Island Inn, Charleston, SC

MAR. 6–9 — **Twenty-seventh Annual Scientific Session.** Dean T. Mason, FACC, president. Anaheim Convention Center and Disneyland Hotel, Anaheim, CA

MAR. 10–11 — **Post Anaheim, California. Symposium on Clinical Cardiology.** Anthony N. DeMaria, FACC, director. Kauai Surf Hotel, Kauai, HI

MAR. 27–31 — **Electrocardiographic Interpretation of Complex Arrhythmias: A Physiological Approach.** Charles Fisch, FACC and Douglas P. Zipes, FACC, directors. Indiana University Medical Center, Indianapolis, IN

MAR. 30–APR. 1 — **Contemporary Management of Acute Myocardial Infarction by the Family Physician.** Robert S. Eliot, Chairman and Ernie J. Chaney, Alan D. Forker, Harold Kalman and Thomas Nicholas, program committee. Sarasota Hyatt House, Sarasota, FL

APR. 3–7 — **Consultant's Course in Cardiology.** Michael V. Herman, FACC, director and Simon Dack, FACC, Richard Gorlin, FACC and Louis E. Teicholz, FACC, co-directors. Mount Sinai Medical Center, New York, NY

APR. 3–12 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC and James E. Crockett, FACC, directors. Rancho Santa Fe Inn, Rancho Santa Fe, CA

APR. 12–14 — **Vectorcardiography: A Basic Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, AZ

APR. 19–21 — **Echocardiographic Solutions to Clinical Cardiovascular Problems.** Joseph K. Perloff, FACC and John S. Child, FACC, directors. Century Plaza Hotel, Los Angeles, CA

Easy does it
Cardiac patients simply can't afford straining. To help your constipated cardiacs, DIALOSE PLUS combines an effective fecal softener with a lubricating agent, so stools are moister and elimination becomes easier. In addition, because so many constipated cardiacs require some peristaltic activation, DIALOSE PLUS provides 30 mg casanthranol to gently provide the needed stimulation.
easier defecation makes it easier on his heart
DIALOSE® PLUS
(dioctyl sodium sulfosuccinate, 100 mg; and sodium carboxymethylcellulose, 400 mg; plus casanthranol 30 mg)
STOOL SOFTENER/LUBRICANT/ PERISTALTIC ACTIVATOR

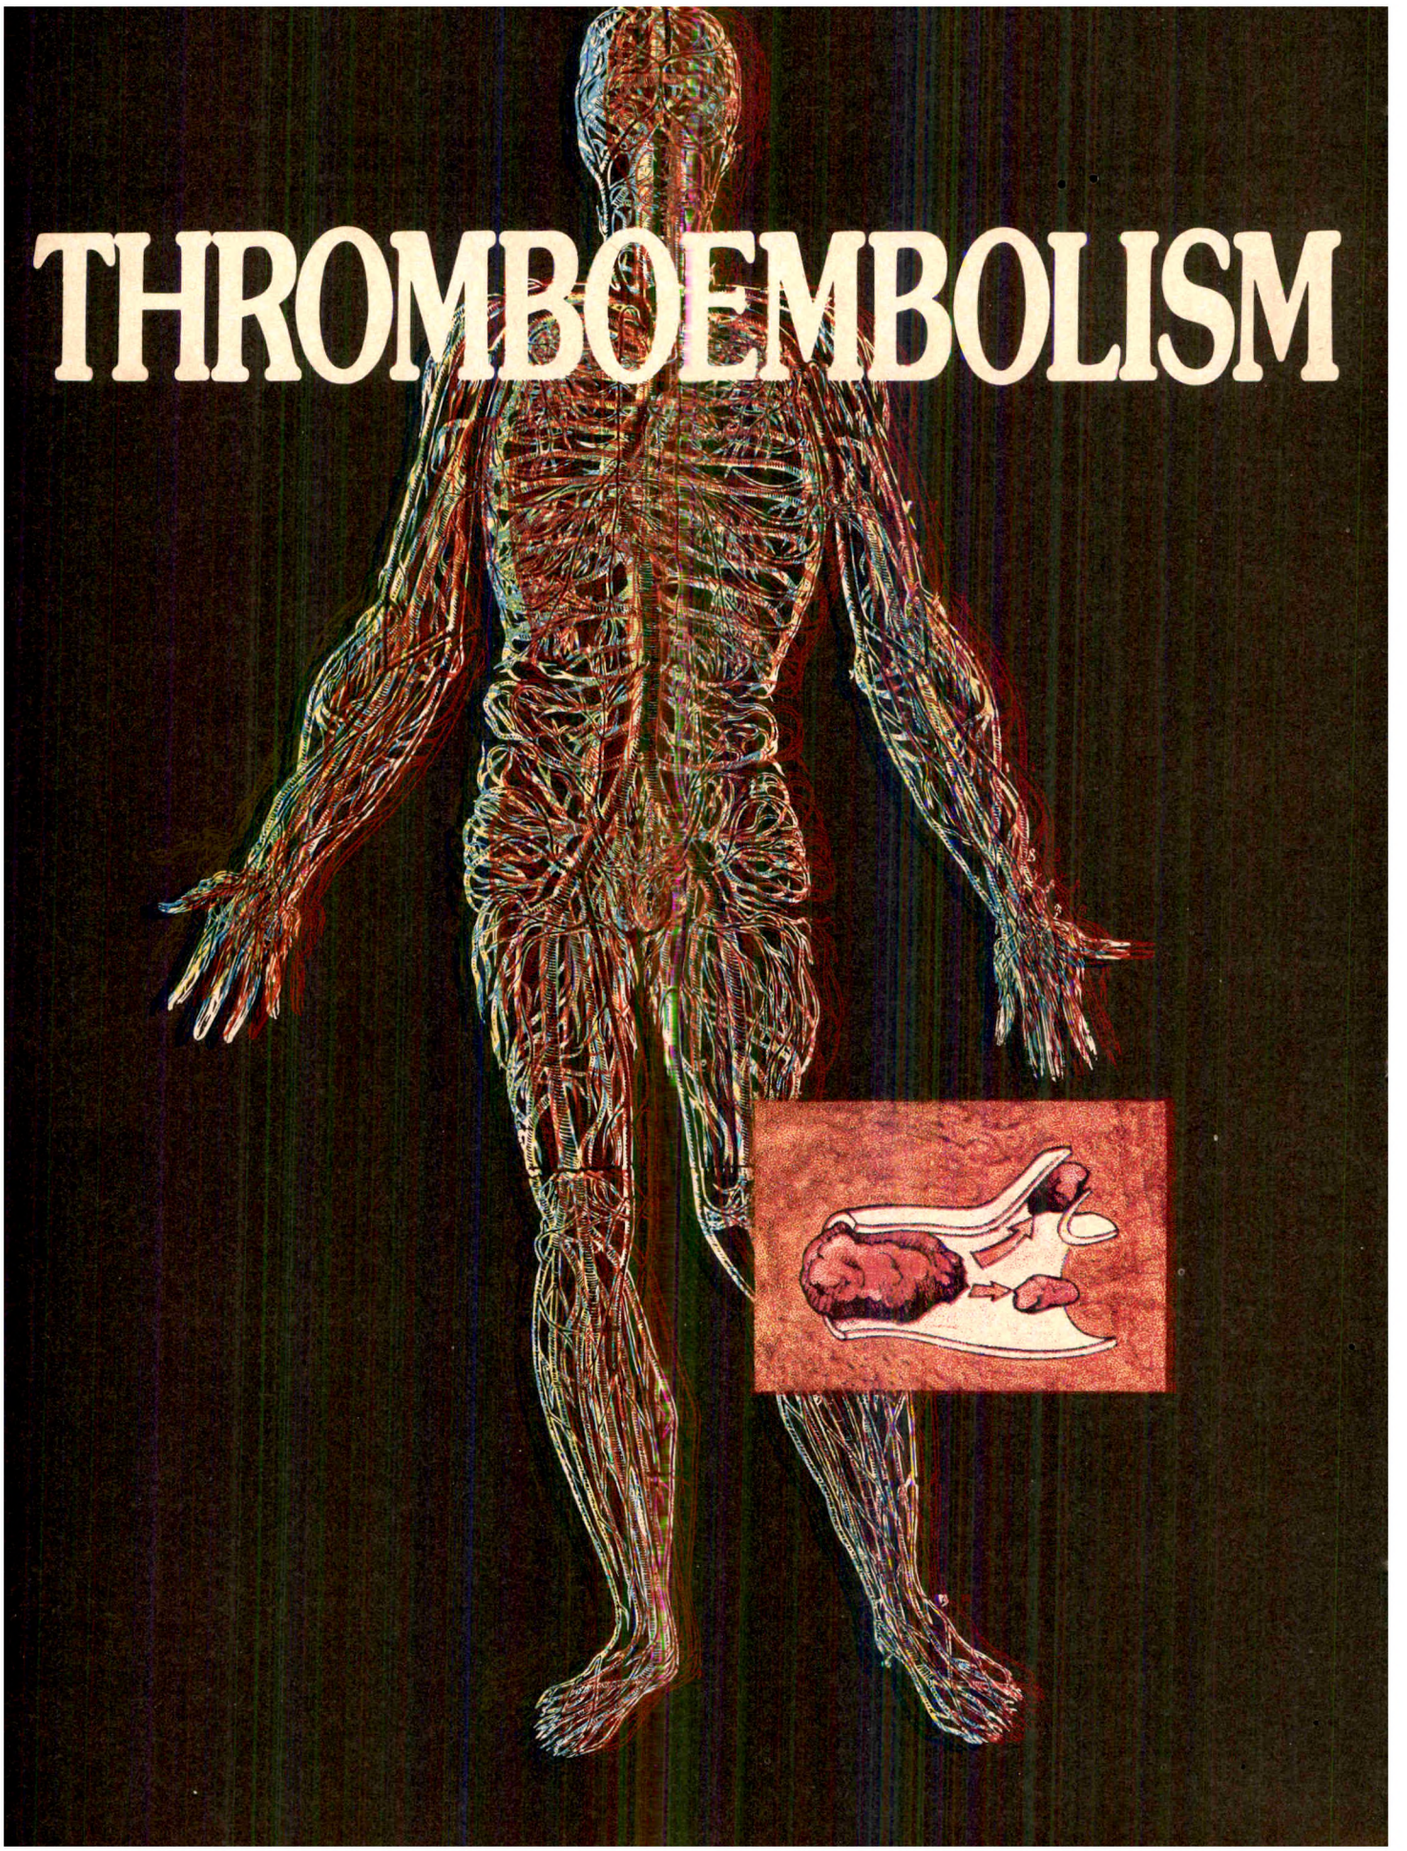
THROMBOEMBOLISM



COUMADIN® (CRYSTALLINE SODIUM WARFARIN U.S.P.)

FOR ORAL ANTICOAGULATION

Prophylactic Use

A number of cardiac syndromes can predispose patients to thromboembolic episodes. The greatest threat of thromboembolism, however, exists in patients with a history of obesity, excessive cigarette smoking or previous episodes of venous thrombosis or pulmonary embolism. Postoperative patients requiring extended immobilization and the elderly are at high thromboembolic risk as are the severely injured—particularly those over 40 years with fractures of the hip, pelvis or lower extremities—and patients undergoing elective cup arthroplasty or pelvic surgery.

Emphasis should be placed on prophylaxis for those patients predisposed to thromboembolism. The oral anticoagulant of choice is COUMADIN® (crystalline sodium warfarin U.S.P.)

Therapeutic Use

For established thromboembolism, administration of I.V. heparin followed by oral anticoagulant therapy is a cornerstone of treatment. COUMADIN,® a chemically pure oral anticoagulant with high predictability of response, is a mainstay of effective therapy.

Dosage and Administration

In patients receiving COUMADIN,® prothrombin time should be maintained at 1.5 to 2.5 times the control until results stabilize. Dosage and administration should be individualized according to prothrombin time results and reevaluated periodically throughout therapy.

Patients should be well informed about their condition and medication, since factors such as dietary change, travel, other medication, change in physical condition and abrupt environmental change may influence prothrombin time and, therefore, response to COUMADIN.®

The oral anticoagulant of choice

COUMADIN®

(CRYSTALLINE SODIUM WARFARIN U.S.P.)

Endo Laboratories, Inc.

Before prescribing, please see prescribing information on following page.

COUMADIN® is an Endo registered U.S. trademark;
U.S. Pat. No. 3,077,481 (Reissue No. 25,866)

COUMADIN®

(CRYSTALLINE SODIUM WARFARIN*)

DESCRIPTION COUMADIN® (crystalline sodium warfarin), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of sodium warfarin virtually eliminates trace impurities present in amorphous sodium warfarin, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN® (crystalline sodium warfarin) is therapeutically equivalent to amorphous sodium warfarin.

ACTIONS COUMADIN® and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN® usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN® is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN® (crystalline sodium warfarin) is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1) central nervous system; (2) eye; (3) traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1) gastrointestinal, genitourinary or respiratory tracts; (2) cerebrovascular hemorrhage; (3) aneurysms–cerebral, dissecting aorta; (4) pericarditis and pericardial effusions; (5) subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis; or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** polyarthritis, vitamin C deficiency, major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Sodium warfarin is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN® are given together, a period of 4 to 5 hours should elapse after the last intravenous dose and 12 to 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when sodium warfarin is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:
Lactation–coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Prolonged dietary deficiency** (cachexia, vitamin K). **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**–sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, menometrorrhagia, allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN®, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN®.

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders–infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency–steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cinchophen; clofibrate; COUMADIN® overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

†Increased and decreased prothrombin time responses have been reported.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN® underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN®. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN® (crystalline sodium warfarin) include:

1. Minor or major hemorrhage from any tissue or organ–which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and an extremely rare reaction consisting of hemorrhagic infarction and necrosis of the skin.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN® patient aids are available to physicians on request.

The administration and dosage of COUMADIN® must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin* anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN® should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic prothrombinopenia are 1½ to 2½ times the normal prothrombin time (e.g. 21 to 35 seconds, with a control of 14 seconds).

Induction–40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Maintenance–Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy–The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery–The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN® be adjusted to maintain the prothrombin time at approximately 1½ to 2 times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN® with Heparin–Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in situations of great emergency to administer sodium heparin initially along with COUMADIN®. The initial dose of heparin and injectable COUMADIN® may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN®, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, and preferably 4 to 5 hours after the last intravenous injection or 12 to 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN® (crystalline sodium warfarin), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN® may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN® administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can be obtained.

SUPPLIED Tablets: COUMADIN® (crystalline sodium warfarin). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white, 25 mg red. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous sodium warfarin lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution. 50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide; accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

*Present as crystalline sodium warfarin isopropanol clathrate.

Now, One-Stop Medical Paper Preparation

Announcing the new expanded Information to Authors 1976-1977 edition with editorial guidelines reprinted from 140 medical journals

Compiled by Harriet R. Meiss and Doris A. Jaeger of the Levy Library, Mount Sinai School of Medicine of the City University of New York.

At last, a handbook providing the most up-to-date guidelines for the preparation of manuscripts exactly as specified in 140 leading American medical journals. Authors, secretaries, publishers, editors, medical writers and librarians will welcome this greatly needed reference for publishing in clinical medicine.

Information to Authors features the exact replica of each journal's masthead, with editors, editorial boards, mailing addresses and such pertinent information as statements of scope, sponsoring societies, advertising information and subscription rates. Instructions to contributors are reprinted in their entirety—including information on the number of manuscript copies required, desired format, correct style for typing footnotes and references, rules for preparation of illustrations, tables, graphs, etc.

For rapid access, journals are arranged in alphabetical order. A subject index enables you to identify publications in your field of interest.

If you or members of your staff write, submit or review papers for medical journals, this handy 328-page guide will save valuable look-up and research time. *Information to Authors* has everything you need to meet the exact requirements of the editor, avoid costly publication delays, and speed acceptance of your paper.

Use the order form below to obtain your 1976-77 copy now. No orders will be processed unless accompanied by payment.

KayCiel® (potassium chloride) vs. Diet

ORANGE FLAVORED

KayCiel® Elixir		KayCiel® Powder	
Each 15 ml (20 mEq of potassium chloride) contains:		Each *Solodose*® packet (20 mEq of potassium chloride) contains:	
Calories	17	Calories	0
Sodium	0 mg	Sodium	0 mg

CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps and hyperkalemia.
WARNING: Do not use excessively.
PRECAUTIONS: Administer with caution and adjust to the requirements of the individual patient. The patient should be checked frequently and periodic ECG and/or plasma potassium levels made. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
Patients should be cautioned to adhere to dilution instructions.
ADVERSE REACTIONS: Potassium intoxication indicated by listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac depression, arrhythmias, arrest and heart block. Vomiting, nausea, abdominal discomfort and diarrhea may occur.
OVERDOSAGE: In case of excessive use resulting in hyperkalemia or potassium intoxication, discontinue potassium chloride administration or take other steps to lower serum levels if indicated.

Cooper Compliance Tip

Help assure that your older patients take medications properly by printing your instructions in large letters. You might also send a copy of the instructions to the patient's spouse. Please forward your compliance tip to Cooper Laboratories, 300 Fairfield Road, Wayne, N.J. 07470, Att: W.F. Cronin.

Cooper Laboratories, Wayne, New Jersey 07470 143-48

For the PVD patient, walking can be productive instead of just painful

The Role of Walking

Exercise-induced pain is a cardinal symptom of Peripheral Vascular Disease. Often, because of intermittent claudication, patients may tend to exercise...even to walk...as little as possible.

Studies† have demonstrated that a program of regular walking exercise can significantly extend the distance and time these patients can walk without claudication. In one study walking exercise of one hour daily has been shown to effect noticeable improvement in a month. After six months, pain-free walking increased to twice that of pre-exercise levels.

Investigators have attributed the improvement to vasodilating effects of exercise, increased venous return and development of the collateral circulation. It is clear that exercise produces a tolerance for more exercise, and a program of regular walking, in the absence of any contraindications, appears to be an appropriate measure in the management of Peripheral Vascular Disease.

The Value of Proper Gait

Patients often compensate for claudication in calf muscles by adopting a shuffling gait. This "shuffling" utilizes calf muscles only minimally.

The diagram on this page illustrates the normal gait—described as "heel-and-toe" walking. Patients who are encouraged to become more conscious of their gait and to walk properly will utilize calf muscles to a greater degree—and maximize the therapeutic effects of a prescribed walking program.

The Role of Arlidin® (nylidrin HCl)

Arlidin improves blood flow by dilating responsive vessels in skeletal muscles. The symptoms of ischemia may therefore be relieved thus encouraging the patient to begin or continue with an appropriate exercise program.

Furthermore, Arlidin maintains mean arterial pressure, thus maximizing delivery of blood to ischemic areas and minimizing the risk of postural hypotension. Its vasodilating effect in skeletal muscles and maintenance of mean arterial pressure make Arlidin an appropriate adjunct to other measures—such as walking—in the management of Peripheral Vascular Disease.*

PROPER HEEL-AND-TOE WALKING

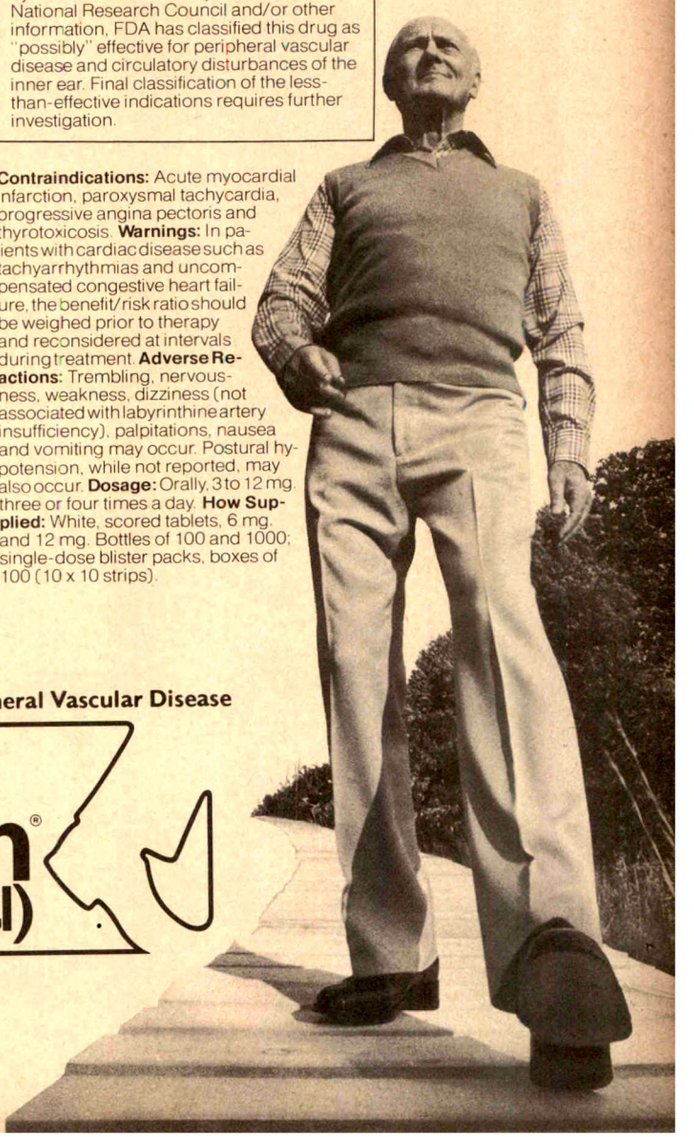
HEEL STRIKE PUSH-OFF HEEL STRIKE

You can obtain a more detailed version of this chart, explaining heel-and-toe walking to patients, from your USV Representative or by writing to Medical Department, USV Laboratories Inc., Tuckahoe, N.Y. 10707.

Brief Summary

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified this drug as "possibly" effective for peripheral vascular disease and circulatory disturbances of the inner ear. Final classification of the less-than-effective indications requires further investigation.

Contraindications: Acute myocardial infarction, paroxysmal tachycardia, progressive angina pectoris and thyrotoxicosis. **Warnings:** In patients with cardiac disease such as tachyarrhythmias and uncompensated congestive heart failure, the benefit/risk ratio should be weighed prior to therapy and reconsidered at intervals during treatment. **Adverse Reactions:** Trembling, nervousness, weakness, dizziness (not associated with labyrinthine artery insufficiency), palpitations, nausea and vomiting may occur. Postural hypotension, while not reported, may also occur. **Dosage:** Orally, 3 to 12 mg. three or four times a day. **How Supplied:** White, scored tablets, 6 mg. and 12 mg. Bottles of 100 and 1000; single-dose blister packs, boxes of 100 (10 x 10 strips).



The new prescription for Peripheral Vascular Disease

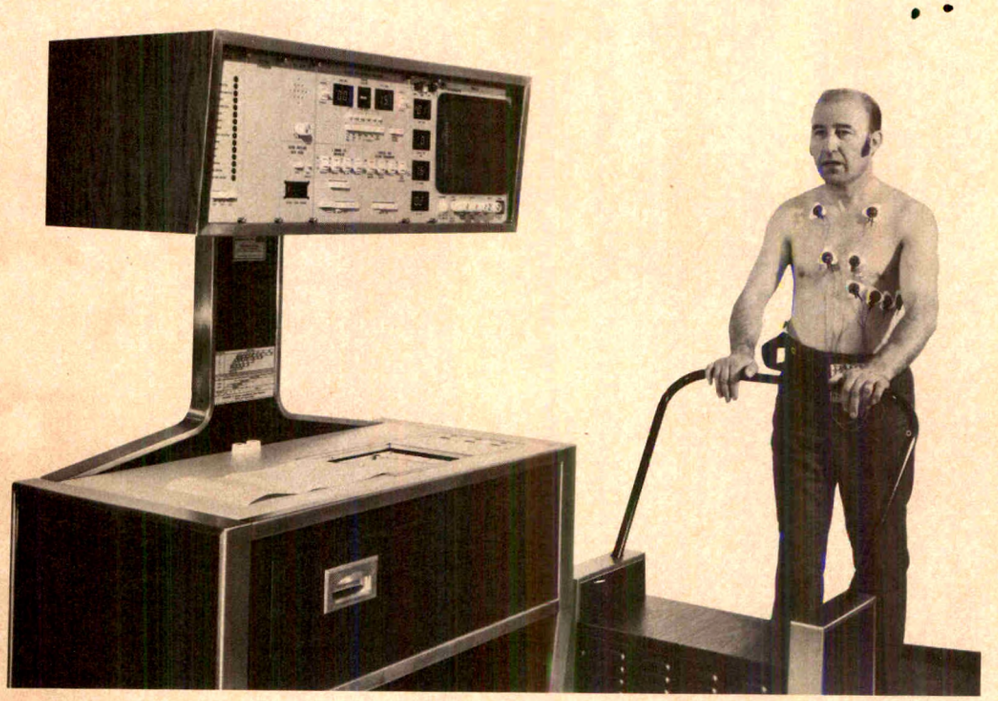
It's a Long, Emotional Walk for Your Patient.



Make it more meaningful with viagraph II™

Your patient is walking for a reason . . . to provide you with the greatest amount of meaningful stress ECG data.

Now there's a system unmatched in functional features that helps you capture that meaningful data, then presents it to you in a clear, concise manner.

It's called VIAGRAPH II™, a stress ECG system that's unmatched in function and features.

- Ten preprogrammed protocols let you more accurately match the workload to the capabilities of your patient.
- Instant readout of pertinent in-test data (including ST Level and ST Integral) is yours at a glance on digital displays.
- A non-fade graph of rate and ST level appears on the monitor providing a minute-by-minute trend of patient response.
- 16-beat averaged complexes for both resting and exercise conditions offer a ready comparison to identify ischemic changes.
- A blood pressure entry system to store manually-measured blood pressure in memory for subsequent recording on a final summary report.
- At test completion, you receive a full summary of significant data on the unique FINAL REPORT.

Remember, a meaningful test begins with a meaningful system.
And it happens with VIAGRAPH II™.

viagraph II™

The Meaningful System Designed for the High Volume Hospital Lab.

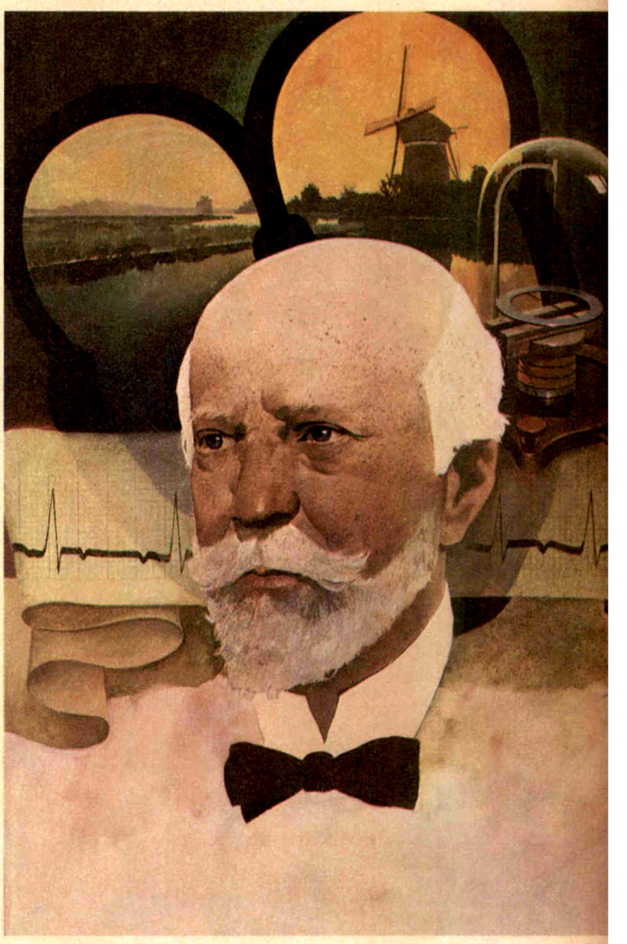
One of Holland's greatest works of art came from a man who couldn't draw a straight line.



In 1902, Willem Einthoven created a masterpiece.

And although it never hung in the Rijksmuseum, the Louvre or the Met, what the electrocardiograph did for human life was priceless all the same.

Today, we Dutch are still very much involved with cardiac medicine.

In fact, at Vitatron, we've been responsible for more innovations in pacemakers and pacemaking systems than anyone else in the world.

First to introduce a dual rate ventricular asynchronous pacemaker.

First to make pacemakers with large radius, highly rounded edges for better biocompatibility and patient comfort.

First to use current limited output circuitry for battery energy conservation.

First to make pacemakers suitable for waveform photo analysis.

First to feature external pacing threshold analysis by radio frequency suppression.

First to introduce externally controlled magnetic switching from on-demand to fixed mode stimulation.

First to offer dual indicators of impending end-of-service-lifetime.

First to provide greater safety margins by using the stimulus energy compensation principle during partial battery depletion.

First to develop a comprehensive pacemaker function analyzer.

First to introduce a simple, reliable connection compatible with most electrodes, with or without adaptors.

First to use battery by-pass diodes to extend service life and patient safety.

First to make endocardial anchoring electrodes to reduce dislodgment problems.

And, of course, our latest innovation, the Vitalith lithium powered pacemaker with the extraordinary service life of 12 years*.

All of which prompts us to leave you with this closing thought: when a Dutchman talks about the art of pacing, he knows from where he speaks.

If you'd like to learn more about Vitatron, or to receive our new Vitalith brochure, write Vitatron Medical, Inc., One Gateway Center, Newton, MA 02158. Vitatron Medical b.v., P.O. Box 76, Kanaalweg 24, Dieren, The Netherlands.

*Over 10 years' service life expected under worst case conditions, 500 ohm load with 1.0 millisecond pulse duration; over 15 years with 0.5 ms duration.

VITATRON MEDICAL

Quantitate Risk of Pulmonary Edema with the New IL 186 WEIL ONCOMETER™ SYSTEM

Now, there is an instrument to measure colloid oncotic pressure — the new IL186 Weil Oncometer™ System from Instrumentation Laboratory Inc.

This important measurement:

- Provides early data for diagnosis and treatment of pulmonary edema.
- Simplifies assessment of fluid balance/extent of cardiopulmonary failure.
- Aids in prescribing form of fluid therapy (crystalloid versus colloid).
- Helps determine necessity of costly albumin treatment, leading to substantial budget savings and improved patient care. Colloid oncotic pressure (COP) values are optimally used with pulmonary capillary wedge pressure (PCWP), obtained with IL's flow-directed thermal dilution catheters.

Recent studies demonstrate a highly significant relationship between low COP-PCWP difference (COP minus PCWP) and pulmonary edema.[1]

The IL Oncometer is reasonably priced and easy to operate. COP in mmHg is displayed in less than two minutes from serum or plasma samples of only 300μl. The IL702 Recorder provides convenient record of changing pressure, clearly showing equilibrium point and any interferences.

For demonstration of the new IL186 WEIL Oncometer™ System, technical papers, literature or further information, contact your local IL Representative or call IL *toll-free: 800 225-1481.*

Ambulatory Blood Pressure Recorder

Light, compact one-piece unit weighs only 25 ounces.

The Remler patented Ambulatory Blood Pressure Recorder has been in use for more than ten years by leading physicians and research institutions throughout the world. It is a proven, easy-to-use system that relieves the doctor of the time-consuming traditional auscultatory procedure.

Now, by miniaturizing circuits and components, we have produced a smaller and easier to wear *single-unit* version.

This Model M-2000 records blood pressures during the wearer's working or leisure day. Wearing this unobtrusive, lightweight device on a belt, any patient can easily record blood pressure data onto the micro-cassette as many as fifty times daily. This method *totally eliminates bias,* and the pressor effect of an observer's presence.

The Remler system is especially useful in determining the efficacy of medication in the treatment of hypertension.

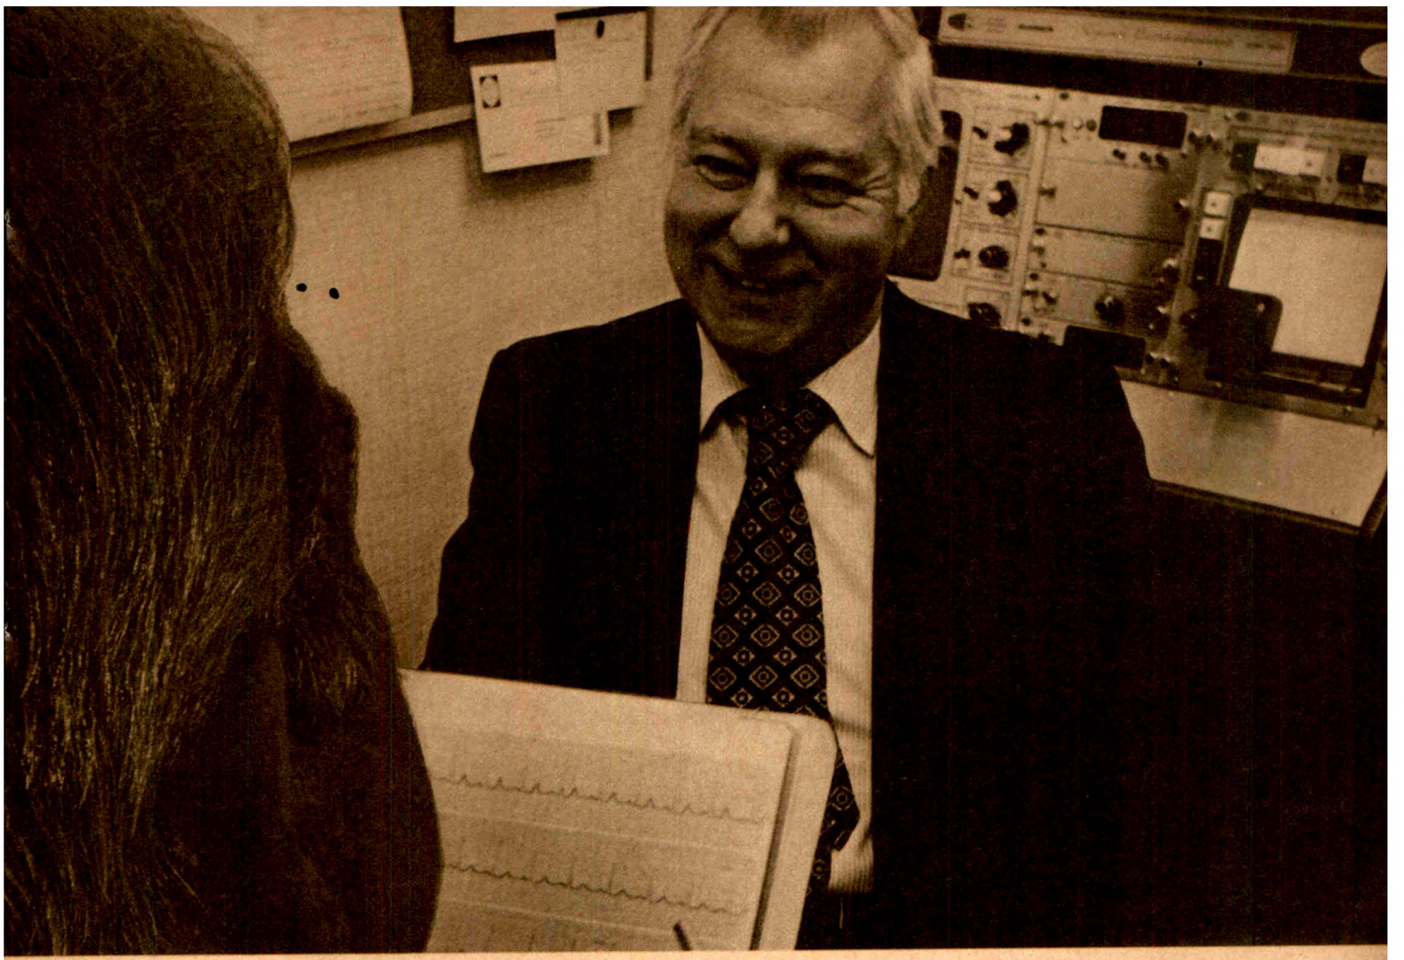
Diagnosis: PVC's
(Premature Ventricular Contractions)

initial therapy:
quinidine sulfate tablets
at
9 a.m.
1 p.m.
5 p.m.
9 p.m.



Then, for convenience and compliance... a welcome change- simple q 8-12 hour dosage

Quinidex Extentabs®

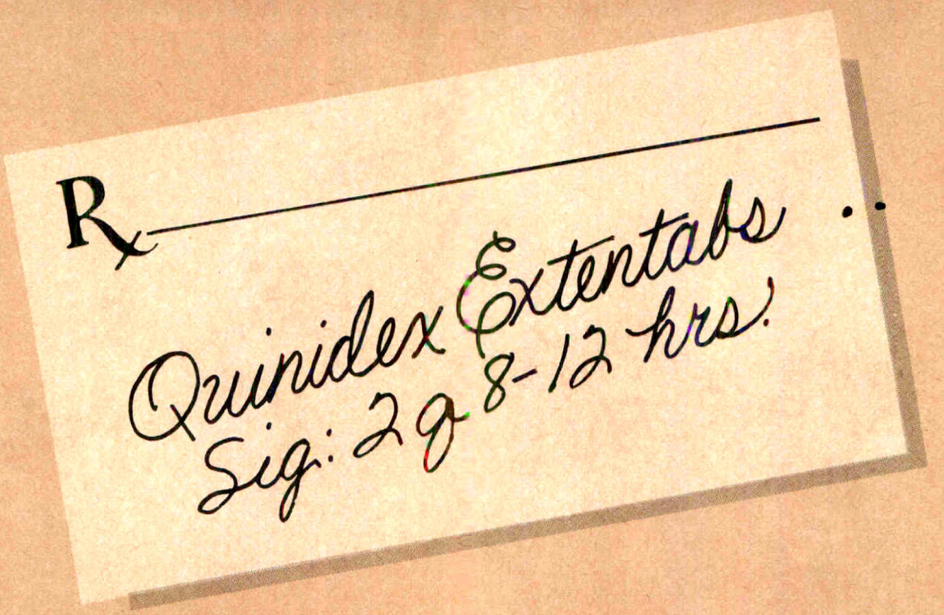
(Quinidine Sulfate, USP)

300 mg in each Extentab

A·H·ROBINS

After the PVC's have been successfully suppressed with quinidine sulfate tablets, you can *maintain* normal sinus rhythm with Quinidex Extentabs. The simple q 8-12 hour dosage is more convenient for the patient than the usual q.i.d. dosage for short-acting tablets. Instead of having to remember to carry his medication with him during the day, he simply leaves the bottle in the medicine cabinet. There's less risk of a missed dose . . . better compliance with your dosage regimen. The unique construction of Quinidex Extentabs provides continuous absorption of quinidine sulfate over an 8-12 hour period. Each of the Extentabs contains 300 mg quinidine sulfate – approximately 23% more quinidine alkaloid than 324 mg quinidine gluconate.

See full prescribing information on following page.



Indications:

Quinidex Extentabs are indicated in the treatment of:
Premature atrial and ventricular contractions.
Paroxysmal atrial tachycardia.
Paroxysmal A-V junctional rhythm.
Atrial flutter.
Paroxysmal atrial fibrillation.
Established atrial fibrillation when therapy is appropriate.
Paroxysmal ventricular tachycardia when not associated with complete heartblock.
Maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

The only long-acting form of quinidine sulfate

Quinidex® Extentabs®

ROBINS

(Quinidine Sulfate, USP)

A·H·ROBINS

A. H. Robins Company, Richmond, Va. 23220

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, lightheadedness, and tremor; (3) G-I symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at a rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G-I symptoms can also be minimized by giving the drug with food.

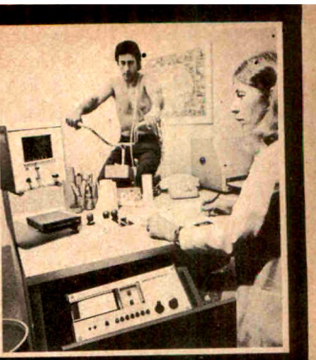
Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

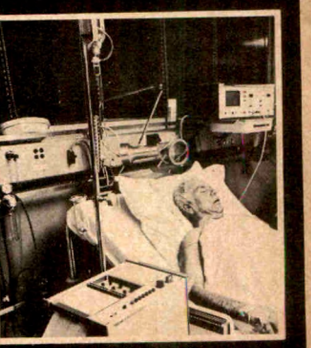
Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 and 250 (NDC 0031-6649).

The new Electrocardiographs

SIMPLISCRIPTOR EK 31
MULTISCRIPTOR EK 33





small, compact, high-efficiency instruments which comply today with the standards of tomorrow: the new no-compromise electrocardiographs.

- new design for line and battery operation
- patient safety complying with international requirements
- thermoreactive writing method for precise R-wave tracings, 40-mm writing width
- electronic lead selector, sensitivity in 4 calibrated steps

SIMPLISCRIPTOR EK 31 MULTISCRIPTOR EK 33

1. *New*—**SELF-ASSESSMENT IN ELECTROCARDIOGRAPHY**

By **STELIO MANGIOLA, M.D., F.A.C.C.**
This review of simple and complex electrocardiographic studies is illustrated with 100 actual full-size ECGs covering a wide range of frequently-encountered rhythm and pattern abnormalities, and is designed as a practical self-assessment tool. Each ECG is followed by a brief patient history and questions with clues to correct interpretation. Properly labeled ECGs appear on reverse pages.

205 pages / 100 ECG studies / 1977 / flexible binding, $15.00

2. *New (2nd) Edition*

DIAGNOSTIC ELECTROCARDIOGRAPHY

By **MICHAEL C. RITOTA, M.D., F.A.C.P.**
With new diagrams, new ECGs, and new chapters, this concise edition presents basic knowledge of electrocardiography as a working tool for the student and practitioner. Some 40 of the most common and important ECG patterns are illustrated and described succinctly to aid quick understanding. Included are clinical definitions of normal and abnormal ECGs, pathological conditions associated with described patterns, and lists of essential criteria.

210 pages / 289 illustrations / 2nd edition, 1977 / $22.50

3. **CARDIAC ARRHYTHMIAS: Practical ECG Interpretation**

By **STELIO MANGIOLA, M.D., F.A.C.C.; and MICHAEL C. RITOTA, M.D., F.A.C.P.**
Each arrhythmia in this unique approach to interpretation is presented on *facing pages;* left hand pages have full-size tracing with ECG criteria and analytical Lewis Ladder diagrams; right hand pages illustrate the arrhythmia with 3–8 tracings. Magnified details focus on key features, and arrhythmias are presented in terms of atrial, nodal and ventricular components.

215 pages / 400 illustrations / 1974 / $22.00

4. **ELECTROCARDIOGRAPHIC EXCURSIONS**

By **LEO SCHAMROTH, M.D., D.Sc., F.R.C.P., F.A.C.C.**
This book focuses on the essential features—at times a single complex—of ECG presentations which constitute clues to the ultimate diagnosis. Studies range from the elementary to the exotic, and include salient, yet often overlooked, aspects of ECG interpretation. For beginners and experienced practitioners.

158 pages / 102 illustrations / 1975 / $31.00

Lippincott

J. B. Lippincott Company
East Washington Square Philadelphia, Pa. 19105

5. **THE ELECTROCARDIOLOGY OF CORONARY ARTERY DISEASE**

By **LEO SCHAMROTH, M.D., D.Sc., F.R.C.P., F.A.C.C.**
This book provides clinicians of all levels with a compact, integrated review of electrocardiology in the diagnosis of coronary heart disease. Emphasis is on the importance of recognizing not only distinguishing features of normal and abnormal ECGs, but variations that may mimic cardiac disease. With 113 annotated illustrative ECG studies.

356 pages / 71 illustrations / 1975 / $55.00

6. *New (5th) Edition*

AN INTRODUCTION TO ELECTROCARDIOGRAPHY

By **LEO SCHAMROTH, M.D., D.Sc., F.R.C.P., F.A.C.C.**
A classic work, revised and updated, with emphasis on deductive rather than empirical ECG interpretation. The entire text has been revised to reflect findings of the past six years, and new sections and new electrocardiographic illustrations have been added. Primarily for the beginner, the book's aim is *simplicity.*

240 pages /217 illustrations / 5th edition, 1977 / soft cover, $10.00

7. *New*—**QUICK REFERENCE TO CARDIOVASCULAR DISEASES**

By **EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C.**
A valuable new addition to Lippincott's "quick reference" series, this book provides clinically relevant data, succinctly presented in a convenient format. Each entry is numbered to reveal crucial information at a glance. Step-by-step instructions are given in easy-to-follow outline form. Pages are protected by a durable flexible binding to withstand the wear and tear of hard use. Coverage includes all kinds of cardiovascular diseases . . . all aspects of each disease . . . all clinical situations . . . and all phases of medical care.

469 pages / 48 illustrations / 1977 / flexible binding, $20.00

CORNELL MEDICAL UPDATE 1

NOW—in book form—the famous UPDATE YOUR MEDICINE CONFERENCES

EDITED BY Lila A. Wallis, MD, FACP

Your "instructors" include some of the foremost people in:

- Endocrinology
- Cardiology
- Neurology
- Diabetes
- Cancer
- Gastroenterology
- Immunology
- Asthma
- Radiology

This new book is designed for the busy physician who finds it difficult to keep up with the growing literature in his profession. Up until now the only way this could be done was to attend such conferences as the highly acclaimed Update Your Medicine sponsored by New York Hospital, Cornell Medical Center. These programs were developed to prepare doctors for Recertification despite heavy work loads.

In response to demands by those physicians who were unable to attend in person, it is a pleasure to announce that Update Your Medicine is now available in book form under the title CORNELL MEDICAL UPDATE I. The original Conferences have been transcribed . . . edited for easy reading and absorption . . . and completely updated right to press time.

The lectures treat each topic in depth from the basic physiologic and biochemical principles up to application in patient management. To save the time of the audience—and of those who use the book—the text has been edited to the bone. Do not look for historical reviews, lengthy descriptions of investigative methods, ambiguous discussions, or rehashes of what you have known for years. The doctors who attended the lectures did not need this "filler" material . . . and you don't either.

What you want is the new knowledge and techniques developed in recent years. And that is what you get from CORNELL MEDICAL UPDATE I. The goal is to give you the knowledge . . . and the confidence . . . to incorporate these new techniques into your clinical practice.

The 16 Lectures are Presented in Compact Workbook Style for Quick Reading and Easy Comprehension:

1. Update Your Endocrinology I: Thyroid & Gonad
2. Update Your Endocrinology II: Hypothalamus and Anterior Pituitary
3. Update Your Cardiology
4. Update Your Gastroenterology: Chronic Active Hepatitis
5. Update Your Gastroenterology: GI Hormones
6. Nephrology: Renal Physiology and Diuretic Therapy
7. Recent Advances in Cancer Chemotherapy
8. Compendium of Antineoplastic Agents
9. Update Your Immunology: Hypersensitivity States
10. Update Your Immunology: Immunopharmacology of Asthma
11. Advances in Neurology
12. Update Your Radiology: Angiography of the GI Tract in Management of Acute Arterial Bleeding
13. Update Your Radiology: Sonography of the Abdomen
14. Recent Advances in Diabetes Mellitus and Hypoglycemia
15. Evaluation of the Program by the Reader
16. Evaluation of the Reader—for the AMA Physician's Recognition Award Credits

AMA Physician's Recognition Award

CORNELL MEDICAL UPDATE I has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit is included with every copy.

Read it for 30 days—FREE

Use it to check any problems which come up in your practice throughout a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

Yorke Medical Books AJC-1/78
666 Fifth Ave., New York, NY 10019

YES! Please send me a copy of CORNELL MEDICAL UPDATE I at $32.00. I may use the book for 30 days and if not completely satisfied, return it for full credit or refund.

☐ Payment enclosed, publisher pays shipping cost
☐ Bill me, plus cost of shipping

Introducing the Portable 741 Monitor. The small monitor with large capabilities.

In its new 741 Portable Monitor, Mennen Greatbatch has enlarged the capabilities of the small monitor.

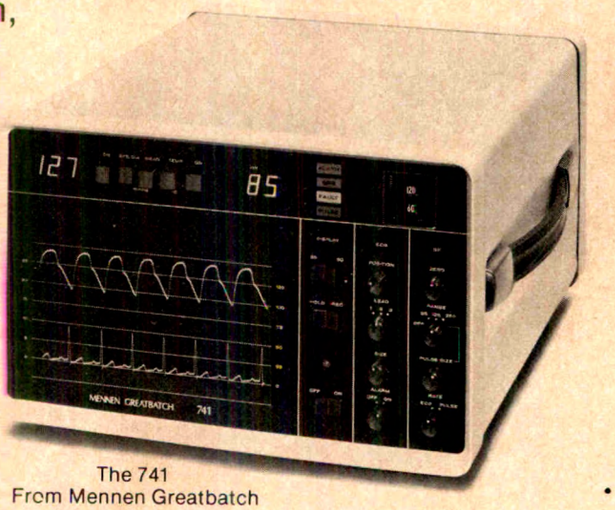
Its two digital displays (one more than most portable monitors have) keep two parameters continuously monitored. One shows heart rate, the other shows temperature or blood pressure (alternating systolic and diastolic or mean). On its two-channel display screen, non-fading waveforms of blood pressure (or pulse) and ECG tell more.

And, the 741 monitor has many of the special features valued in larger Mennen Greatbatch monitors. Like thumbwheel-set, continuously visible ECG alarm limits; push-button cal signals and quick gain adjusting for easy setup; direct circuit access for easy in-house servicing. Plus human engineering... every control just where user convenience dictates.

All this in a monitor that's 18 pounds light.

But portability isn't everything. The 741's output makes it compatible with a wide variety of monitoring systems, a rare feature in portable monitors. In the CCU, ICU, in the OR and the recovery room, the 741 offers superior performance, dependability and cost effectiveness.

The 741 Portable Monitor. It's a lot of useful monitor packed small.



The 741

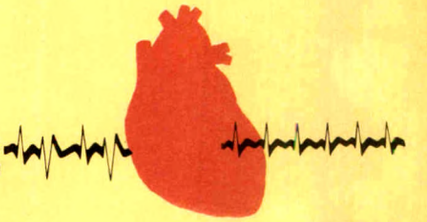
Searle announces...

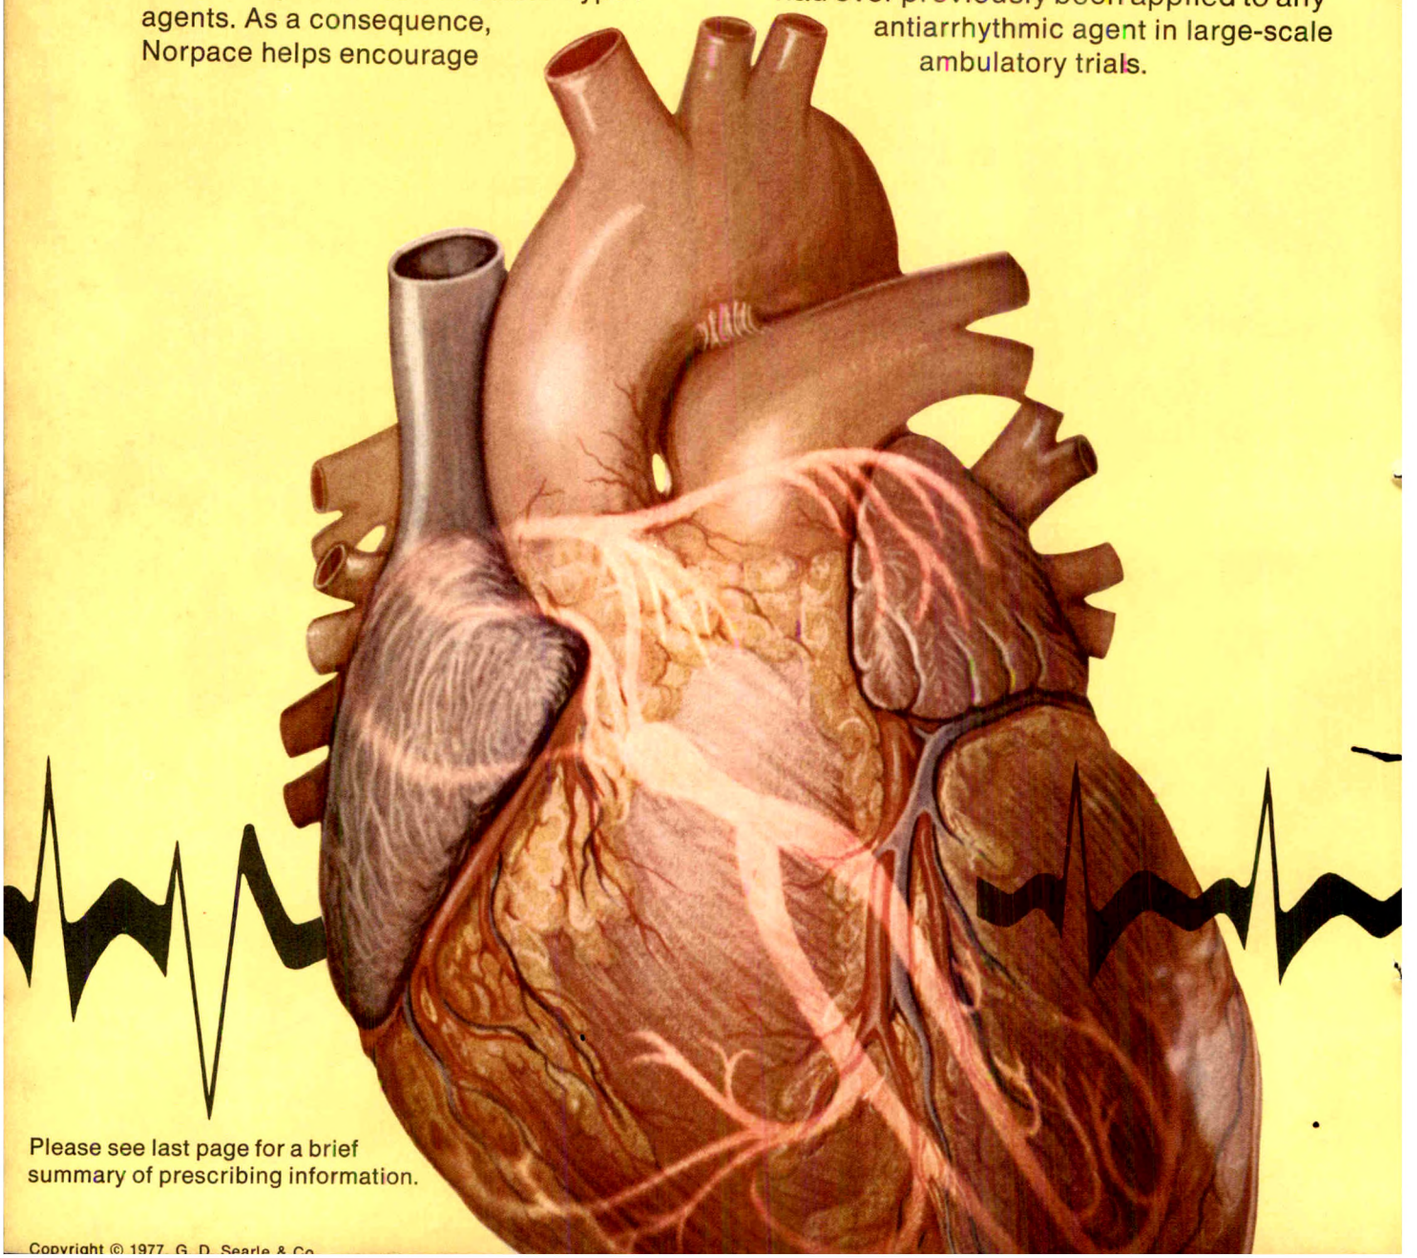
a unique agent for the treatment of specific ventricular cardiac arrhythmias



Introducing
the first antiarrhythmic proved

Norpace (disopyramide phosphate) is a product of Searle Laboratories and the result of many years of research and clinical testing. It satisfies the recognized need for a new oral agent that effectively treats serious ventricular arrhythmias and is relatively safer than available Type I agents. As a consequence, Norpace helps encourage patient compliance and can be prescribed with confidence.

Searle Laboratories will be pleased to provide detailed information on the clinical trials, which used a more sophisticated means of evaluating efficacy than had ever previously been applied to any antiarrhythmic agent in large-scale ambulatory trials.



Please see last page for a brief summary of prescribing information.

Copyright © 1977 G. D. Searle & Co.

effective by extensive Holter monitoring

Norpace®

(disopyramide phosphate)

as effective as quinidine sulfate for specific ventricular arrhythmias...but with less severe side effects

Norpace efficacy was thoroughly proved and documented

Norpace was clinically evaluated in patients monitored by 9-hour Holter ECGs while receiving placebo (two distinct periods) and Norpace (two distinct periods). Significant reductions in ventricular ectopy were recorded during Norpace therapy. Norpace was also compared with quinidine sulfate (quinidine), a standard antiarrhythmic agent, in patients randomly assigned in double-blind studies, and was shown on the basis of 9-hour Holter monitoring to be as effective as quinidine in reducing ventricular ectopic activity. Finally, in oral acute studies involving 3-hour continuous ECGs, Norpace demonstrated the following: 1) a rapid onset of antiarrhythmic activity following an initial loading dose—achieving therapeutic plasma levels usually within ½ to 3 hours; 2) continued suppression of ectopy as a result of maintenance dosing over the subsequent 3 days; and 3) further suppression of ectopy when dosage was increased in most cases where breakthrough was noted. No currently available antiarrhythmic agent has been subjected to such a rigidly controlled program of study prior to introduction as has Norpace, nor have other antiarrhythmics been evaluated in a controlled comparison with a known standard such as quinidine.

Norpace effectively treats specific ventricular arrhythmias

Norpace is indicated when there is electrocardiographic evidence of premature ventricular contractions (PVCs): unifocal, multifocal, or paired PVCs, or episodes of ventricular tachycardia (VT). Significant reductions in these ventricular arrhythmias have been demonstrated by 9-hour ambulatory ECG recording.

During the clinical trials, efficacy in treating ventricular arrhythmias was proved in patients with primary cardiac arrhythmias or arrhythmias associated with coronary artery disease, and also in patients who were digitalized.

Norpace demonstrated excellent patient tolerance

In a double-blind multicenter clinical study (see next page for details), Norpace was found to have less severe side effects than quinidine sulfate and to be significantly better tolerated. The side effects of Norpace, in contrast with those of quinidine, were generally mild, being primarily anticholinergic in nature and frequently transient.

Norpace demonstrated dose-related plasma levels

Therapeutic levels ranging from 2-4 μg/ml are attained in response to 150 mg q 6 h. Some patients with unusually refractory ventricular arrhythmias have required doses up to 400 mg q 6 h which produced plasma levels in the range of 4-8 μg/ml.

Norpace has minimal effect on hemodynamics

At recommended oral doses, Norpace rarely produces significant alterations of blood pressure. Hemodynamic studies of the intravenous administration of Norpace in patients with coronary artery disease have revealed minimal cardiac depression with approximately a 10% reduction in cardiac output.

SEARLE

from clinical studies...

Norpace®
(disopyramide phosphate)

proved as effective as quinidine sulfate for specific ventricular arrhythmias...

Results of double-blind controlled studies

A double-blind multicenter clinical study, involving five investigators, was conducted to compare the relative effectiveness and safety of Norpace and quinidine sulfate. Prior to qualifying for the study, each patient had antiarrhythmic medication discontinued for at least one week. Nine-hour Holter recordings were then used to establish an admission criterion of at least 60 ectopic beats per hour (PVCs, PACs or combination of the two). All other arrhythmias were excluded except paroxysmal ventricular or atrial tachycardias occurring in conjunction with the above.

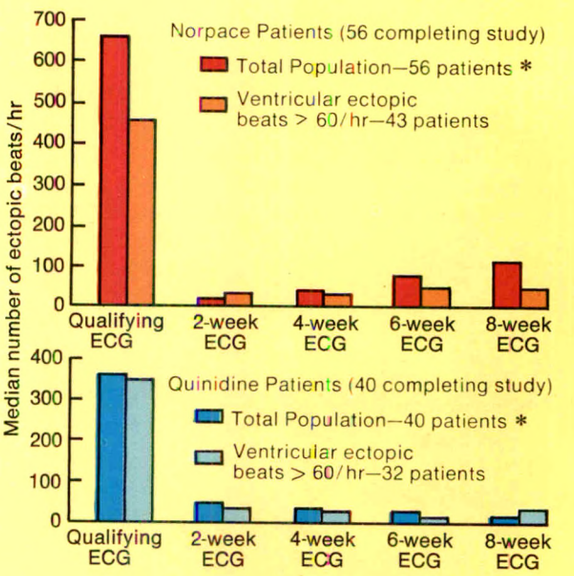
Study protocol

After qualifying, patients were randomly assigned to receive either Norpace (150 mg q 6 h) or matching capsules of quinidine sulfate (325 mg q 6 h). Consultant cardiologists, based on their clinical experience, predicted these dosages to be comparable in effect. Every two weeks during the 8-week course of the study each patient returned to the investigator for a new supply of capsules and a 9-hour Holter recording. The four Holter recordings during therapy plus the qualifying recording provided objective, quantifiable electrocardiographic evidence of patient response to therapy.

Norpace proved comparable to quinidine sulfate in reducing ventricular ectopic beats

Figure 1 presents the relative effectiveness of Norpace and quinidine sulfate in reducing total and ventricular ectopy. It was apparent that both drugs were capable of reducing ectopic activity and maintaining suppression throughout the course of therapy.

Fig 1. Median number of ectopic beats during successive 2-week Holter recordings for Norpace- and quinidine-treated patients.



* Includes patients with more than 60 total (atrial and ventricular) ectopic beats per hour but who had fewer than 60 ventricular ectopic beats per hour.

There was no statistically significant difference in reduction of ectopy between the two drugs.

SEARLE

with less severe side effects

Relative safety of Norpace (disopyramide phosphate) and quinidine sulfate

Reported side effects
The entire study population was analyzed for side effects. The side effects experienced by Norpace patients were usually mild and mainly anticholinergic, including: dry mouth, urinary hesitancy, constipation, blurred vision. The anticholinergic side effects were generally transient.

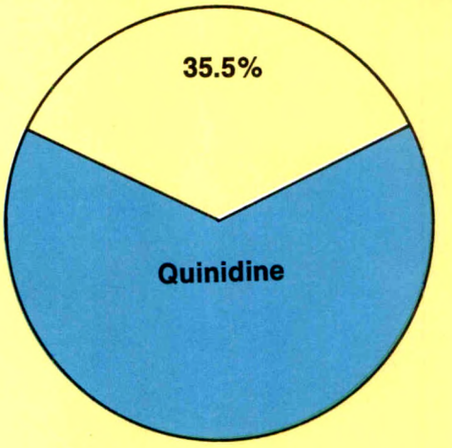
Adverse reactions with quinidine were more serious and affected a greater number of patients. The most common symptoms were: severe diarrhea, cramps, nausea, vomiting, headache, dizziness, blurred vision, fever, chills and diaphoresis.

Reasons for discontinuation of therapy
Twenty-two quinidine patients discontinued therapy because of toxic effects, most of them within the first 2 weeks of treatment. Most of the quinidine sulfate dropouts experienced combinations of gastrointestinal symptoms often accompanied by dizziness and in five cases by a generalized pruritic rash.

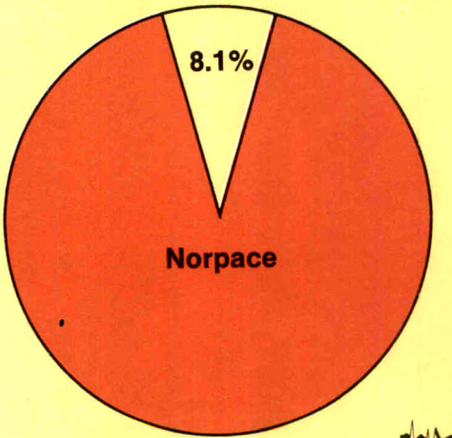
Five Norpace patients dropped out of the study, as a result of the following side effects: nausea and dizziness (2); pains in neck and back (1); urinary complaints in patient with known benign prostatic hypertrophy (1); and persistent paroxysmal ventricular tachycardia (1). (One patient dropped out because of lack of interest.)

Norpace patient group had significantly fewer dropouts due to side effects

Quinidine dropouts in 62 patients



Norpace dropouts in 62 patients



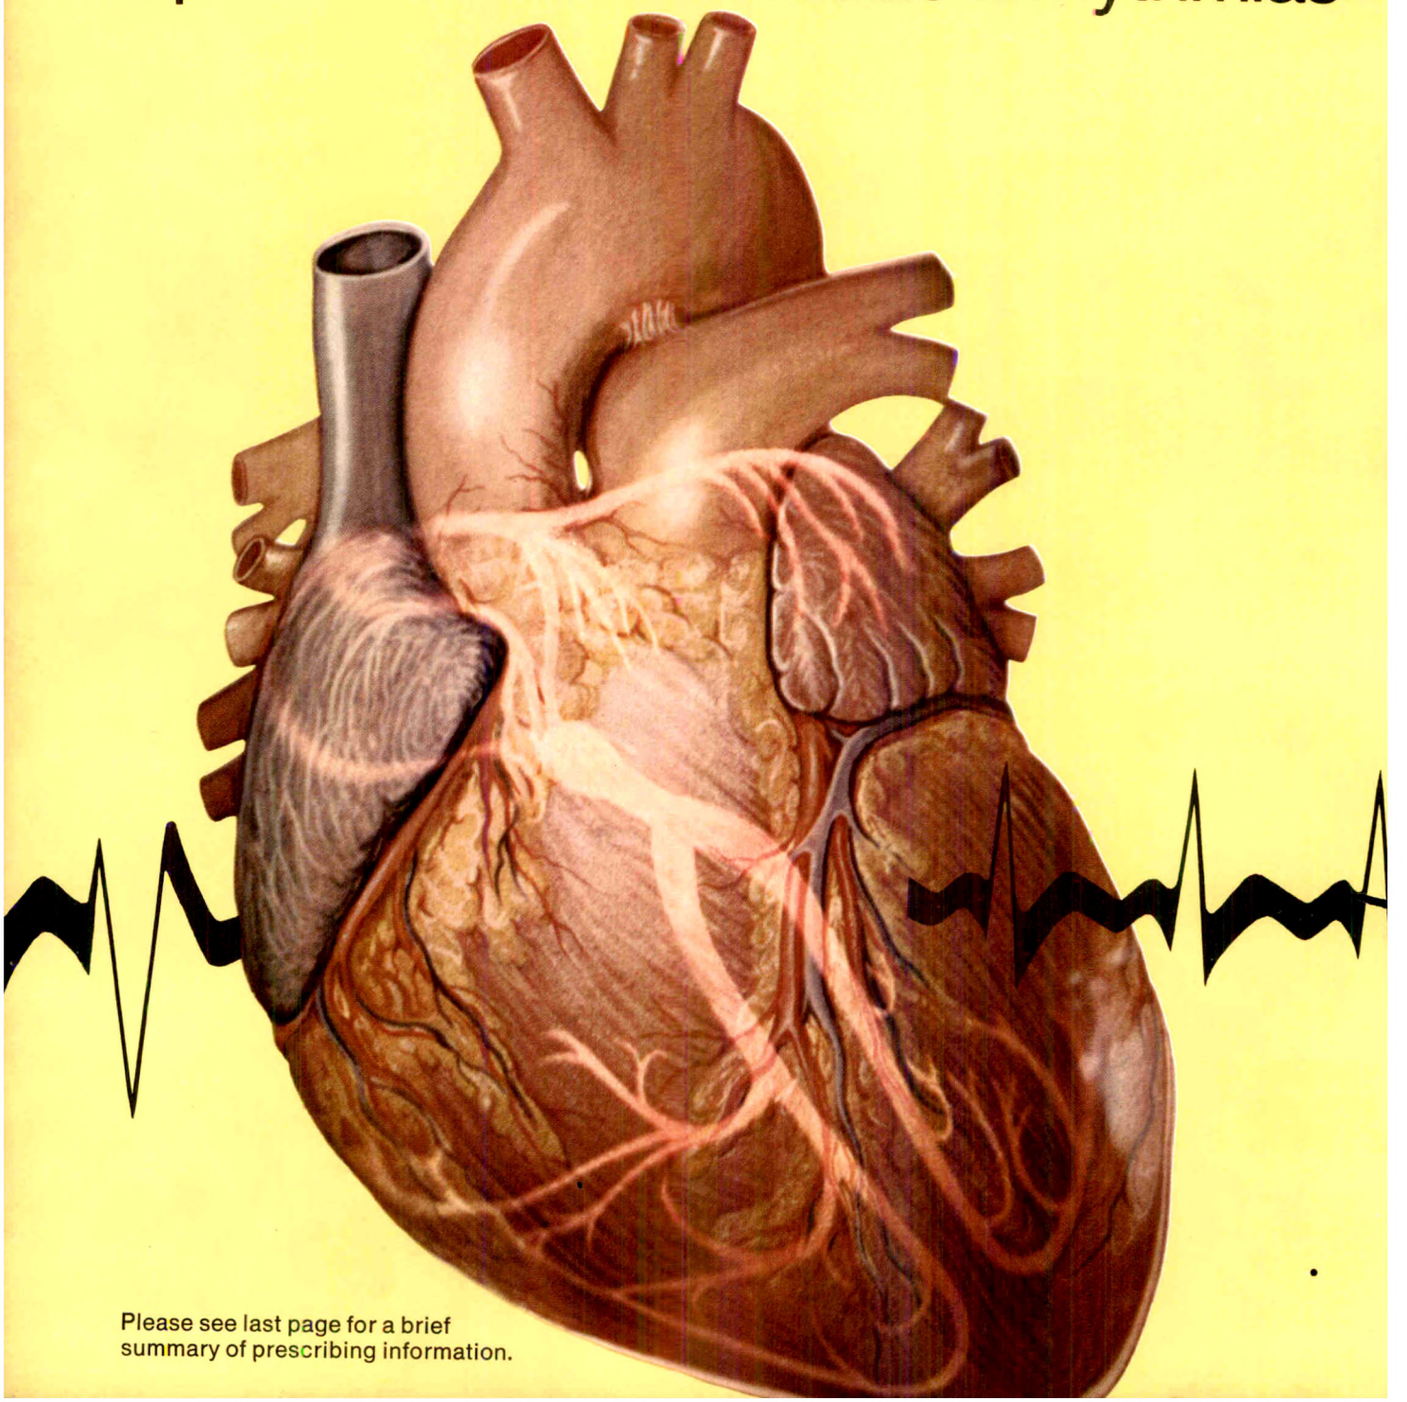
Please see last page for a brief summary of prescribing information.

New from Searle

Norpace®

(disopyramide phosphate)

a unique agent for the treatment of specific ventricular cardiac arrhythmias



Please see last page for a brief summary of prescribing information.

Dosage and administration

Supplied as 100-mg and 150-mg capsules. Dosage should be individualized based on response and tolerance.

Usual adult dosage is 400 to 800 mg per day given in divided doses four times daily, following an initial loading dose.

Recommended dosage regimen

Patient type	Loading dose	Maintenance dose
Adult	300 mg	150 mg q 6 h
Adults of smaller stature; or with moderate renal insufficiency, hepatic insufficiency, cardiomyopathy, or possible cardiac decompensation	200 mg	100 mg q 6 h
Adults with severe renal insufficiency C_{cr} less than 40 ml/min	200 mg	100 mg given approximately every half-life (see Note below)

Note: Since Norpace is excreted in the urine, renal insufficiency appreciably extends the half-life of the drug. The chart below provides guidelines to the appropriate Norpace dosage in such patients.

Norpace dosage interval adjustment for renal insufficiency

Creatinine clearance ml/min.	40-15	15-5	5-1
Approximate maintenance dosing interval	q 10 h	q 20 h	q 30 h

- Norpace plasma half-life may also be prolonged in patients with significant liver disease.

Norpace®
(disopyramide phosphate)

- Effective as quinidine sulfate for specific ventricular arrhythmias and significantly better tolerated
- Compatible with digitalis
- Minimal effect on hemodynamics

SEARLE

Norpace®
(disopyramide phosphate)

as effective as quinidine sulfate for specific ventricular arrhythmias... with less severe side effects

SEARLE
NORPACE® CAPSULES
brand of disopyramide phosphate

Before prescribing Norpace, please consult complete prescribing information, a summary of which follows:
Indications: Norpace is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).

Norpace is equally effective in treating the above arrhythmias in both digitalized and non-digitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia, atrial arrhythmias or arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.
Contraindications: Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.
Warnings: Severe hypotension has been observed on rare occasions, primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. If hypotension develops Norpace should be discontinued promptly unless it is due to the arrhythmia.

Norpace should not be used in the presence of poorly compensated or uncompensated congestive heart failure unless it is exacerbated by or caused by an arrhythmia and proper treatment including optimal digitalization has been accomplished. In some patients with marginally compensated heart failure, Norpace may cause cardiac decompensation. In these patients, progressing congestive heart failure should generally be treated with cardiac glycosides and diuretics and the course of treatment closely followed. Norpace dosage should be reduced or discontinued if adequate control of congestive failure is not attained.

If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of the benefit versus the risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker.

Because of its anticholinergic properties, Norpace should not be used in patients with glaucoma or urinary retention, unless adequate overriding measures are taken.
Precautions: If significant widening (greater than 25%) of the QRS complex occurs, Norpace should be discontinued.

Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits.

The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block.

Norpace should be administered cautiously to patients who are receiving or who have recently received other antiarrhythmic drugs. Excessive widening of the QRS complex may occur in such instances.

Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage.

Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy.
Use in Pregnancy and Lactation: Safe use in pregnancy has not been established. The use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus.

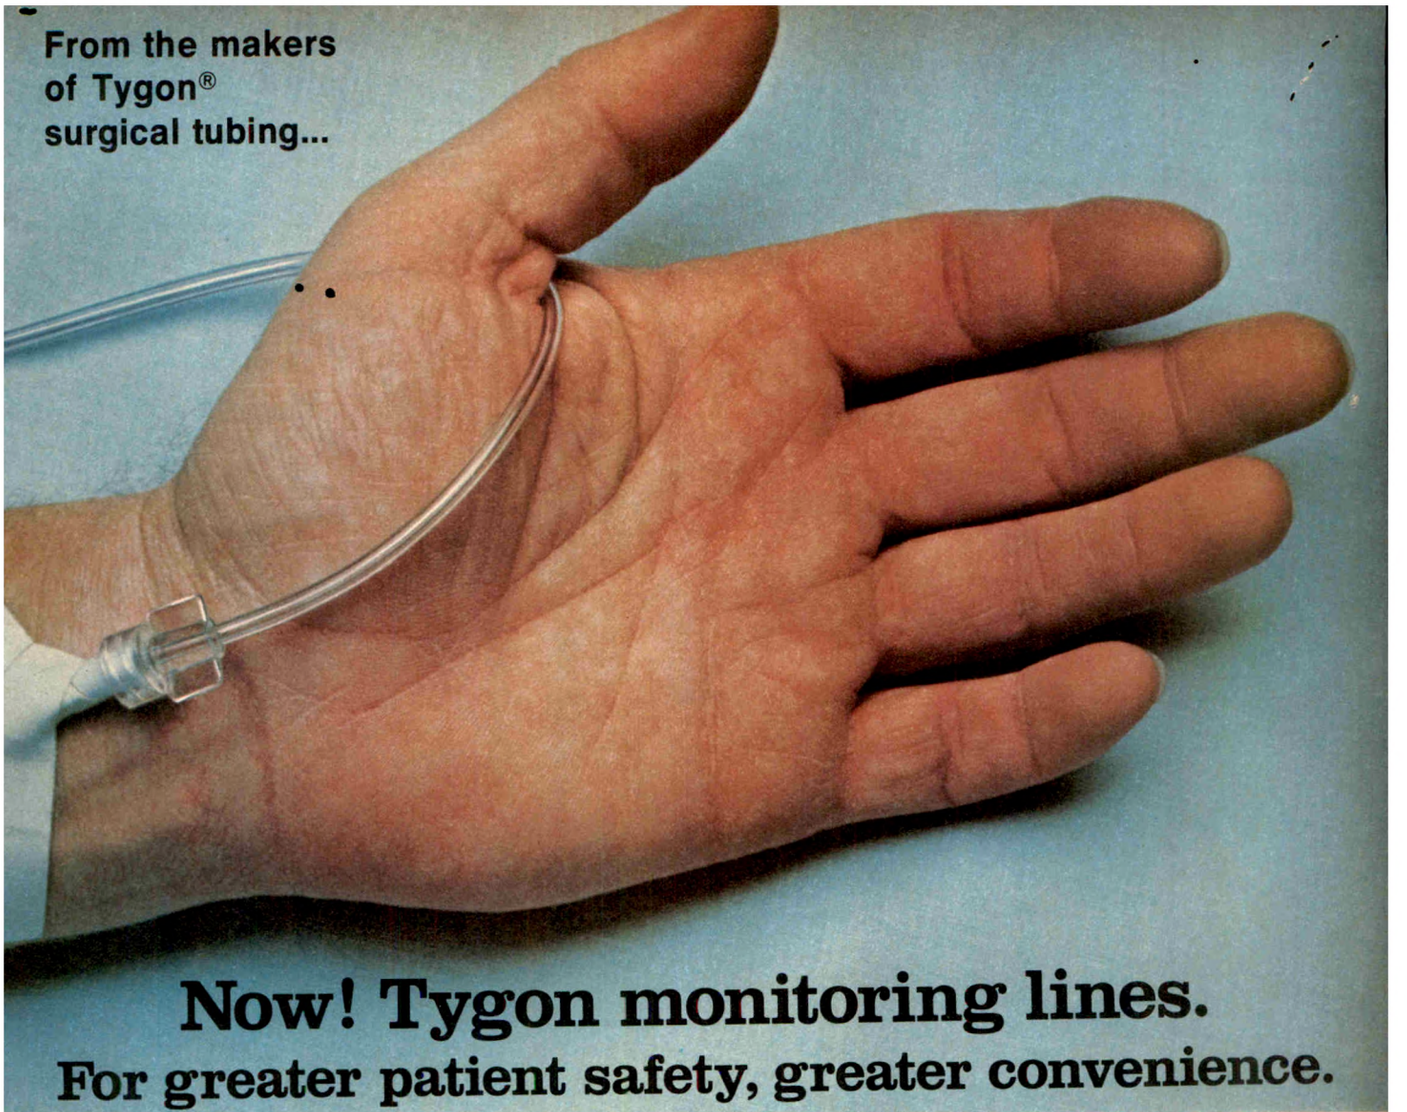
It is not known whether disopyramide is excreted in human milk. However, studies in rats have shown that the concentration of disopyramide and its metabolites in milk is up to three times greater than in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted.
Labor and Delivery: The effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown.
Pediatrics: The safety and effectiveness of Norpace in children have not been established.
Adverse Reactions: *Anticholinergic:* dry mouth, urinary hesitancy, constipation, blurred vision, dry nose-eyes-throat, urinary retention. *Genitourinary:* urinary frequency and urgency, dysuria. *Gastrointestinal:* nausea, pain/bloating/gas, anorexia, diarrhea, vomiting. *Central Nervous System:* nervousness, depression, insomnia, impotence, dizziness, general fatigue/muscle weakness, headache, malaise. A single case of acute psychosis has been reported following Norpace therapy with prompt return to normal mental status when therapy was stopped. *Cardiovascular:* edema/weight gain, cardiac conduction disturbances, shortness of breath, syncope, chest pain, hypotension. *Dermatologic:* generalized rash/dermatoses.
Dosage and Administration: Dosage must be individualized for each patient based upon response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily, following an initial loading dose. The recommended initial dosage schedule for adults is a single loading dose of 300 mg, followed by 150 mg every six hours.

For patients of small stature, or those with moderate renal insufficiency, hepatic insufficiency, cardiomyopathy, or possible cardiac decompensation, a loading dose of 200 mg is recommended, followed by 100 mg every six hours.

For patients with severe renal insufficiency lower doses are recommended. See complete prescribing information for details.
Overdosage: No specific antidote for Norpace has been identified; treatment of overdosage should be supportive. Overdosage might be expected to produce excessive widening of the QRS complex, worsening of congestive heart failure, hypotension, varying kinds and degrees of conduction disturbance, bradycardia and finally asystole. Obvious anticholinergic effects might also be observed. The electrocardiogram should be monitored and supportive therapy with vasopressors, sympathomimetics, cardiac glycosides and diuretics should be given as required. In vitro studies have demonstrated good dialyzability for disopyramide.

SEARLE

Searle Laboratories
Division of G. D. Searle & Co.
Box 5110, Chicago, Illinois 60680



Now! Tygon monitoring lines.

For greater patient safety, greater convenience.

The new Tygon family of monitoring/administration lines brings to the medical profession significant safeguards and conveniences found in no other monitoring lines.

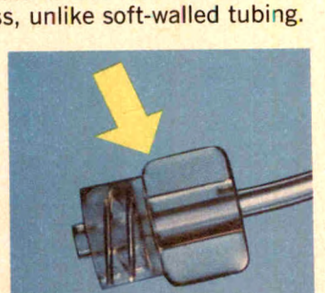
Clarity

From end to end, Tygon monitoring/administration lines are clear. Not only the tubing, but the fittings as well. This offers an important advantage: easier, positive visual checking for air bubbles or other emboli — at a glance.

Controlled Damping

The sturdy Tygon tubing walls assure faithful transmission of pressure without loss, unlike soft-walled tubing.

Integral fittings



The luer lock connectors are **molded** to the tubing, not glued-on. This eliminates the danger of leakage and the possibility of contamination by solvent transfer. Another advantage is the little "wings" on the connectors which permit easy manipulation with gloved hands for fast assembly.

Ready to use, disposable

Each Tygon monitoring/administration line is sterile-packaged in a peel-open pouch and is designed for single patient use.

The name "Tygon" — your best assurance

Tygon® tubing, a product of the Norton Company, has earned a reputation for undeviating excellence in the health care field...particularly where critical procedures are concerned.

Tygon monitoring/administration lines are formulated and produced with this same uncompromising attention to excellence. From raw material to finished product, Norton alone has total manufacturing responsibility. This way, Norton can completely control and maintain the high quality that the medical profession expects from the trusted name "Tygon".

For detailed information on Tygon monitoring/administration lines including sizes, end connector options, and selection data, write for Bulletin MA-1000. Better yet, call Norton toll-free 800-321-9634 (Ohio call collect 216-633-3224).

THE STRENGTH TO OVERCOME EXCESSIVE ANXIETY IN THE ELDERLY CARDIAC PATIENT.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

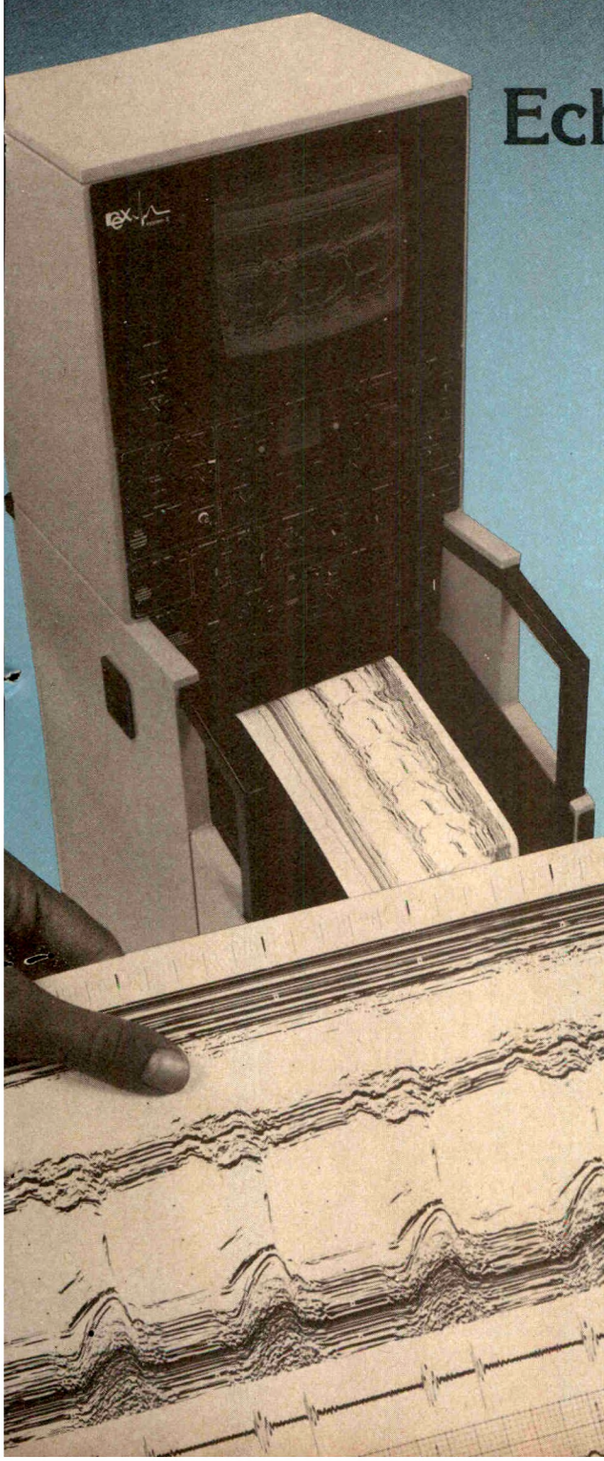
IREX SYSTEM II
AS SIMPLE AS BLACK AND WHITE
. . . with a new dry process



The Best Echocardiography System That Money Can Buy Costs $13,500*

The heart of the Irex System II consists of a completely new medical instrumentation recorder which produces instant, dry, permanent, high resolution **black and white records**.

Irex System II features:

*Ultra high resolution for superb echoes.
*Fully diagnostic phono and pulse channels.
*Selectable recording speeds of 5, 10, 25, 50, 75, 100 and 200 mm/se
*Large screen, long persistence monitor.
*Linearity of better than one percent over the full chart width.

Irex System II has been engineered for **optimum serviceability.** Modular electronic and mechanical components of the system are readily accessible for ease of adjustment or replacement.

The art of the heart...
"Heart," an original composition by the contemporary American graphic artist, Joseph Harris.
Persantine is a non-nitrate coronary vasodilator, with no known contraindications, for the long-term therapy of chronic angina pectoris.*
The key to Persantine efficacy: *give enough...long enough.*
(dipyridamole)
Persantine®

Persantine®
(dipyridamole)

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg

REFLECTION OF PROGRESS:

THE MEDTRONIC 5375 EXTERNAL PACEMAKER.

FROM THE COMPANY THAT HAS ALWAYS SET THE STANDARDS FOR EXTERNAL PACEMAKERS

From our long-standing tradition of providing products for the pacemaker patient has evolved the 5375. Engineering advancements allow the 5375 to provide safe, convenient operation for the physician, nurse and patient.

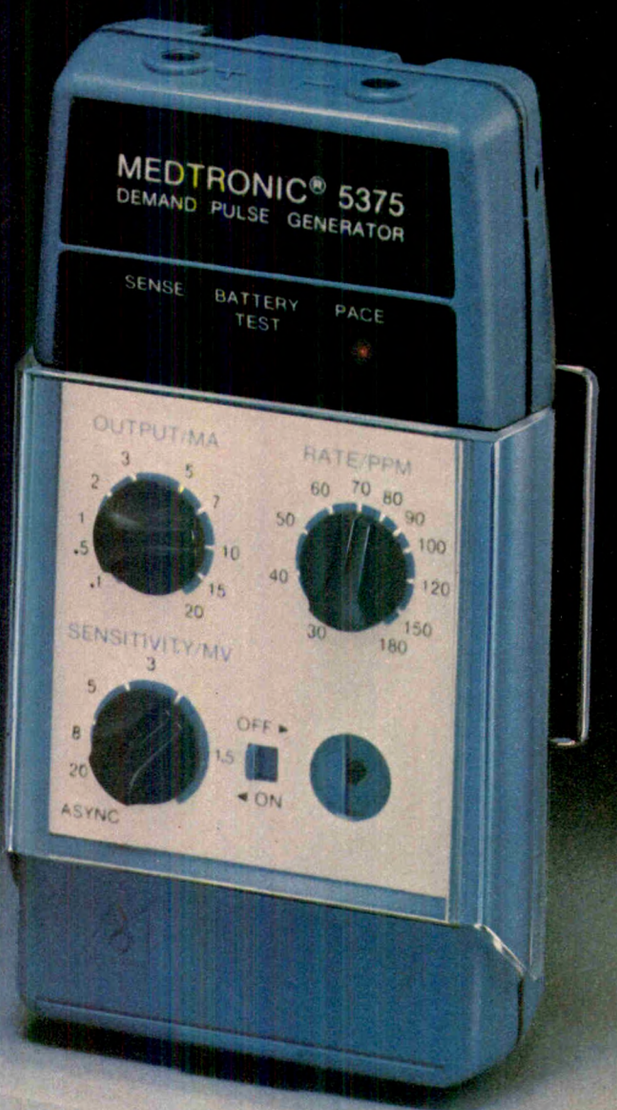
THE STANDARD OF SAFETY

5375 features provide protection against leakage current, EMI and inadvertent inhibition. Splash resistant terminal connections greatly reduce chances of contact with sources of dangerous leakage current — especially important on the busy CCU and ER service floors.

THE STANDARD OF CONVENIENCE

Cables connect by push button. Sliding transparent faceplate protects against accidental movement of controls. Retractable handles allow easy fastening of unit to patient's arm or waist. Indicator lights offer durable, visible verification of pacing, sensing and battery operation. And batteries can be changed quickly and easily, without tools, without interrupting pacing.

Evaluate the 5375. Contact Medtronic. We've been setting the standards for external pacemakers for more than 20 years.



Medtronic

Helping you help the pacemaker patient

MEDTRONIC 5375 EXTERNAL PACEMAKER PRODUCT INFORMATION

INTENDED USES
The Model 5375 External Demand Pulse Generator is intended for use in conjunction with a cardiac lead system for temporary demand or asynchronous pacing. The Model 5375 can be used where therapeutic, prophylactic or diagnostic cardiac pacing is indicated. It can also be used to estimate stimulation thresholds and the R-wave potentials sensed by the pacing lead system electrodes (see product labeling for details).

CONTRAINDICATIONS
There are no known contraindications to the use of external pacing as a means to temporarily pace the heart. The patient's age and medical condition, however, may dictate a particular external pulse generator and the lead system used by the physician.

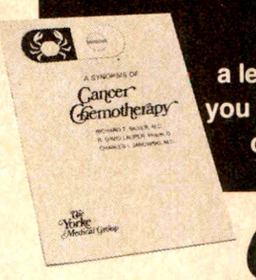
WARNINGS
A cardiac lead system constitutes a direct, low resistance current path to the myocardium. Extreme caution must be taken to properly ground all line-powered equipment used in the vicinity of the patient to protect against ventricular fibrillation induced by leakage current.

Electrosurgical units should be used with caution in the vicinity of an external pacemaker system because of the danger of introducing extrinsic currents into the heart from the external pacemaker system which could cause fibrillation. When operating in the demand mode, the pulse generator output may revert to the asynchronous mode or inhibit the pulse generator in the presence of excessive levels of interference from equipment such as: electrosurgery units, diathermy equipment and some medical telemetry systems. Defibrillation discharges will probably not affect external pulse generators.

PRECAUTIONS
The physician should be aware that the Model 5375 can malfunction for reasons such as: random component failure, battery depletion and mishandling which cannot be predicted prior to failure. The pacing lead system may malfunction at any time due to lead system-related problems. Appropriate standby equipment should be available when the Model 5375 pulse generator is used.

POTENTIAL COMPLICATIONS
Potential complications associated with the use of an external pacemaker system are asystole following abrupt cessation of pacing and lead system-related problems such as: myocardial irritability, local tissue reaction, muscle and nerve stimulation, infection, erosion of the lead system through the skin, transvenous lead-related thrombosis and embolism, myocardial lead-related hemorrhage and cardiac tamponade.

How to Keep Up with Drug Interaction in Cancer Chemotherapy



Three authorities from a leading medical center show you how to use the most current chemotherapeutic agents

A SYNOPSIS OF
Cancer Chemotherapy

At last a way to keep up with the bewildering proliferation of new chemotherapeutic drugs which have come into use relatively recently. This just published guide will be valuable to every hospital, and every oncology specialist, general internist, clinical pharmacist, and nurse oncologist.

A SYNOPSIS OF CANCER CHEMOTHERAPY is a concise, readily understandable "how to" manual. Developed originally for staff use at The New York Hospital-Cornell Medical Center, the concept proved so successful it was decided to make it available to other professionals. The new users of the SYNOPSIS have the advantage of a proven, time-tested learning system. It is written in a unique, compact work-book style to keep reading time to a minimum.

The reader can quickly find the following for both commercially available and investigational drugs:
- Structure
- Mechanism of Action
- Pharmacokinetics
- Toxicity
- Therapy
- Availability

The chemotherapeutic agents in the main listing section cover these categories:
- Alkylating Agents
- Antimetabolites
- Mitotic Inhibitors
- Antibiotics
- Miscellaneous (includes such drugs as Mithramycin, Mitotane, etc.)

New wide-angle probe for EkoSector I.™

It gives you .. the big picture.

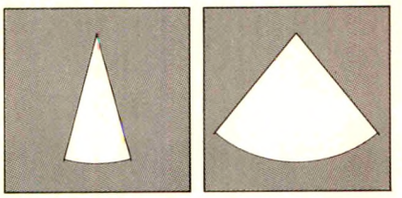
Our remarkable new wide-angle probe gives you an enlarged cross-sectional scan of the heart, making it easier for you to visualize and correlate relative position and motion patterns of intracardiac structures for a more accurate diagnosis.

In addition this new probe provides an image of extremely high resolution.

More innovation without obsolescence.

The new wide-angle probe is yet another SKI innovation designed to protect your original investment while providing extra value to you.

If you already own an EkoSector I™, a modification will enable you to use the standard probe and the new wide-angle probe interchangeably. Both heads simply attach to the existing probe handle.



The new wide-angle probe displays a scan that is 50° greater than the standard 30° probe. Both probes will be supplied with all new EkoSector I units. The wide-angle probe is supplied for existing systems as an optional accessory.

Real-time cross-sectional scanning and unique design.

The SKI patented direct processing method provides distortion-free electronic images and correct, spatially-oriented, information concerning the depth relative to the chest wall, and real-time motion of cardiac structures.

Clinically reported uses for EkoSector I include quantitation of mitral and aortic stenosis, detection of ventricular aneurysms and localization of ventricular outflow obstructions.

Transducers provide A-mode, M-mode or sector scanning of the heart or other organs. Images can be displayed on the oscilloscope or on the large external X-Y monitor. A videotape recorder allows recording of M-mode or cross-sectional scans along with verbal comments. Playback can be at normal speed, slow motion or stop-frame projection. Recorded images can be selectively altered in size by means of the tissue depth control.

If you already own an Ekoline 20A, the EkoSector I can easily be interfaced with it, cutting your cost for the whole system by almost half. Even if you do not already own an Ekoline 20A, the complete system still costs less than competing systems.

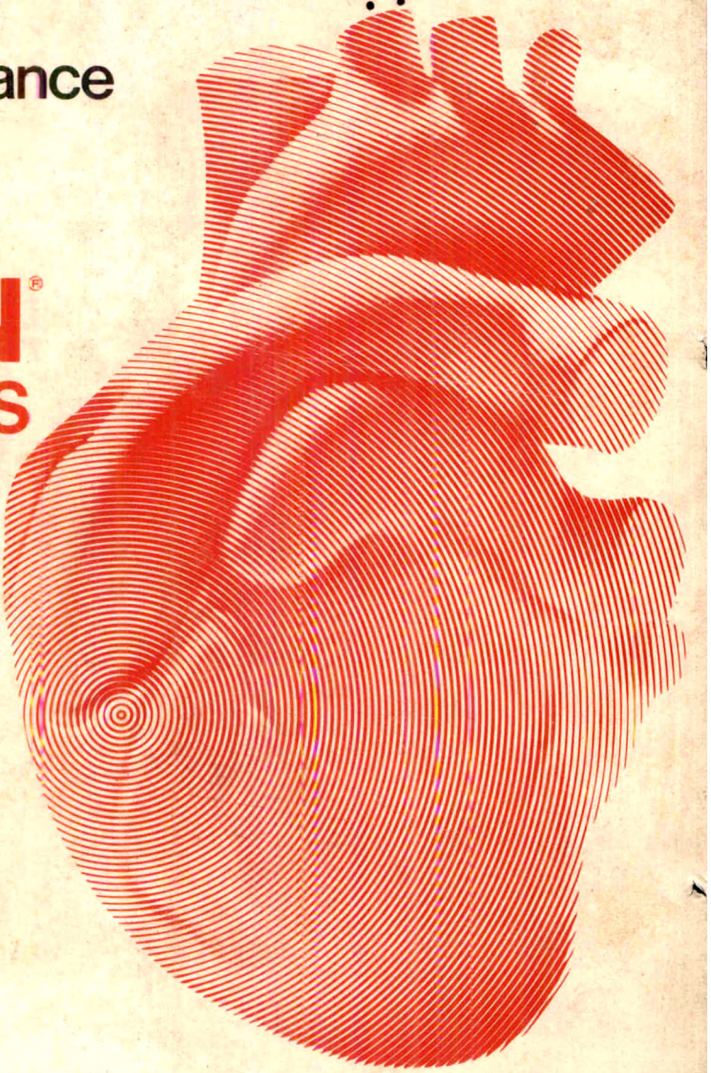
The Pacekeeper™

For the broad spectrum of cardiac arrhythmias broad-range treatment... conversion and maintenance



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance
- ☐ Full quinidine cardiodynamics
- ☐ Convenient B.I.D. or T.I.D. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm—whether with CARDIOQUIN Tablets or electroconversion—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart-block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

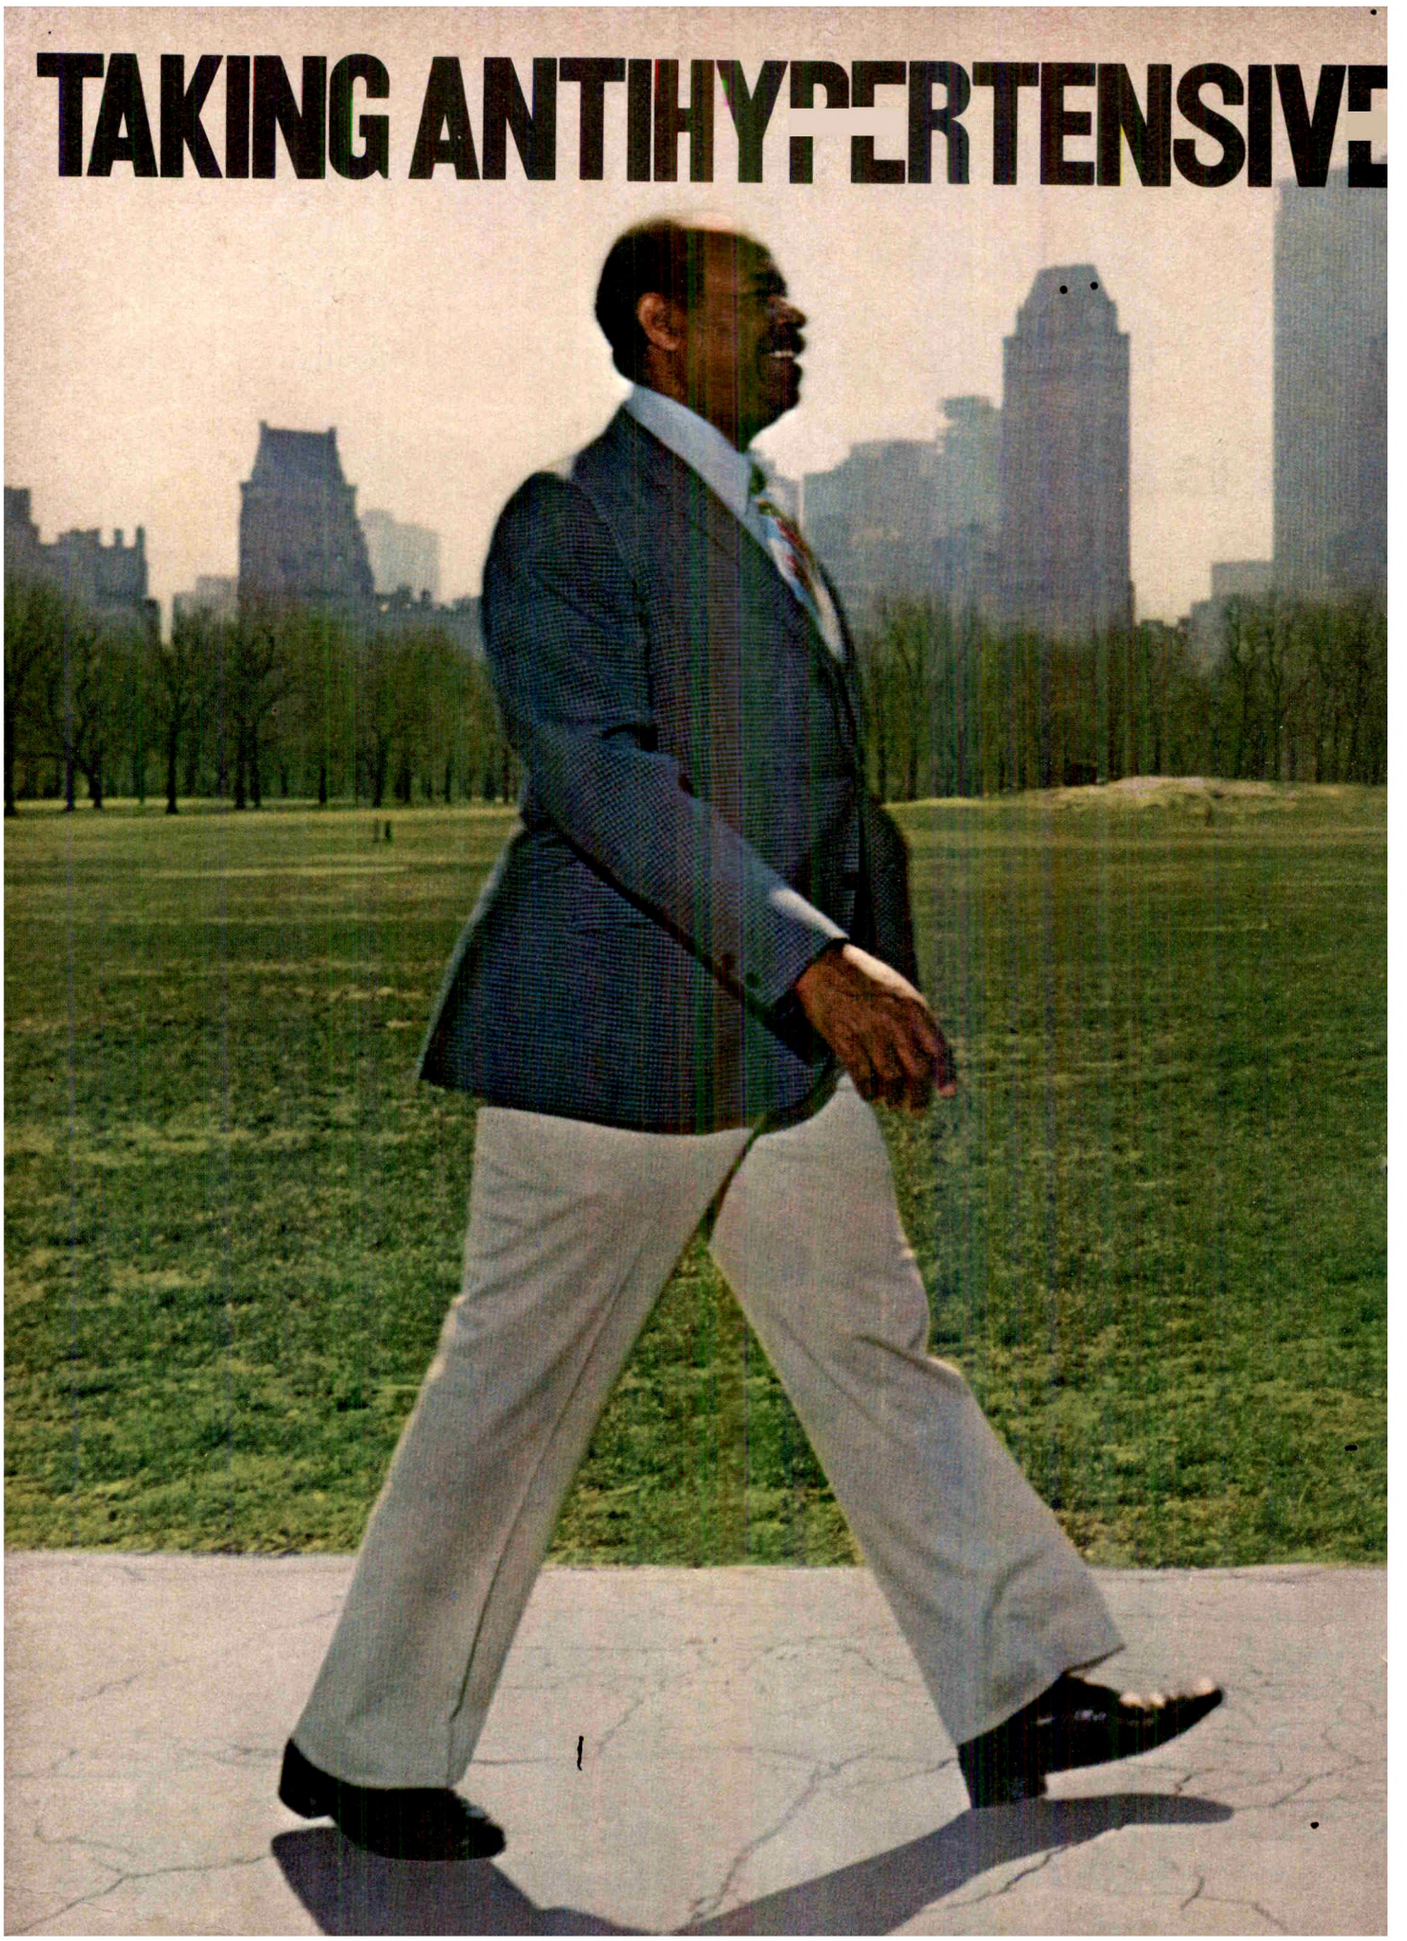
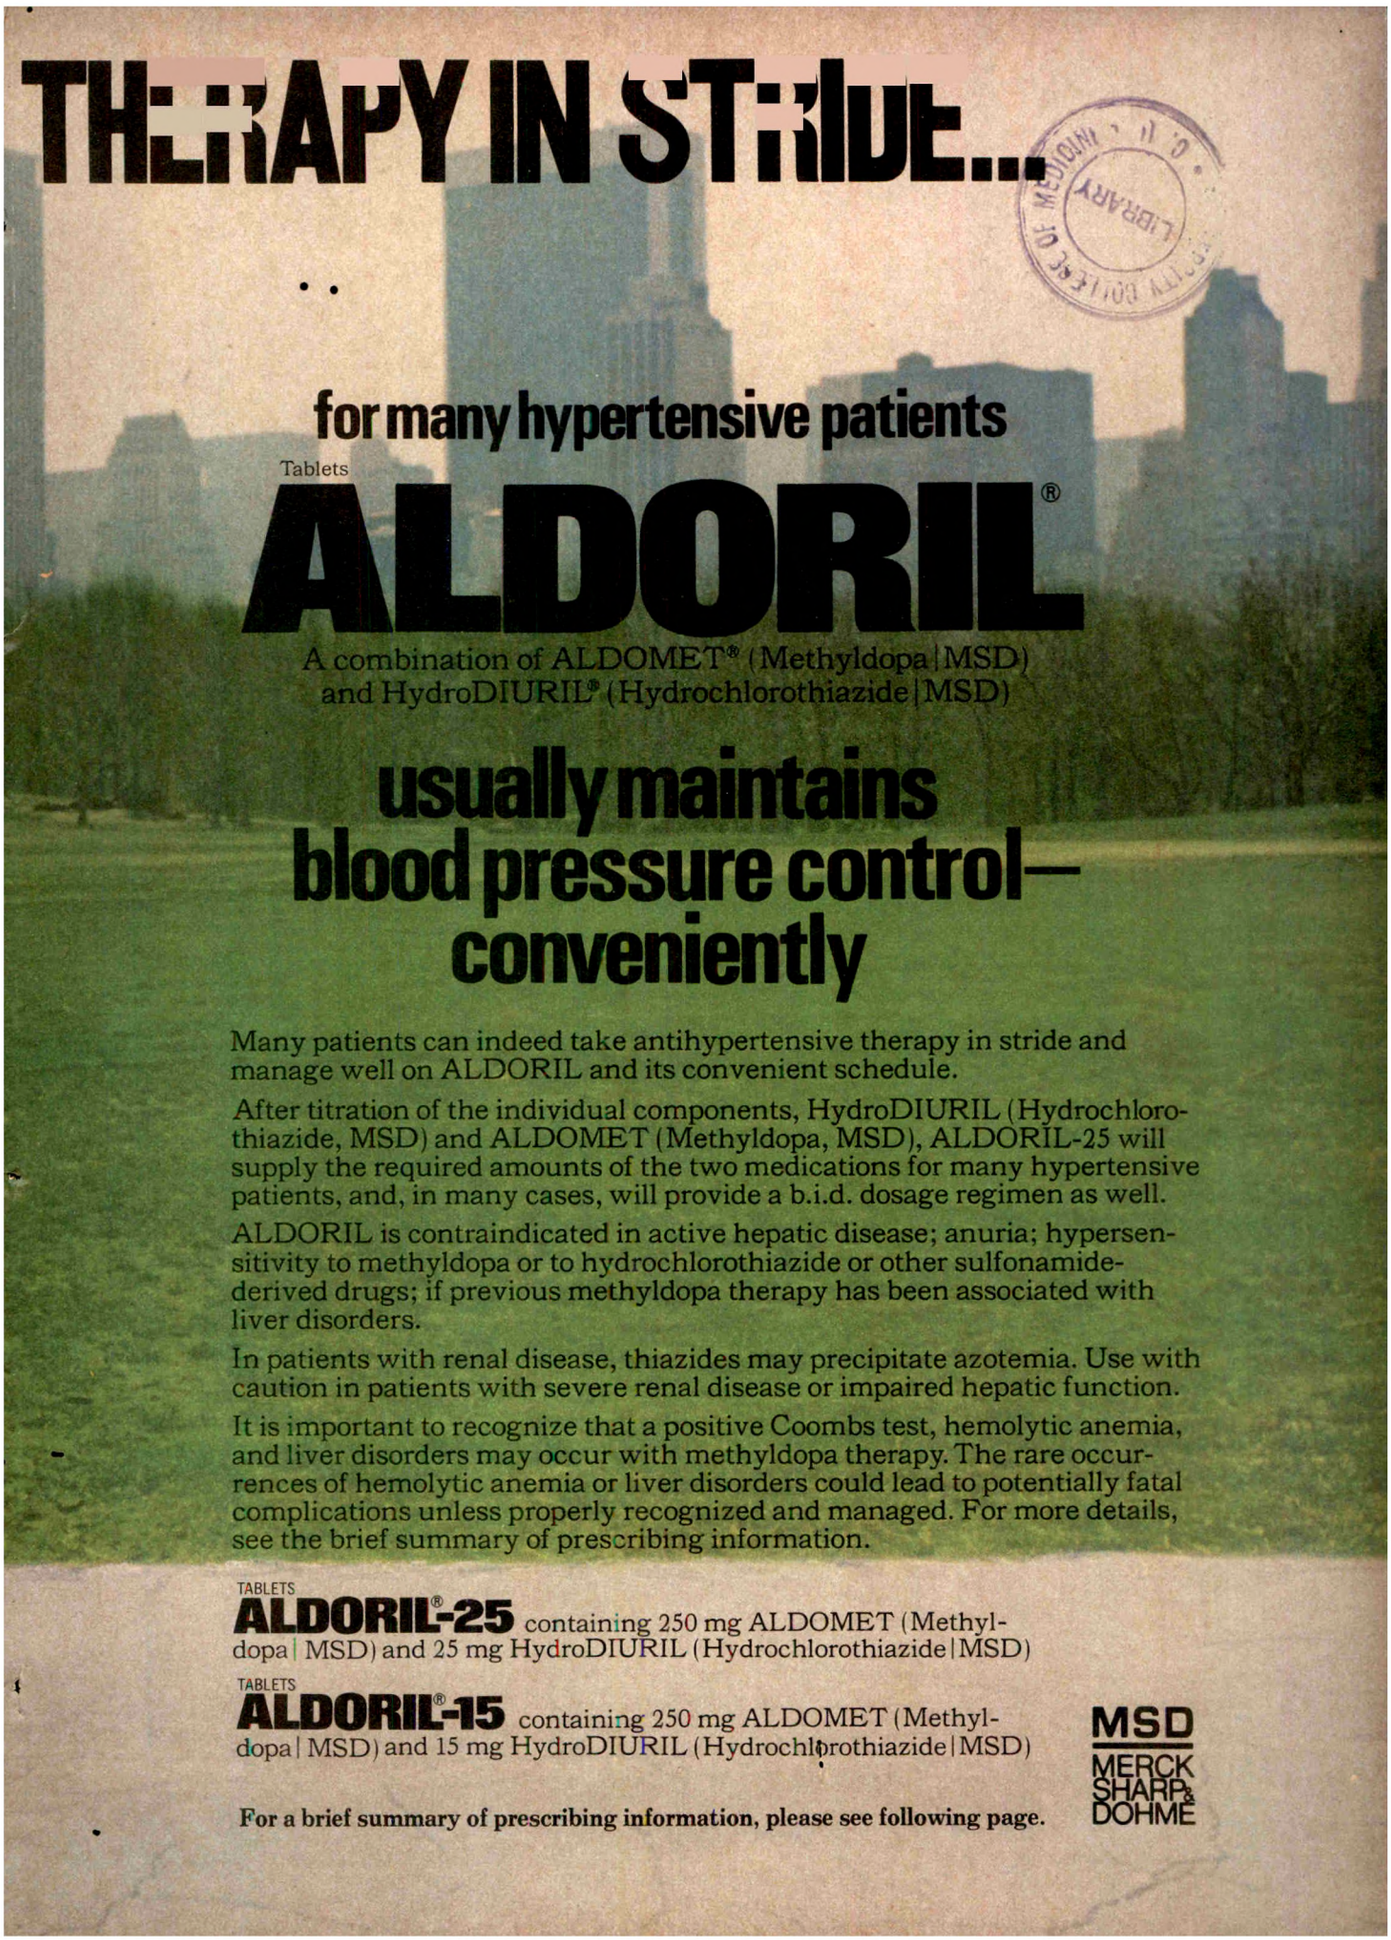
TAKING ANTIHYPERTENSIVE





THERAPY IN STRIDE...
for many hypertensive patients
Tablets
ALDORIL®
A combination of ALDOMET® (Methyldopa | MSD)
and HydroDIURIL® (Hydrochlorothiazide | MSD)
usually maintains
blood pressure control—
conveniently
Many patients can indeed take antihypertensive therapy in stride and manage well on ALDORIL and its convenient schedule.
After titration of the individual components, HydroDIURIL (Hydrochlorothiazide, MSD) and ALDOMET (Methyldopa, MSD), ALDORIL-25 will supply the required amounts of the two medications for many hypertensive patients, and, in many cases, will provide a b.i.d. dosage regimen as well.
ALDORIL is contraindicated in active hepatic disease; anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs; if previous methyldopa therapy has been associated with liver disorders.
In patients with renal disease, thiazides may precipitate azotemia. Use with caution in patients with severe renal disease or impaired hepatic function.
It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details, see the brief summary of prescribing information.
TABLETS
ALDORIL®-25 containing 250 mg ALDOMET (Methyldopa | MSD) and 25 mg HydroDIURIL (Hydrochlorothiazide | MSD)
TABLETS
ALDORIL®-15 containing 250 mg ALDOMET (Methyldopa | MSD) and 15 mg HydroDIURIL (Hydrochlorothiazide | MSD)
For a brief summary of prescribing information, please see following page.
MSD
MERCK SHARP & DOHME

Antihypertensive TABLETS

ALDORIL®-25
methyldopa 250 mg and hydrochlorothiazide 25 mg

Antihypertensive TABLETS

ALDORIL®-15
methyldopa 250 mg and hydrochlorothiazide 15 mg

WARNING

This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be re-evaluated as conditions in each patient warrant.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see **Warnings**); anuria; routine use in an otherwise healthy pregnant woman with or without edema; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs.

Warnings: METHYLDOPA—**It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.**

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within the first three weeks of therapy, sometimes with eosinophilia or abnormalities in one or more liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually within the first two to three months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests, or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, reversible reduction of white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Follow patients carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

HYDROCHLOROTHIAZIDE—Use with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs; potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity; read circulars for lithium preparations before use of such concomitant therapy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant requires that anticipated benefits be weighed against possible risks.

Methyldopa and thiazides cross the placental barrier and appear in cord blood.

No unusual adverse reactions have been reported in association with the use of methyldopa during pregnancy. Although no obvious teratogenic effects have been reported, the possibility of fetal injury cannot be excluded.

The hazards of thiazides crossing the placental barrier include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in adults. Methyldopa and thiazides appear in breast milk. Patients taking ALDORIL should not nurse.

Precautions: METHYLDOPA—Should be used with caution in patients with history of previous liver disease or dysfunction (see **Warnings**). May interfere with measurement of urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites. Involuntary choreoathetotic movements have been observed in patients with severe bilateral cerebrovascular disease. If such movements occur, stop the drug. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

HYDROCHLOROTHIAZIDE—Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Warning signs, irrespective of cause, are dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroids or ACTH, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or frank gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid glands with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: METHYLDOPA— *Central nervous system:* Sedation, headache, asthenia or weakness; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

HYDROCHLOROTHIAZIDE—*Gastrointestinal system:* Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. *Central nervous system:* Dizziness, vertigo, paresthesias, headache, xanthopsia. *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia. *Cardiovascular:* Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). *Hypersensitivity:* Purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), fever, respiratory distress including pneumonitis, anaphylactic reactions. *Other:* Hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, transient blurred vision. Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: Tolerance may occur, usually between the second and third month of therapy. Increasing dosage of either component separately or together frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets ALDORIL®-15, containing 250 mg methyldopa and 15 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL®-25, containing 250 mg methyldopa and 25 mg hydrochlorothiazide, bottles of 100 and 1000.

A new and more precise Holter System

Now, with Accuscan, physicians can command three major diagnostic functions in the one instrument: Holter scanning; stress testing; and 12-lead resting ECG.

This complete system is engineered for fast, easy operation in your office, clinic or hospital.

The Accutape 24 cassette recorder is an integral part of the Accuscan system. This hand-size unit can record diagnostic ECG continuously for 24 hours — without patient intervention. It also permits patients to clock and mark events automatically.

For accurate scanning of recorded tape, the digital clock on the Accuscan panel is set to correspond with the start of the patient's recording. From that point on, Accuscan's time relates precisely with the crystal controlled time of the Accutape recording.

Accuscan can be programmed to stop automatically (or manually) at every event marked by the patient. At the press of a button it will also search for any selected time segment.

Other noteworthy features include: automatic "reverse jog"; digital rate meter; non-fade scope with freeze capability; optional arrhythmia counter — and surprising simplicity of operation.

There's much more to say about the new Accuscan, so if you're interested in leasing or purchasing or would simply like more information, phone or mail coupon below.

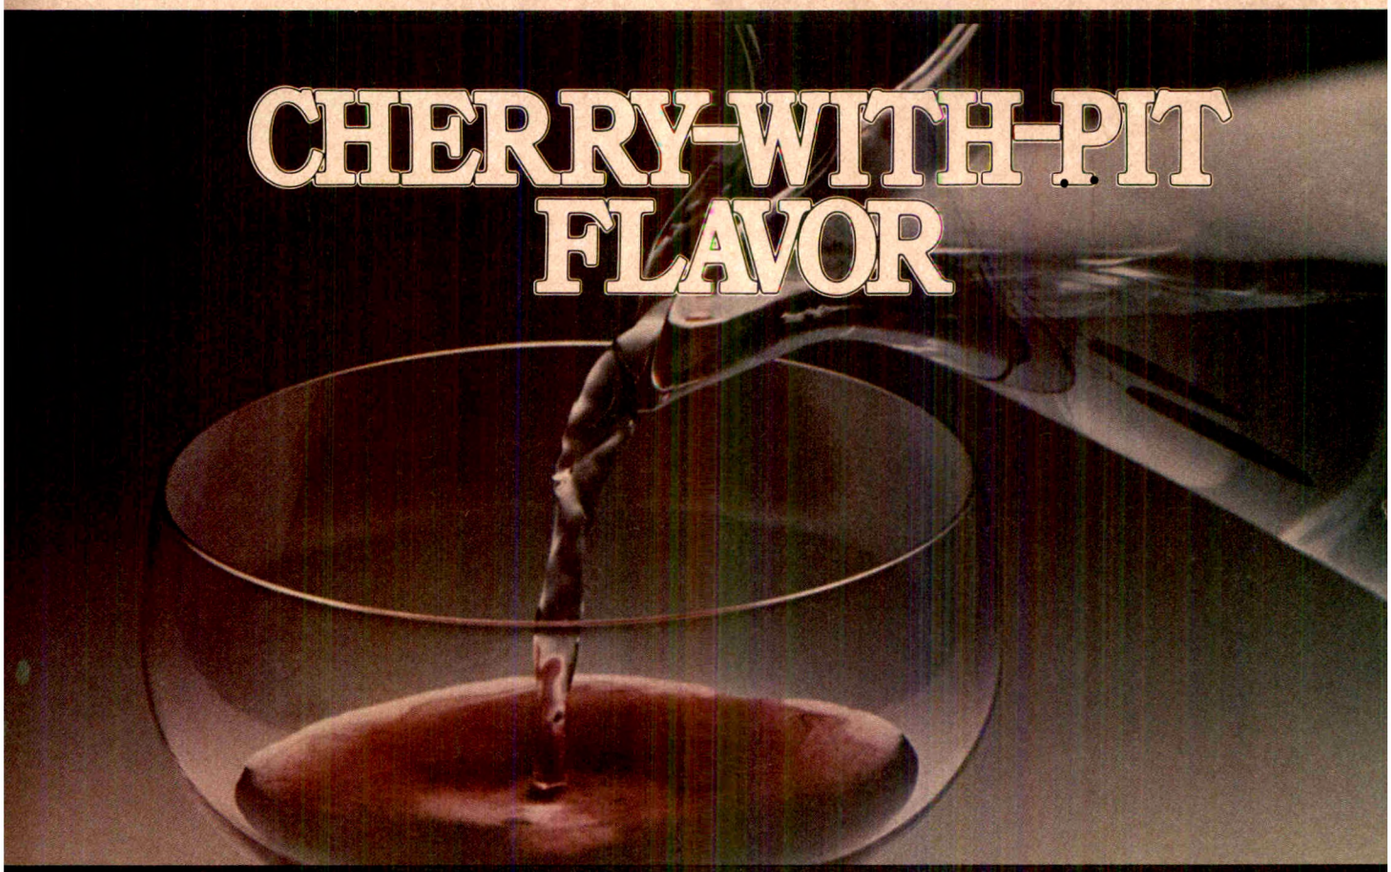
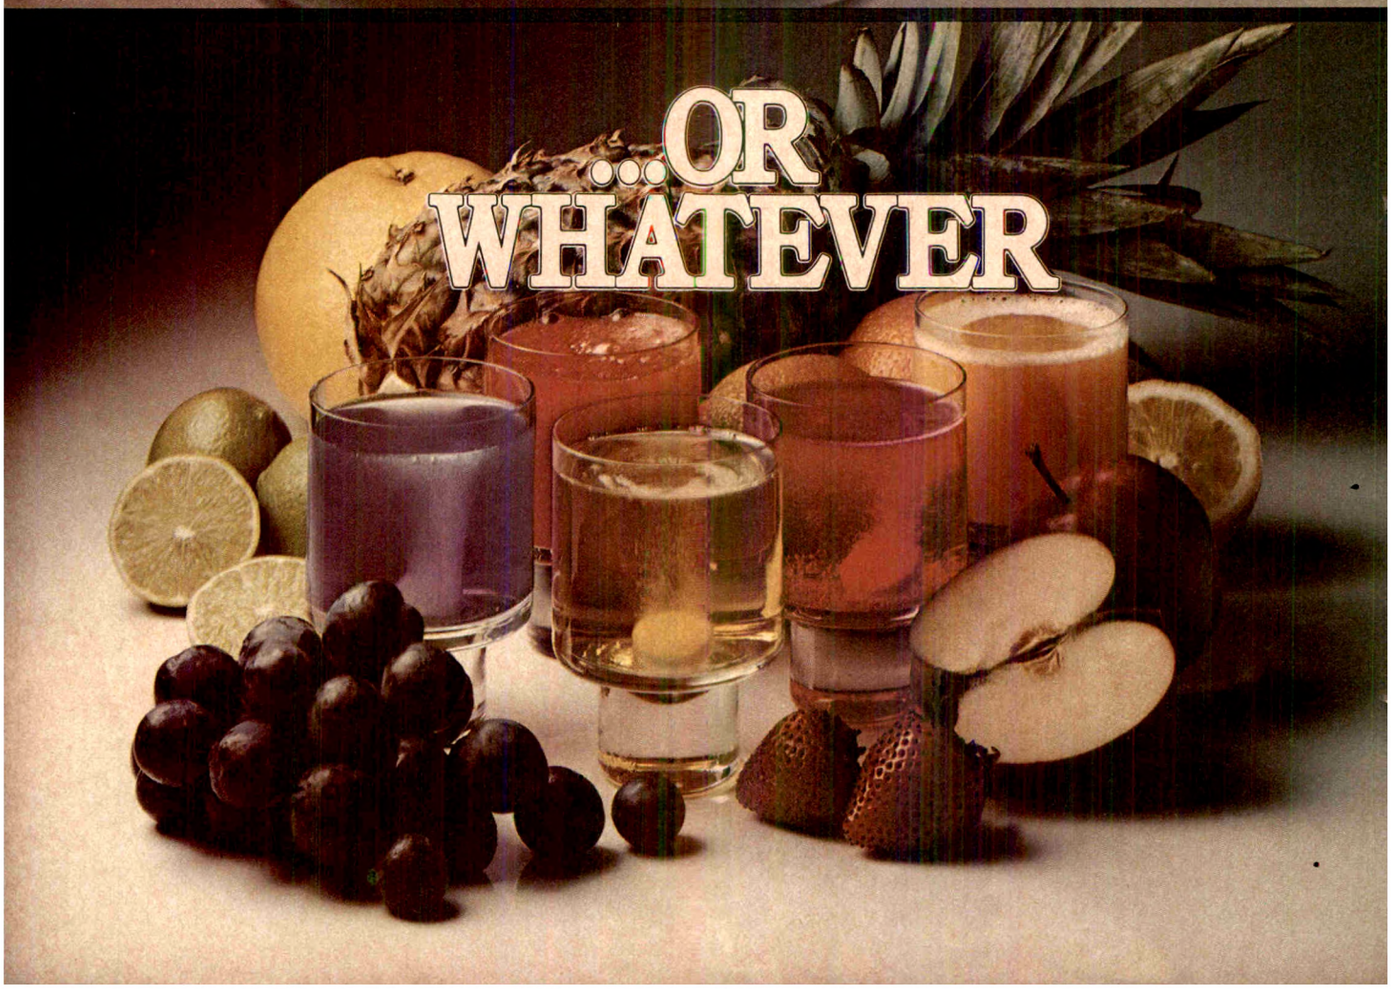
FOR PATIENT COMPLIANCE IN

CHERRY-WITH-PIT FLAVOR



...OR WHATEVER



POTASSIUM SUPPLEMENTATION

DELICIOUS

KLORVESS® 10% LIQUID (potassium chloride)

Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable cherry-with-pit flavored vehicle, alcohol 1%.

Delicious cherry-with-pit flavor.
If you've tasted it, you know KLORVESS® (potassium chloride) 10% Liquid provides a delicious natural flavor. So good, in fact, that it should be mixed only with water.

THE SUBTLE MIXER

KLORVESS® EFFERVESCENT TABLETS

Each dry, sodium- and sugar-free effervescent tablet contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g.

Or whatever flavor your patients like . . . because the taste of KLORVESS® Effervescent Tablets is determined by what they're mixed with. The subtle mixer.

Convenience in therapeutic doses.
Both forms of KLORVESS offer 20 mEq of potassium and chloride in each dose. There is no need to prescribe several slow-release tablets per dose or space dosage administration beyond the patient's normal routine. Prescribe KLORVESS Liquid or KLORVESS Effervescent Tablets . . . for potassium supplement therapy that offers good taste and convenience at therapeutic dosages.

Description: Klorvess Effervescent Tablets: Each dry, sodium- and sugar-free effervescent tablet contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g. Dissolution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

Indications: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

Contraindications: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements.

Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis.

High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest.

To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve each Klorvess Effervescent Tablet in 3 to 4 ounces of water or fruit juice, or dilute each tablespoonful of Klorvess (potassium chloride) 10% Liquid in 3 to 4 ounces of water. Both of these solutions should be ingested slowly with or immediately after meals.

Adverse Reactions: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts.

The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest.

The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

Dosage and Administration: Klorvess Effervescent Tablets: Adults—One Klorvess Effervescent Tablet (20 mEq each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water or fruit juice 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) of Klorvess Liquid (20 mEq of potassium chloride) completely diluted in 3 to 4 ounces of water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating. Deviations from these recommended dosages may be indicated in certain cases of hypokalemia based upon the patient's status. The average total daily dosage must be governed by the patient's response as determined by frequent evaluation of serum electrolytes, EKG and clinical status.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

Treatment of Hyperkalemia: 1. Dextrose solution, 10 or 25% containing 10 units of crystalline insulin per 20 g dextrose, given IV in a dose of 300 to 500 ml in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resins, orally and as retention enema. (Caution: Ammonium compounds should not be used in patients with hepatic cirrhosis.) 3. Hemodialysis and peritoneal dialysis. 4. The use of potassium-containing foods or medicaments must be eliminated. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

How Supplied: Klorvess Effervescent Tablets (white)—60 tablets (2 Rx units of 30 effervescent tablets each). Each tablet is individually foil wrapped. Klorvess (potassium chloride) 10% Liquid (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Tablets and Liquid are also available in institutional packaging as follows: Klorvess Tablets—30 and 1000 tablets; Klorvess Liquid—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

CONTENTS

CLINICAL STUDIES

197 **Identification of High Risk Subsets of Acute Myocardial Infarction. Derived from the Myocardial Infarction Research Units Cooperative Study Data Bank**

KARL T. WEBER, JOSEPH S. JANICKI, RICHARD O. RUSSELL and CHARLES E. RACKLEY

High risk subsets in 400 patients with acute myocardial infarction were as follows: In class I, nonsurvivors had significantly higher values for pulmonary capillary wedge pressure (16 mm Hg) and heart rate (76 beats/min); nonsurvivors in class II also had a significant elevation of pulmonary capillary wedge pressure (23 mm Hg); and in class IV the high risk subset was characterized by pulmonary capillary wedge pressure (21 mm Hg), heart rate (100 beats/min), cardiac index (1.6 liters/min per m^2), stroke index (14 cc/m^2) and stroke work index (12 g-m/m^2). Nonsurvivors in class III could not be identified from hemodynamic criteria, but the small population sample prohibits meaningful analyses and comparisons. In individual patients the clinical examination did not consistently reflect the degree of ventricular dysfunction, but careful bedside examination and hemodynamic monitoring of wedge pressure, cardiac output and heart rate together best identify the high risk patient after acute myocardial infarction. It is in these patients that an aggressive, goal-oriented management program directed at reducing myocardial energy utilization must be instituted to control infarct size and reduce patient morbidity and mortality.

204 **Coronary Anatomy and Arteriography in Patients With Unstable Angina Pectoris**

HAROLD W. ALISON, RICHARD O. RUSSELL, Jr., JOHN A. MANTLE, NICHOLAS T. KOUCHOUKOS and CHARLES E. RACKLEY

In this prospective series of 188 subjects undergoing coronary arteriography, patients with the syndrome of unstable angina pectoris usually presented with severe coronary artery disease and were candidates for coronary revascularization. Ten percent of patients with left main coronary artery disease were thought to have died as a result of cardiac catheterization because they had symptoms or evidence of myocardial necrosis within 24 hours of the procedure. The anatomic severity of coronary artery disease, primarily associated with left main coronary artery disease, appeared to be the most important factor contributing to myocardial infarction or death after cardiac catheterization. Of the patients presenting with the syndrome of unstable angina pectoris, 10.6 percent had normal coronary arteriograms. The majority of patients had severe coronary artery disease and were candidates for coronary revascularization.

210 **Tortuosity as an Index of the Age and Diameter Increase of Coronary Collateral Vessels in Patients After Acute Myocardial Infarction**

GROVER M. HUTCHINS, MARTIN M. MINER and BERNADINE H. BULKLEY

Measurements of diameter and tortuosity of 140 collateral vessels identified in postmortem coronary arteriograms of 35 autopsy patients with a myocardial infarct of known age showed that collateral diameter and tortuosity increased with time after the infarction. These results suggest that the identification of tortuosity in a coronary

IN PREDICTABLE ANGINA*

...during periods of physical exertion

SUMMARY OF PRESCRIBING INFORMATION

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classifications of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: *Individual Dose:* To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.

Duration of Effect: One to two hours.

CHEWABLE SORBITRATE® 5 mg.

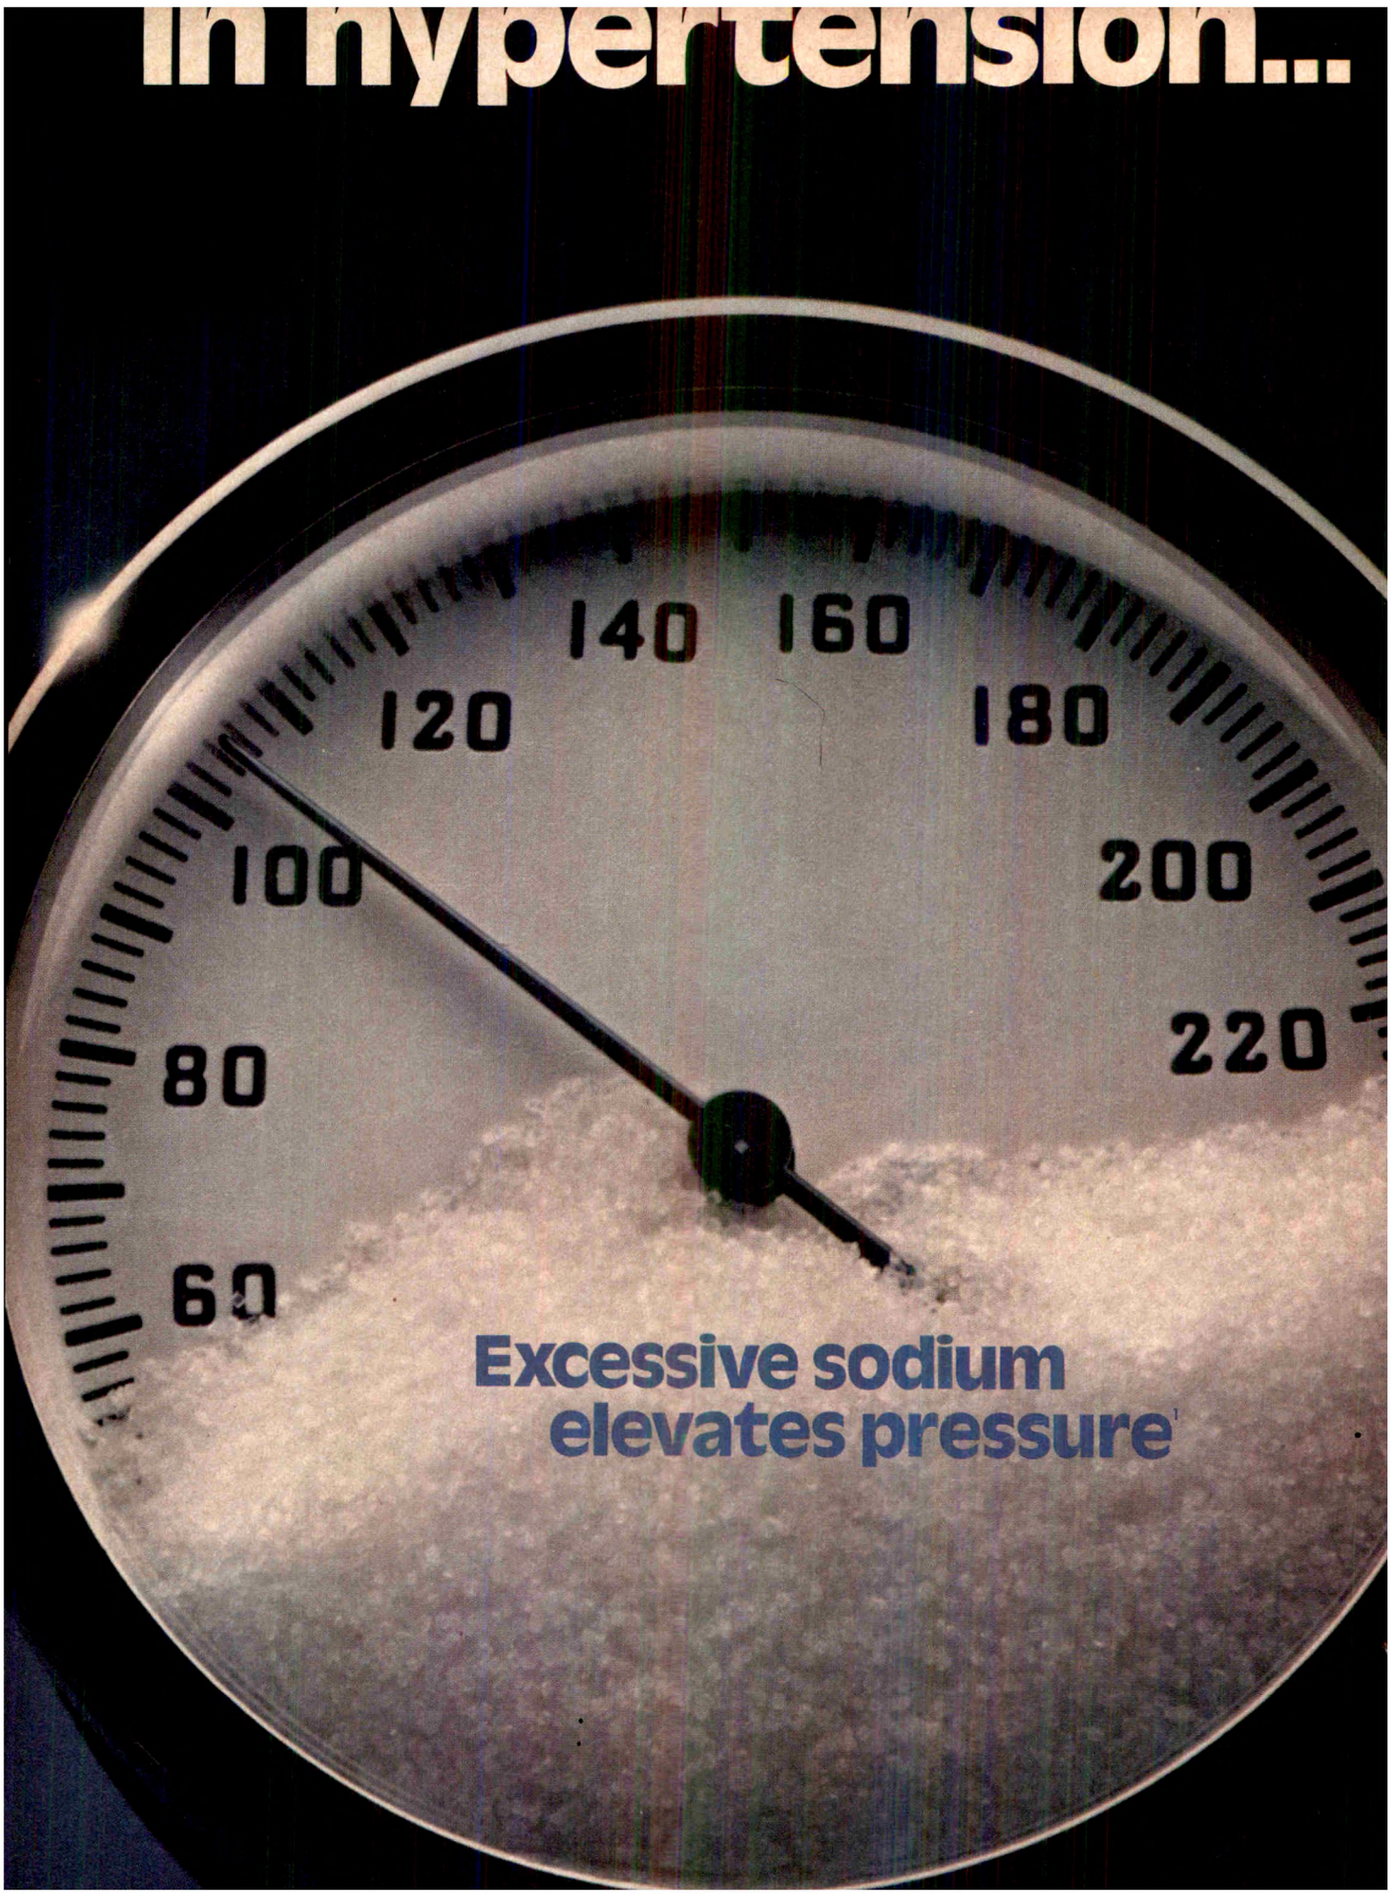
(ISOSORBIDE DINITRATE)

and a new 10 mg.

UP TO 2 HOURS OF ANGINA PROTECTION. AT MEALTIME...AND ANY OTHER TIME OF STRESS.

STUART PHARMACEUTICALS | Div. of ICI Americas Inc
WILMINGTON, DELAWARE 19897

In hypertension...



Hygroton® 50 mg. one a day
(chlorthalidone USP)

Blocks sodium retention longer

As step-1 therapy

Diuretics reduce blood pressure by blocking sodium retention to lower "effective" volume. But, the body's renal compensatory mechanisms are mobilized to promote sodium conservation, expand "effective" volume and reelevate blood pressure. Sustained control of "effective" volume is therefore essential to treatment. Hygroton blocks sodium retention longer than any other diuretic available.

As baseline diuretic in step-2 therapy

Reduced blood pressure resulting from the use of step-2 agents (reserpine, methyldopa, propranolol) may cause compensatory sodium retention, secondary volume expansion and, eventually, reelevation of blood pressure. For this reason, the National Task Force[2] recommends the use of diuretics as baseline agents with step-2 therapy. Hygroton is an "ideal" choice because of its sustained blockade of sodium retention, dosage simplicity and enhanced patient compliance.

Hygroton® 50 mg.
(chlorthalidone USP)

Provides smooth, sustained control

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema.

Contraindications: Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs.

Warnings: Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing.

Precautions: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance.

Adverse Reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.

Usual Dose: One tablet daily.

How Supplied: Tablets—100 mg. (white, scored) and 50 mg. (aqua) in bottles of 100 and 1000; PAKs of 28 tablets, boxes of 6.

USV LABORATORIES

USV Laboratories Inc.
Manati, P.R. 00701

vessel may indicate its functions as a collateral channel and the degree of dilatation may be a measure of the time it has been such a collateral channel. Collateral vessels, like normal vessels, grow by both dilatation and lengthening. However, in the collateral vessel, which is constrained by relatively fixed points of origin and termination, the excess length is accommodated by increasing tortuosity.

216 Angiographic Evaluation of the Natural History of Normal Coronary Arteries and Mild Coronary Atherosclerosis

BAUDOUIN MARCHANDISE, MARTIAL G. BOURASSA, BERNARD R. CHAITMAN and JACQUES LESPERANCE

These angiographic studies in 48 patients with normal coronary arteries or nonsignificant coronary atherosclerosis who underwent a second angiogram because of persistent or recurrent chest pain showed no development of coronary disease in 22 patients with normal coronary arteries after a minimal interval of 13 months and an average interval of 52 months. The combined data suggest that middle-aged adult men and women with normal coronary arteries rarely manifest subsequent coronary arteriosclerosis. In the 26 patients with minimal lesions, 27 percent showed progression of coronary disease on restudy after an average interval of 3 years. Because these studies dealt with a select group of symptomatic patients, these conclusions may not be applicable to unselected asymptomatic men and women.

221 Incidence and Significance of Decreases in Systolic Blood Pressure During Graded Treadmill Exercise Testing

STEPHEN N. MORRIS, JOHN F. PHILLIPS, JOHN W. JORDAN and PAUL L. McHENRY

In this group of 460 patients with definite or suspected coronary heart disease a sustained exercise-induced decrease in peak systolic blood pressure of 10 mm Hg or more was a highly specific sign of multiple vessel coronary artery disease, especially when cardiomyopathy or significant heart valve disease was absent. Acute left ventricular pump failure secondary to extensive myocardial ischemia best explains this phenomenon. Decreases in blood pressure were not observed during 650 maximal exercise tests performed by 560 clinically normal men or by 6 patients after coronary bypass graft surgery.

227 Significance of Chest Pain During Treadmill Exercise: Correlation With Coronary Events

JOHN P. COLE and MYRVIN H. ELLESTAD

This follow-up study of 1,402 patients with a positive maximal treadmill stress test shows that angina during exercise identified 85 percent of true positive tests for coronary artery disease, whereas S-T depression alone identified only 64 percent of such tests. Coronary events (myocardial infarction, progression of angina and coronary death) were twice as frequent in subjects with angina and S-T segment depression as in those without angina. The incidence of coronary events was more than twice as great when the angina was induced by a light work load (4 METS) as when it was induced by a heavy work load (8 to 9 METS). In women, chest pain during the abnormal treadmill test was a less useful prognosticator of future coronary events than in men.

233 Plasma Norepinephrine in Congestive Heart Failure

JAMES A. THOMAS and BERNARD H. MARKS

This study demonstrates that plasma norepinephrine concentration in patients with congestive heart failure due to atherosclerotic heart disease, congestive cardiomyopathy or hypertensive cardiovascular disease is directly related to the degree of left ventricular dysfunction. Progressively increasing plasma concentrations of norepinephrine significantly prolonged the preejection period but reduced the left ventricular ejection time. Plasma lymphocytes from patients with the greatest degree of left ventricular dysfunction failed to generate normal amounts of cyclic 3′,5′-adenosine monophosphate after beta adrenergic receptor stimulation with isoproterenol, suggesting that beta adrenergic receptors are desensitized in these patients and that this desensitization contributes to the observed alterations in myocardial contractility.

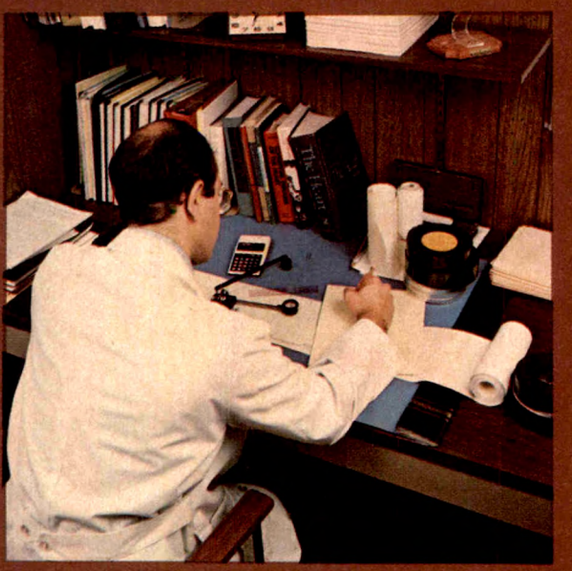
IF HE HAD THE E for M CATH LAB COMPUTER,



HIS REPORTS WOULD BE OUT BY NOW!

Our users tell us about many things they like in their E for M Cath Lab Computer System, such as —

- Ventriculography results are available in-lab.
- Hemodynamic calculations are done with an accuracy and reliability they found hard to get manually.
- Waveforms and calculated results are displayed and permanently stored.
- Extensive editing facilities permit introduction of personal judgment.
- Latest generation software provides some unique capabilities such as shunt calculations based on the tentative diagnosis of congenital anomaly.
- The computer-accessible cardiac data base greatly simplifies cross-population and other statistical studies.

But the part our users like most is getting all their reports written by the computer, to their specifications, immediately after the procedure is finished.

If you are thinking about a computer for your cath lab, it will pay you to talk with us. Call your local E for M representative, or our computer group in Sudbury, Massachusetts, 617-443-9969.

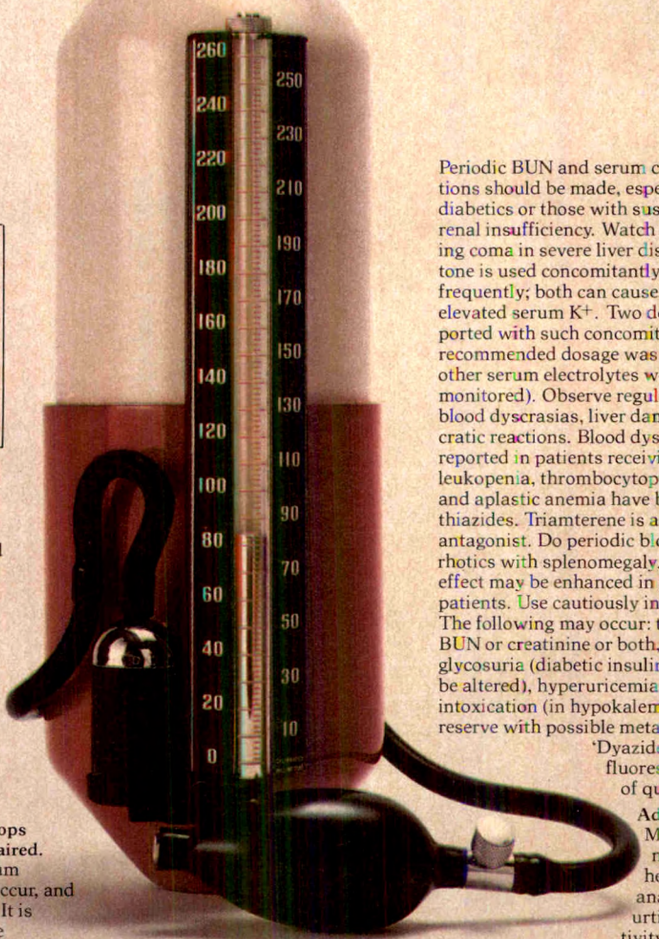
ELECTRONICS FOR MEDICINE, INC.
PLEASANTVILLE, NEW YORK 10570 • 914-769-6700

TRIAMTERENE CONSERVES POTASSIUM WHILE HYDROCHLOROTHIAZIDE LOWERS BLOOD PRESSURE

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (triamterene, SK&F Co.) and 25 mg. of hydrochlorothiazide.

MAKES SENSE



Before prescribing, see complete prescribing information in SK&F Co. literature or PDR. A brief summary follows:

* **Warning**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

***Indications:** When the combination represents the dosage determined by titration: Adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, the nephrotic syndrome. Corticosteroid and estrogen-induced edema, idiopathic edema; hypertension, when the potassium sparing action of triamterene is warranted. (See Box Warning.) Routine use of diuretics in healthy pregnant women is inappropriate; they are indicated in pregnancy only when edema is due to pathological causes.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone.

Supplied: Bottles of 100 and 1000 capsules; Single Unit Packages of 100 (intended for institutional use only).

FOR LONG-TERM CONTROL OF HYPERTENSION.* SERUM K^+ AND BUN SHOULD BE CHECKED PERIODICALLY. (SEE WARNINGS SECTION.)

EXPERIMENTAL STUDIES

244 **Electrophysiologic Studies on Atrioventricular Nodal Wenckebach Cycles**

MICHAEL B. SIMSON, JOSEPH F. SPEAR and E. NEIL MOORE

With the aid of programmed stimulation, Wenckebach cycles with a 4:3 ratio were produced by rapid atrial pacing and studied in 27 anesthetized denervated dogs. All animals showed a progressive increase in atrioventricular (A-V) nodal refractoriness in the effective refractory period for each beat and a rightward shift of the A′-H′ relative to the A-A′ refractory curves. In Wenckebach cycles there is a progressive increase in refractoriness, caused by cumulative effect similar to that seen after a blocked beat during stressed 1:1 conduction, until block occurs and the cycle resets. No evidence for overt or concealed reentry was found during anterograde Wenckebach cycles. It appears most likely that Wenckebach cycles and reentry are associated conditions, not necessarily causally related.

259 **Myocardial Hemorrhage After Coronary Reperfusion in Pigs**

ROBERT J. CAPONE and ALBERT S. MOST

Occlusion of the left anterior descending coronary artery for 1 hour in anesthetized closed chest pigs using an intracoronary balloon occluding technique resulted in the occurrence of postreperfusion myocardial hemorrhage in an animal with a coronary circulation similar to man's. The hemorrhage was directly related to the duration of occlusion and was unaffected by mannitol given before reperfusion or general anesthesia. In the pig the critical period with respect to intramyocardial hemorrhage lies between occlusion times of 15 and 60 minutes. No improvement was observed in function of the most depressed left ventricular segment or adjacent segments during reperfusion. These results suggest that additional measures may be necessary to reduce temporary occlusion time or otherwise improve vascular integrity during revascularization surgery in man.

METHODS

267 **Noninvasive Assessment of Coronary Stenoses by Myocardial Perfusion Imaging During Pharmacologic Coronary Vasodilatation. I. Physiologic Basis and Experimental Validation**

K. LANCE GOULD

These results from 145 external myocardial perfusion images of thallium-201 and technetium-99M–labeled particles obtained at rest, during exercise or after coronary vasodilators in 20 dogs with mild to severe coronary stenoses demonstrated the following: (1) The ratio of maximal flow in a normal to stenotic coronary artery must be at least 2:1 before defects appear in the myocardial perfusion image of thallium-201. (2) A diagnostic technique that utilizes a maximal stimulus for increasing coronary flow and an imaging agent that is distributed to the myocardium in linear proportion to coronary flow at flow rates up to four or five times resting levels will be the most sensitive method for detecting mild coronary stenosis. Furthermore, the effect of intravenously administered dipyridamole on the coronary circulation can be closely regulated by adjusting the dose rate of infusion and can be instantaneously reversed with intravenous administration of aminophylline, a dipyridamole antagonist.

279 **Noninvasive Assessment of Coronary Stenoses by Myocardial Imaging During Pharmacologic Coronary Vasodilatation. II. Clinical Methodology and Feasibility**

K. LANCE GOULD, R. JEFFREY WESTCOTT, PETER C. ALBRO and GLEN W. HAMILTON

A noninvasive method utilizing myocardial imaging of thallium-201 injected intravenously at rest and during coronary vasodilatation induced with intravenously administered dipyridamole, a patent selective coronary vasodilator, is shown to be feasible as a routine diagnostic procedure in 62 patients. However, it is necessary to pay close attention to dose rates of infusion, timing of thallium injection, body position and proper monitoring of the patient's blood pressure, electrocardiogram and clinical symptoms. Patients with angina pectoris at rest should not be studied with dipyridamole because diagnostic image defects would be expected without introduction of a stress. These initial results warrant a larger clinical study to define the diagnostic sensitivity and specificity of the technique.

PEDIATRIC CARDIOLOGY

288 **New Serial Contrast Technique for Assessment of Left to Right Shunting Patent Ductus Arteriosus in the Neonate**

HUGH K. ALLEN, DAVID J. SAHN and STANLEY J. GOLDBERG

A new serial echocardiographic contrast technique for detection of patent ductus arteriosus demonstrated a left to right shunt in 30 of 33 prospectively studied premature infants. This serial study also helped elucidate the natural history of patent ductus arteriosus. Twenty-four of the 30 patients with a positive study initially had a left to right shunting patent ductus arteriosus without an audible murmur. Three of these patients later had congestive heart failure, and two required operative ligation of the patent ductus. The high rate of detection of silent patent ductus arteriosus and its bedside confirmation when suspected are important in the serial management of critically ill newborns with this condition. The only potential hazards are related to the safety of umbilical arterial catheters.

295 **Abnormal Right Ventricular Size and Ventricular Septal Motion After Atrial Septal Defect Closure. Etiology and Functional Significance**

ALAN S. PEARLMAN, JEFFREY S. BORER, CHESTER E. CLARK, WALTER L. HENRY, DAVID R. REDWOOD, ANDREW G. MORROW and STEPHEN E. EPSTEIN. *With the technical assistance of Cora Burn, RN, Estelle Cohen and F. Joyce McKay, RN*

To determine the significance of postoperative echocardiograms that demonstrate persistent right ventricular dilatation and paradoxic ventricular septal motion after repair of an atrial septal defect, 31 patients were studied before and after repair of an atrial septal defect. These echocardiographic abnormalities correlated with age at operation and length of postoperative follow-up study but not with the degree of preoperative right ventricular enlargement, shunt size or right ventricular pressure before or after operation. These abnormalities do not indicate incomplete closure of the atrial septal defect. Abnormalities of ventricular septal motion may be partly related to the posterior displacement of the septum within the heart at end-diastole (as a consequence of right ventricular dilatation) but not to the nature of the hemodynamic burden causing such dilatation.

REPORTS ON THERAPY

302 **Nitroglycerin-Induced Improvement in Exercise Tolerance and Hemodynamics in Patients With Chronic Rheumatic Heart Valve Disease**

JEFFREY S. BORER, DAVID R. REDWOOD, SAMUEL B. ITSCOITZ, ROBERT E. GOLDSTEIN and STEPHEN E. EPSTEIN

The short-term administration of nitroglycerin increased exercise capacity and the hemodynamic response to mild and intense upright exercise in 11 severely symptomatic patients with various ranges of rheumatic heart valve disease who had already received optimal conventional therapy. Nitroglycerin decreased systemic and pulmonary arterial pressures, increased heart rate and cardiac output, produced a small but significant increase in maximal oxygen consumption and improved exercise capacity. The mechanisms responsible for this nitroglycerin-mediated improvement in hemodynamics and cardiac function during exercise are probably related primarily to the peripheral venous and arteriolar dilatation produced by the drug. Additional studies appear indicated to determine the efficacy of long-term administration of nitrates in patients with rheumatic heart disease.

308 **Atrial Pacing for Cardioversion of Atrial Flutter in Digitalized Patients**

GOPAL DAS, KAMANAHALLY M. ANAND, KAUR ANKINEEDU, TRIAM CHINNAVASO, FREDERICK N. TALMERS and ARNOLD M. WEISSLER

Atrial pacing successfully converted atrial flutter on 43 occasions (98 percent) in 31 of 32 consecutive digitalized patients with this arrhythmia. One patient required transthoracic direct current synchronized countershock car-

8 things to look for in a new cardiograph:

Versatility

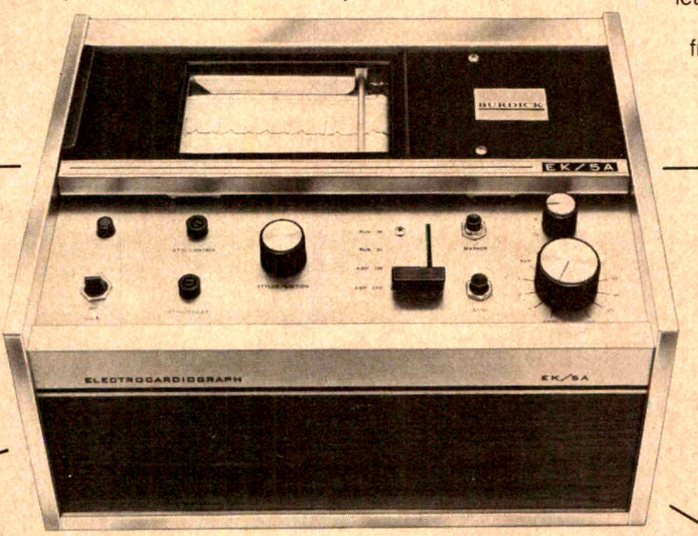
The EK-5A is ideal for routine ECGs, exercise tolerance testing procedures, ECG data-phone transmissions, surgery and emergency departments, and ICUs. It's also compatible with other instrumentation in multiple-use situations. That means cost-effectiveness for you.

Solid return on investment

The Burdick EK-5A electrocardiograph is an income-producing center that quickly pays for itself. With special tax savings and depreciation advantages available, as few as 27 ECGs can cover your actual net cost of the EK-5A.

"State-of-the-art" electronics

The Burdick EK-5A produces high-fidelity, consistently accurate ECGs. Patient is protected with isolated circuitry. Automatic lead coding and fast lead switching save time and reduce paper usage. Exceeds minimum frequency-response recommendations of the AHA.



Proven-in-service dependability

Backed by years of electrocardiograph manufacturing experience. Ready for rigorous use day after day. Every Burdick EK-5A is live-patient tested before passing final inspection; added assurance for you.

ECG technician training seminars

Burdick has conducted more than 750 technician training seminars for over 35,000 nurses and technicians nationwide, demonstrating proper technic that contributes to accurate, consistently high-quality ECGs; builds confidence in taking electrocardiograms. Your staff, too, is welcome. Ask us for details.

Local dealer service

Service is readily available through Burdick-trained and authorized local dealers. Proper installation, careful analysis of environmental interference problems, and provision of loaner equipment are all part of Burdick's *service after the sale.*

Ease of operation

Well arranged panel and easy top loading paper save time and reduce labor costs. Fewer retakes; more top quality ECGs. Your staff will appreciate its attractive appearance, compactness, and light weight.

A warranty you can trust

Enjoy the security gained from purchasing the best in ECG instrumentation. Know that it's backed by Burdick, with more than 64 years of ethical, warranted service to the medical profession.

If your electrocardiograph can't offer you all these advantages and benefits, it makes good sense, diagnostically and financially, to buy one that does—the Burdick EK-5A. Ask your participating Burdick dealer about special tax advantages and trade-in allowances available to you. Convert your old cardiograph into a partial payment on a Burdick EK-5A, and start taking advantage of its many benefits. And now, Burdick's new BlueTrace/200 ECG paper will give you distinct blue tracings that contrast clearly with a red grid on bright white paper.

For a demonstration, or more information, call toll-free, (800) 356-0701. Within Wisconsin, (608) 868-7631. Or write to **The Burdick Corporation, Milton, Wisconsin 53563.**

BURDICK®

dioversion. With atrial pacing the atrial flutter reverted immediately to sinus mechanism in 20 instances. There were 23 episodes of atrial fibrillation; 11 of the latter reverted to sinus rhythm within 24 hours. Immediately after the rhythm conversion three patients had periods of severe sinus bradycardia (heart rate 30 to 40 beats/min) and required cardiac pacing. One patient with persistent sinus bradycardia and a prolonged sinus recovery time required a permanent transvenous pacemaker.

313 **Multiple Bolus Technique for Lidocaine Administration During the First Hours of an Acute Myocardial Infarction**

MILFORD G. WYMAN, DAVID LALKA, LUCILLE HAMMERSMITH, DAVID S. CANNOM and BRUCE N. GOLDREYER

Multiple bolus injections of lidocaine every 5 minutes, if ventricular extrasystoles are not controlled, to a total of 225 mg over 16 minutes provide adequate blood levels, result in no significant toxicity and may be safely used with excellent results in patients with infarction, even in the presence of moderate congestive heart failure. The mean plasma level at the end of the last infusion was only 2.3 μg/ml. In this study the half-life of lidocaine after the first bolus dose was approximately 8 minutes in patients with class 0–1 failure, but only 4 minutes in those with class II–III failure. The clinical effect of a single bolus dose may last no longer than a few minutes. For patients with shock or pulmonary edema one half of the dose is recommended.

318 **Effects of Digitalis on Sinus Nodal Function in Patients With Sick Sinus Syndrome**

ZAKAUDDIN VERA, RICHARD R. MILLER, DON McMILLIN and DEAN T. MASON

This study dispels the fears of clinicians that digitalis may be harmful in patients with sick sinus syndrome. Assessment of the effects of digitalization in 14 patients with sick sinus syndrome, using ambulatory Holter monitoring of the electrocardiogram, treadmill exercise testing and sinus nodal recovery time determinations, clearly showed that digoxin does not exert adverse effects on sinus nodal function and can be safely used in such patients when indicated for cardiac pump dysfunction or for control of tachyarrhythmia. Digitalis produces the favorable effects of decreasing sinus nodal recovery time and eliciting ectopic escape pacemakers. The sinus nodal response to exercise was unaffected after digitalization.

324 **Effects of Morphine Sulfate on Human Coronary Blood Flow**

DAVID M. LEAMAN, STEPHEN H. NELLIS, ROBERT ZELIS and JOHN M. FIELD

The intravenous injection of morphine in 10 patients produced slight coronary vasodilation, in marked contrast to the significant coronary vasoconstriction reported in the unanesthetized dog. Four patients with normal coronary arteries showed a mild increase in coronary blood flow after morphine, whereas six with coronary artery disease showed no change. In general coronary blood flow increased from a baseline value of 104.4 ± 13.4 to 113.0 ± 17.4 ml/min (difference not significant) 15 minutes after the administration of morphine. Because morphine did not significantly alter myocardial oxygen requirements or coronary blood flow, it remains a safe drug to use in patients with heart disease, as countless years of clinical experience have proved.

REVIEW

327 **The Myocardial Supply:Demand Ratio—A Critical Review**

JULIEN I. E. HOFFMAN and GERALD D. BUCKBERG

Animal experiments indicate that relative subendocardial ischemia (a reduced inner-outer flow ratio) can be accurately predicted from the ratio of two pressure-time areas: DPTI, the area between diastolic aortic and left ventricular pressures, and SPTI, the area beneath the systolic left ventricular pressure curve. However, caution is needed in applying these results to man. The critical DPTI:SPTI ratio below which subendocardial ischemia

For the special needs of patient with hard, dry stools

Hard, dry stools hurt, and may be hazardous by causing straining. SENOKOT S Tablets offer comfortable relief by softening the stool *and* stimulating its movement.

Provides standardized senna concentrate, a clinically established laxative of choice
Standardized senna concentrate is a gentle, effective neuroperistaltic stimulant with documented effectiveness in thousands of patients. Its virtually colon-specific, gentle, predictable action is generally free of side effects at proper dosage levels.

Provides DSS, the classic stool softener
DSS in SENOKOT S Tablets complements the laxative effect of standardized senna concentrate by "moistening" and softening the stool for smoother and easier passage.

Comfortable overnight action
With DSS and standardized senna concentrate, SENOKOT S Tablets provide *both* softness and stimulation for constipated patients with hard, dry stools. Taken at bedtime SENOKOT S Tablets usually induce predictable, comfortable evacuation the next morning.

occurs is about 0.4 to 0.5. This critical ratio is not independent of absolute coronary diastolic pressure and is much lower than 0.4 when coronary pressures are high. As more precise physiologic studies of the ratio are made in patients with coronary arterial obstruction, it should be possible to be more accurate in deciding what is occurring to subendocardial blood flow and oxygen supply.

DIAGNOSTIC SHELF

333 **Group Teaching of Auscultation. Use of a New Wireless Stethoscope-Type Headphone**

ANTONIO C. deLEON, Jr., W. PROCTOR HARVEY, DAVID CANFIELD and EDWARD JOHNSON

The use of an infrared beam as a mode of transmission for sound and physiologic events opens up the potential for transmission also of the electrocardiographic signal and of palpatory events. This technique using a new wireless stethoscope-type headphone enables the simultaneous transmission of heart sounds and murmurs to large groups of persons without the need for hard-wire connections to the amplifying device. The method facilitates teaching of cardiac auscultation at the bedside and in the conference room.

CASE REPORTS

336 **Successful Treatment of Drug-Resistant Atrial Tachycardia and Intractable Congestive Heart Failure With Permanent Coupled Atrial Pacing**

EMANUEL R. ARBEL, HOWARD C. COHEN, RICHARD LANGENDORF and GERALD GLICK

A specially designed implantable pacemaker for coupled atrial stimulation was successfully used to treat an adolescent patient with severe congestive heart failure associated with repetitive drug-resistant supraventricular tachycardia. During a 4 year follow-up period this treatment eliminated the tachycardia; the heart size returned to normal and the patient went on to complete clinical recovery. The necessary electrophysiologic conditions for ventricular slowing by coupled atrial pacing include an atrial effective refractory period shorter than that of the atrioventricular junction and depolarization of the ectopic atrial pacemaker by the responses to coupled atrial stimulation. This technique appears to be effective as a method of treatment in selected cases of drug-resistant chronic ectopic atrial tachycardia.

341 **Use of a Double Atrial-Triggered Standby Pacemaker System for a Patient With a Biventricular Bypass Heterotopic Cardiac Homograft**

BRIAN M. KENNELLY, LAURENCE W. PILLER, PETER P. TARJAN, JACQUES G. LOSMAN, CHRISTIAAN N. BARNARD and WALTER BECK

A double atrial-triggered standby pacemaker system was implanted to allow sequential atrial pacing of both hearts in a patient with a biventricular bypass heterotopic cardiac homograft. The design permitted either the recipient or the donor heart to dictate the rate of its fellow, depending on which heart had the faster spontaneous sinus rate. The potential benefit of sequential contraction of the donor and recipient hearts is that systole of the recipient left ventricle was isovolumic when it occurred synchronously with systole of the healthier donor left ventricle. Alternative systems for achieving sequential contractions of the two hearts were also considered, but these would not permit either heart to dictate the rate of the other.

Better patient compliance because there are fewer doses to take

Quinaglute maintains normal sinus rhythm with a convenient 8 or 12 hour dosage schedule.

The convenient dosage schedule of 1 to 2 tablets every 8 or 12 hours can mean improved compliance in patients who tend to forget or skip medication requiring more frequent administration. In addition, QUINAGLUTE® Dura-Tabs® provide the following advantages:

- Special wax matrix permits gradual release of quinidine gluconate to maintain quinidine plasma levels for 8 to 12 hours
- Convenient 8 or 12 hour dosage schedule helps avoid middle-of-the-night dosage and early morning reversion
- Prolonged control without peaks and valleys in plasma levels
- Well-tolerated, with few gastrointestinal disturbances to interfere with patient cooperation and compliance

Cooper Compliance Tip

Since most pharmacies have established patient drug profiles as a service to the community, you might advise your cardiac patients to use one pharmacy for all their prescription needs. This will help assure that the total therapeutic regimen is being carried out. Should any questions, untoward reactions or other problems develop, each person in the "physician-pharmacist-patient" alliance will be aware of it. Please forward your compliance tip to Cooper Laboratories, 300 Fairfield Road, Wayne, New Jersey 07470, Att: Mr. W.F. Cronin.

Patients with cardiac arrhythmias remember

Quinaglute® Dura-Tabs®
(quinidine gluconate) 324 mg

Indications:
Premature atrial and ventricular contractions. Paroxysmal atrial tachycardia. Paroxysmal A-V junctional rhythm. Atrial flutter. Paroxysmal atrial fibrillation. Established atrial fibrillation when therapy is appropriate. Paroxysmal ventricular tachycardia when not associated with complete heart block. Maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.
NOTE: Depending upon the response desired, the dosage may need to be varied and the blood level and/or electrocardiographic response closely monitored during initial treatment.

Contraindications: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis. Idiosyncrasy or hypersensitivity to quinidine.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.

Quinidine in large doses may reduce the contractile force of the heart; therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication.

It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

Adverse Reactions: Cinchonism, tinnitus, decreased auditory acuity, vertigo, headache, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis, hypotension, respiratory distress, and gastrointestinal disturbances.

101-48R

Cooper Laboratories, Inc., Wayne, N.J. 07470

EXERCISE TESTING BASICS:

Stress testing is rapidly becoming a standard diagnostic tool. But setting up your own stress testing unit can be costly. The equipment shown here will give you a basic system, flexible enough to build on for years to come.

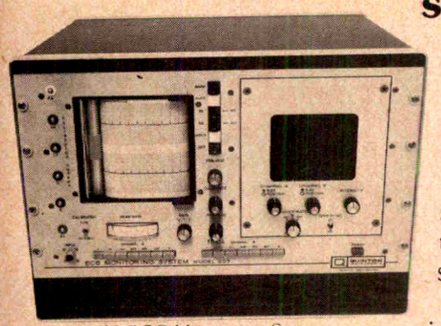
Select a treadmill that will last. The treadmill is the basic workhorse of the system. It has to be durable. For 16 years, Quinton treadmills have been the standard in research centers, heart clinics and everyday practice.

We build seven models. All feature endless nylon belts for extra long service life, aircraft type honeycombed aluminum decks, lifetime lubricated bearings and heavy duty AC motors with "no jerk" speed control.

Quinton treadmills offer variable speed and elevation with metered readouts for both.

Treadmill Model 18-54

Select a practical multi-channel ECG monitor. Quinton offers a variety of ECG monitors. Our Model 623 two-channel unit has the versatility of multiple channel monitoring without the expense of three channel systems.



Model 623 ECG Monitoring System

The Quinton Model 623 gives you pushbutton lead selection and lets you display and record any two leads simultaneously. With the QRS Sync feature, each consecutive QRS complex can be expanded to the full width of the screen, making even small changes obvious immediately.

No battery packs are required with the 623 and the internal calibration system not only checks the recorder before you conduct a test, it also checks the oscilloscope, patient cables and heart rate meter to assure you of total system accuracy.

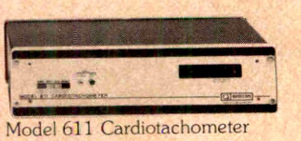
Build the system as your practice grows. Quinton offers a number of special purpose units which will expand the system's capabilities as your needs grow.

A Quinton programmer allows you to concentrate on the monitor and the patient while the test progresses automatically.

Treadmill Programmer

The Quinton ECG Data Computer digitally displays the heartrate, S-T level and S-T slope. It averages the signal to help you "see through" noisy ECG, and it records heartrate, S-T changes, arrhythmias and 20 beat ECG averages.

Model 740 ECG Data Computer

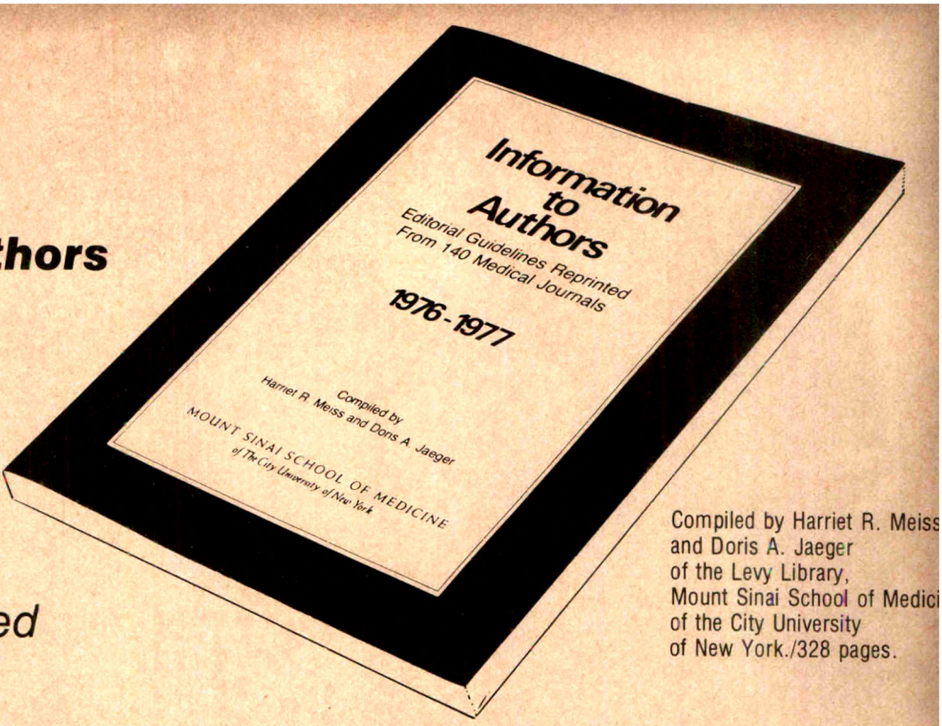


Model 611 Cardiotachometer

The Quinton cardiotachometer computes and digitally displays heartrate on an instantaneous, beat-by-beat basis. For details on all these products, contact Quinton Instrument Co., Dept. E16, 2121 Terry Avenue, Seattle, Washington 98121. Call 206/223-7373 or dial toll free 800-426-0538. **QUINTON**

Medical Authors

How to be professional about being published



Compiled by Harriet R. Meiss and Doris A. Jaeger of the Levy Library, Mount Sinai School of Medici of the City University of New York./328 pages.

If you or members of your staff write, submit or review papers for medical journals you will wonder how you ever did without this handy guide. Here, in one place, is all the information you need to select the publications most likely to publish your paper as well as their requirements for accepting manuscripts.

Information to Authors will save hours of valuable look-up and research time, plus help you avoid costly errors in manuscript preparation. In this one volume you will find everything you need to know about writing for publication including:

- subject index to quickly identify publications in your field of interest
- editors with specialty so manuscripts can be personally directed
- members of editorial board with credentials
- scope and editorial policy of publication
- sponsoring societies
- sources for standard nomenclature
- basic style guides
- number of copies of manuscript
- rules for preparation of illustrations, tables, graphs
- acceptable format
- guide to footnote and reference usage
- address for manuscripts

If you are now writing—or planning to write—send for your copy of *Information to Authors* right away. It will make writing for publication a much easier process.

Use the convenient order form below. Enclose your check, please, as no order will be processed unless accompanied by payment.

140 medical journals representing these specialties:

Allergy	Obstetrics and Gynecology
Anesthesiology	Ophthalmology
Arthritis	Orthopedics
Biology	Otorhinolaryngology
Bone	Pathology
Cancer	Pediatrics
Cardiovascular System	Pharmacology and Therapeutics
Clinical Medicine	Physical Medicine
Communicable Diseases	Plastic Surgery
Critical Care	Preventive Medicine
Dermatology	Psychiatry
Gastroenterology	Public Health
General Medicine	Radiology and Nucle Medicine
Geriatrics	Reproduction
Hematology	Respiratory System
Immunology	Rheumatism
Infectious Diseases	Rhinology
Internal Medicine	Roentgenology
Metabolism	Surgery
Neoplasms	Trauma
Neurology and Neurosurgery	Thoracic Diseases
Nutrition	Urology
	Venereal Diseases

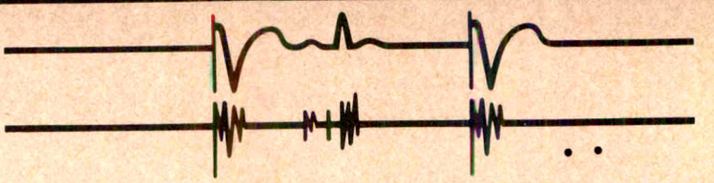
FUTURA ANNOUNCES A NEW QUARTERLY JOURNAL

PACE



Pacing
And
Clinical
Electrophysiology

PACE will welcome communications in laboratory and clinical cardiac pacing, electrophysiology, and the electrostimulation of other organs which affect the cardiovascular system. It will have adequate breadth to accommodate original, review, and didactic articles directed to a readership of a variety of interests.

First Issue January 1978

YEARLY SUBSCRIPTION
(4 ISSUES) $27.50

Editor-in-Chief: Seymour Furman
Senior Editors: Serge Barold, Werner Irnich, Victor Parsonnet, Hilbert J. Th. Thalen
Associate Editor: John D. Fisher
Assistant Editor: Grace A. Giammello
Editorial Board: Salomao S. Amram, Michael Bilitch, Jurgis Bredikis, Agustin Castellanos, William M. Chardack, Philippe Coumel, Jozef K. Cywinski, J. Geoffrey Davies, Bernard Dodinot, Leonard S. Dreifus, Olof Edhag, Doris J.W. Escher, Guy Fontaine, William W.L. Glenn, Bernard S. Goldman, J. Warren Harthorne, Motokazu Hori, Decio Kormann, Dennis Krikler, John W. Lister, Claude Meere, Jacques Mugica, George Myers, Onkar S. Narula, Henry N. Neufeld, Bryan Parker, Thomas A. Preston, David C. Schechter, Graeme Sloman, Nicholas P.D. Smyth, Marius Stopczyk, Albert L. Waldo, Yoshio Watanabe, Hein Wellens, Alexander Wirtzfeld, Douglas P. Zipes, Paul M. Zoll

SAMPLE COPIES AVAILABLE AT BOOTH #433

FUTURA PUBLISHING COMPANY, INC., 295 Main Street, P.O. Box 298, Mount Kisco, N.Y. 10549

The Tunturi ergometer is built to measure precise amounts of work with a variable watt load range of 25 to 300w at 50 rpm. The Tunturi is quiet, affordable and portable, providing exercise your patients can live with.

Call Amerec collect at 206-454-2161 for complete information, including professional discounts.

Imported and Distributed Nationally by:
Amerec Corp., Fitness Equip. Div., P.O. Box 3825, Bellevue, WA 98009.

Distribution Centers in Seattle, Los Angeles, Chicago, Houston and Baltimore.

Tunturi Ergometer:

At home rehabilitation you can prescribe from your office.

KayCiel® (potassium chloride) VS. Diet

ORANGE FLAVORED

KayCiel® Elixir		KayCiel® Powder	
Each 15 ml (20 mEq of potassium chloride) contains:		Each *Solodose*® packet (20 mEq of potassium chloride) contains:	
Calories	17	Calories	0
Sodium	0 mg	Sodium	0 mg

CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps and hyperkalemia.
WARNING: Do not use excessively.
PRECAUTIONS: Administer with caution and adjust to the requirements of the individual patient. The patient should be checked frequently and periodic ECG and/or plasma potassium levels made. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
Patients should be cautioned to adhere to dilution instructions.
ADVERSE REACTIONS: Potassium intoxication indicated by listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac depression, arrhythmias, arrest and heart block. Vomiting, nausea, abdominal discomfort and diarrhea may occur.
OVERDOSAGE: In case of excessive use resulting in hyperkalemia or potassium intoxication, discontinue potassium chloride administration or take other steps to lower serum levels if indicated.

Cooper Compliance Tip

Help assure that your older patients take medications properly by printing your instructions in large letters. You might also send a copy of the instructions to the patient's spouse. Please forward your compliance tip to Cooper Laboratories, 300 Fairfield Road, Wayne, N.J. 07470, Att: W.F. Cronin.

Cooper Laboratories, Wayne, New Jersey 07470 143-48

PRONESTYL® TABLETS (Procainamide Hydrochloride Tablets)
PRONESTYL® CAPSULES (Procainamide Hydrochloride Capsules U.S.P.)

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate considerations of alternative anti-arrhythmic therapy.

DESCRIPTION: Pronestyl (Procainamide Hydrochloride) is the amide analogue of procaine hydrochloride and is available for oral administration as capsules and veneer-coated tablets providing 250 mg., 375 mg., and 500 mg. procainamide hydrochloride.
CONTRAINDICATIONS: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; bear in mind cross sensitivity to procaine and related drugs. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of second degree and third degree A-V block unless an electrical pacemaker is operative.
ADMINISTRATION: Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.
PRECAUTIONS: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous if myocardial damage exists.

The dislodgment of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with severe organic heart disease and ventricular tachycardia that complete heart block, which may be difficult to diagnose, may be present. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related to continued procainamide therapy (see boxed Warning). Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.
ADVERSE REACTIONS: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see Precautions). Reactions consisting of fever and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever or any symptoms of upper respiratory tract infection. If any of these symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions and for full prescribing information.
HOW SUPPLIED: Pronestyl Tablets (Procainamide Hydrochloride Tablets) and Pronestyl Capsules (Procainamide Hydrochloride Capsules U.S.P.) providing 250 mg., 375 mg., and 500 mg. are available in bottles of 100 and Unimatic® single-dose packaging in cartons of 100. The 250 mg. and 500 mg. tablets and capsules are also available in bottles of 1000.

©1978 E. R. Squibb & Sons, Inc. 448-502

tried and true

in the treatment of life-threatening arrhythmias

Documented effectiveness in ventricular arrhythmias; indicated for certain atrial arrhythmias as well.

Backed by 26 years of clinical experience; over 15,000,000 prescriptions written!

Extensively used and studied in post-MI patients.

Compatibility with other cardiovascular drugs researched.

Three oral strengths (250mg, 375mg, 500mg) for dosing flexibility; available in easy-to-swallow veneer coated tablets.

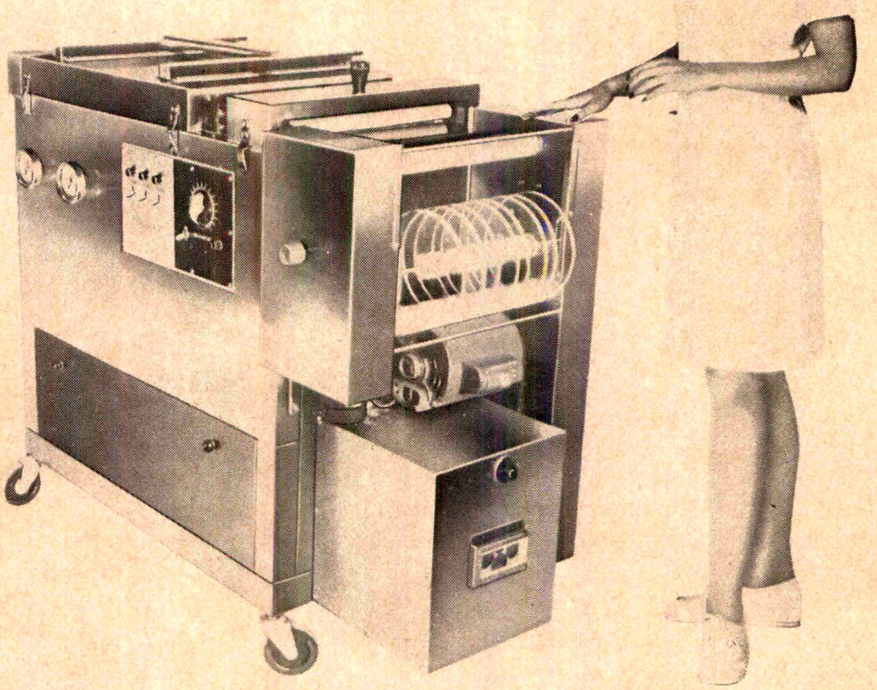
See preceding page for brief summary.

Pronestyl® Tablets
Procainamide Hydrochloride Tablets

Trustworthy antiarrhythmic therapy

Process up to 4 diagnostic films at any interval

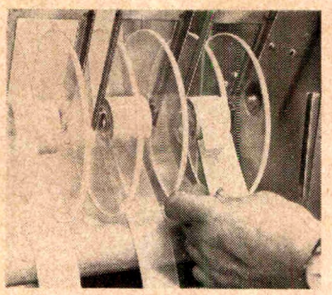
with Processall's new Polytrack® Modification



With the addition of the moderately-priced Polytrack Modification any Processall gains the added flexibility of being able to process 4 films at any interval. Previous to this a Processall was capable of processing up to 4 film cassettes at one time. But there was a limitation. All 4 had to be started simultaneously. And by an experienced operator.

The advantages of the Polytrack Modification are obvious. The operator doesn't have to wait for the first case to be finished before inserting the second, third or fourth film, or stop the machine. During the filming of the diagnostic procedure, exposed reels can be fed right from the camera into the Processall without delay.

As for the machine itself, the fact that Processalls are in daily use at many medical research centers and hospitals wherever diagnostic cardiology is being done says more about the unit than we ever could.



Operator removes finished reel from machine while other tracks continue to be processed.

And now, with the new Polytrack Modification, the Processall is a more efficient, more effective, more important diagnostic tool then ever before ... at a surprisingly modest price.

Without the Polytrack Modification the Processall is considered by many to be the best processing machine available for cine fluorography. With the addition of Polytrack the best becomes that much better.

Other advantages of the Processall System. • Finer Grain Yield • Better Resolution • Rapid Development • Fixation and Drying • Variable Speed and Temperature Control • Automated Processing • Consistent Quality • 316L Stainless Steel Construction.

For more information contact us or your nearest Oscar Fisher dealer.

OSCAR FISHER CO., INC.

P.O. BOX 2305 / NEWBURGH, N.Y. 12550 TELEPHONE (914) 562-3900

All equipment manufactured by Oscar Fisher Company, Inc., is on GSA Contract.

The Dutch connection.

It only stands to reason that the same people who gave the world Willem Einthoven, inventor of the electrocardiograph, would know more than their share about pacemakers.

And the new Vitalith™ lithium-powered pulse generator from Vitatron is a brilliant example. Not only is it long-lived*, its biocompatibility is exceptional.

The connection, for instance. It's simple, smooth and highly reliable. And accepts any lead without adaptors.

Vitalith's smoothly rounded, rectangular shape reduces the chance of rotation and pocket complications. Plus it weighs just 77 grams with a density of only 1.9 gm/cc.

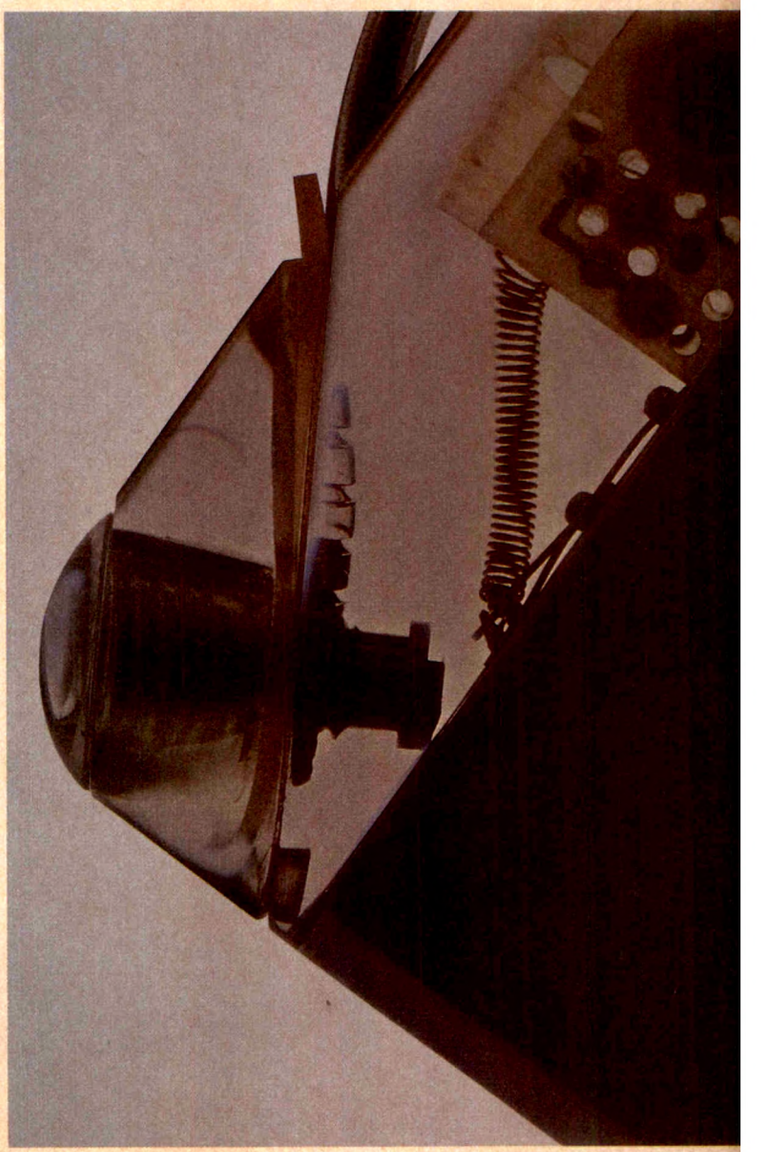
A pure titanium case/lid weld eliminates possible corrosion. With a helium environment to protect internal electronics and to help detect leaks during production.

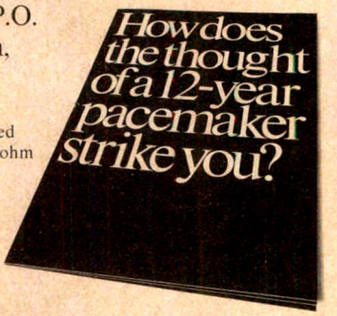
Even the feedthrough has a special redundant insulation to lower the chances of corrosion or current leakage.

Combine all that with Vitalith's long-life* Catalyst Research type 802/23 battery and innovative electronics, and you've got a true evolution in pulse generator design. Vitalith.

To arrange for a Vitatron representative to call on you, call (617) 964-1980. Or write for our 16-page, full-color brochure. Vitatron Medical, Inc., One Gateway Center, Newton, MA 02158. Vitatron Medical b.v., P.O. Box 76, NL6210 Dieren, The Netherlands.

*Over 10 years' service life expected under worst case conditions, 500 ohm load with 1.0 millisecond pulse duration; over 15 years with 0.5 ms duration.

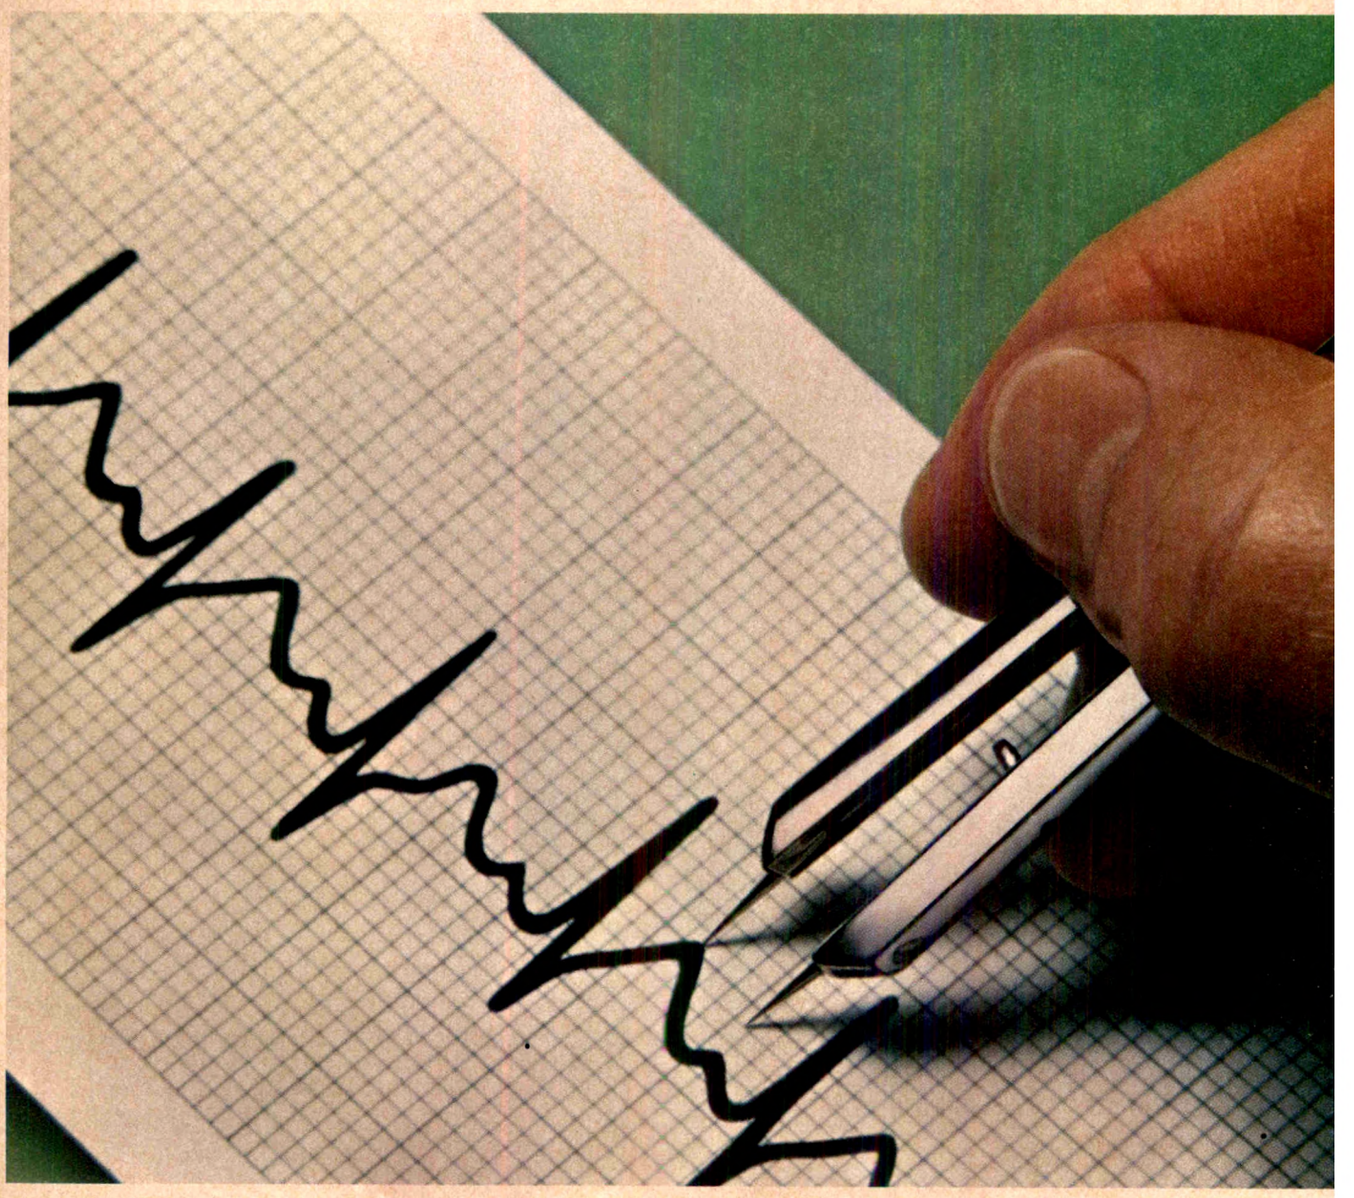




VITATRON MEDICAL

INDERAL®
(propranolol hydrochloride)
PERFORMANCE IN CARDIAC ARRHYTHMIAS

EFFECTIVE ALONE OR IN COMBINATION



INDERAL (propranolol hydrochloride): Successful treatment of supraventricular arrhythmias for over 10 years

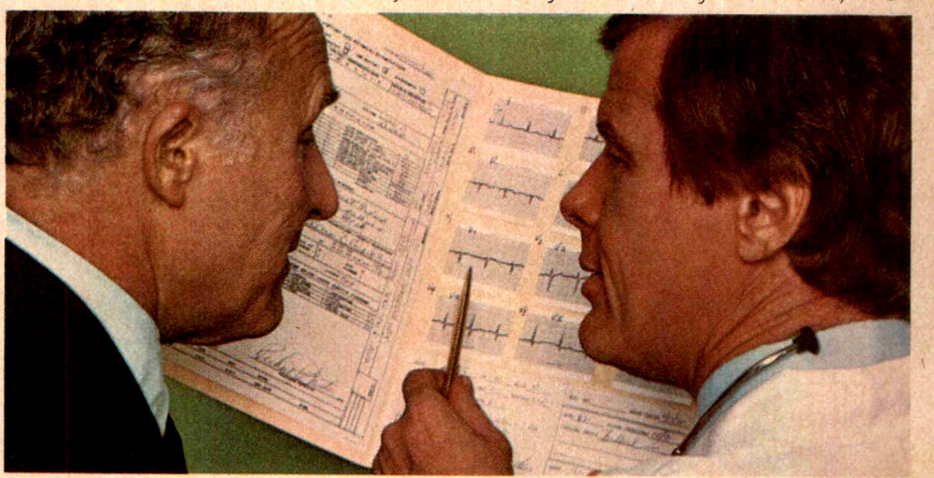
INDERAL, used alone or in combination with other antiarrhythmics, has improved or resolved a variety of supraventricular arrhythmias.[1-7]

INDERAL alone: Results of use against atrial tachyarrhythmias in one series have recently been reported:

Arrhythmia	Patients	Proportion deriving benefit	
		Complete	Partial
Sinus tachycardia	86	59%	22%
Atrial tachycardia (including paroxysmal type)	154	61%	19%
Atrial flutter	50	54%	32%
Atrial fibrillation	139	53%	26%

Adapted from Coodley and Snyder.[8]

INDERAL is particularly effective in therapy of supraventricular tachyarrhythmias.[9] It slows depolarization of sinus and ectopic pacemaker cells, and retards impulse-conduction in the atria and across the AV node.[1,10,11] In cases where it cannot restore normal sinus rhythm, INDERAL is frequently effective in reducing the ventricular rate.[1-3,12-14] INDERAL may prevent recurrent supraventricular tachyarrhythmias when digitalis and quinidine fail to do so.[9,12] In addition, INDERAL is a useful short-term adjunct for arrhythmias of thyrotoxicosis, when



used with specific therapy. Since INDERAL may mask the clinical signs of hyperthyroidism, abrupt withdrawal should be avoided to prevent exacerbation of the symptoms of hyperthyroidism.

And in combination: INDERAL has also been used to complement the actions of other antiarrhythmic agents.[3-5,8,9,13] The combination of INDERAL and quinidine has suppressed supraventricular arrhythmias that have not responded to either drug alone.[3,9]

When toxic doses of digitalis glycosides occasionally fail to control the ventricular rate in patients with atrial fibrillation or flutter, addition of INDERAL to a digitalis glycoside, with reduction of the digitalis dosage, may prolong AV conduction to the point where satisfactory control of ventricular rhythm is established.[8,15]

INDERAL: Often effective in tachyarrhythmias of digitalis intoxication[2,9,10,14] INDERAL has been found useful in the treatment of certain digitalis-induced arrhythmias that persist following discontinuation of digitalis and correction of electrolyte disturbances, particularly hypokalemia. Its use in this setting may be limited by the presence of significant congestive failure or heart block, and the development of severe bradycardia. (Please see prescribing information on the next page for "Overdosage or Exaggerated Response.")

INDERAL is contraindicated in sinus bradycardia, greater than first degree heart block, and congestive heart failure unless the failure is secondary to tachyarrhythmias treatable with INDERAL. (See prescribing information for complete list of CONTRAINDICATIONS.)

Please see next page for prescribing information.

Ayerst

BRIEF SUMMARY
(For full prescribing information, see package circular.)

INDERAL® Brand of propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. Propranolol is not significantly dialyzable. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias. Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyrotoxicosis, exercise).

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like* or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

INDICATIONS: Cardiac Arrhythmias

1.) Supraventricular arrhythmias

a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.)

b) Persistent sinus tachycardia which is noncompensatory and impairs the well-being of the patient.

c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy.

May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.)

d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures.

e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2.) Ventricular tachycardias

Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias.

a) Ventricular tachycardias

With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.*

b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3.) Tachyarrhythmias of digitalis intoxication

If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE:)

Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4.) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia

Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis: INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma: After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL (propranolol hydrochloride) unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the signs of clinical developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION: The dosage range for INDERAL (propranolol hydrochloride) is different for each indication.

ORAL

ARRHYTHMIAS—10-30 mg three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg three or four times daily, before meals and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg daily in divided doses for three days prior to surgery, concomitantly with an alpha-adrenergic blocking agent.

—*Management of inoperable tumor*—30 mg daily in divided doses.

PEDIATRIC DOSAGE: At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS: Intravenous administration is reserved for life-threatening arrhythmias or those occurring under anesthesia. The usual dose is from 1 to 3 mg administered under careful monitoring, *e.g.*, electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg (1 ml) per minute to diminish the possibility of lowering blood pressure and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the site of action even when a slow circulation is present. If necessary, a second dose may be given after two minutes. Thereafter, additional drug should not be given in less than four hours. Additional INDERAL should not be given when the desired alteration in rate and/or rhythm is achieved.

Transference to oral therapy should be made as soon as possible.

The intravenous administration of INDERAL has not been evaluated adequately in the management of hypertensive emergencies.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg). IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.*, LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED: INDERAL (propranolol hydrochloride)

TABLETS

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

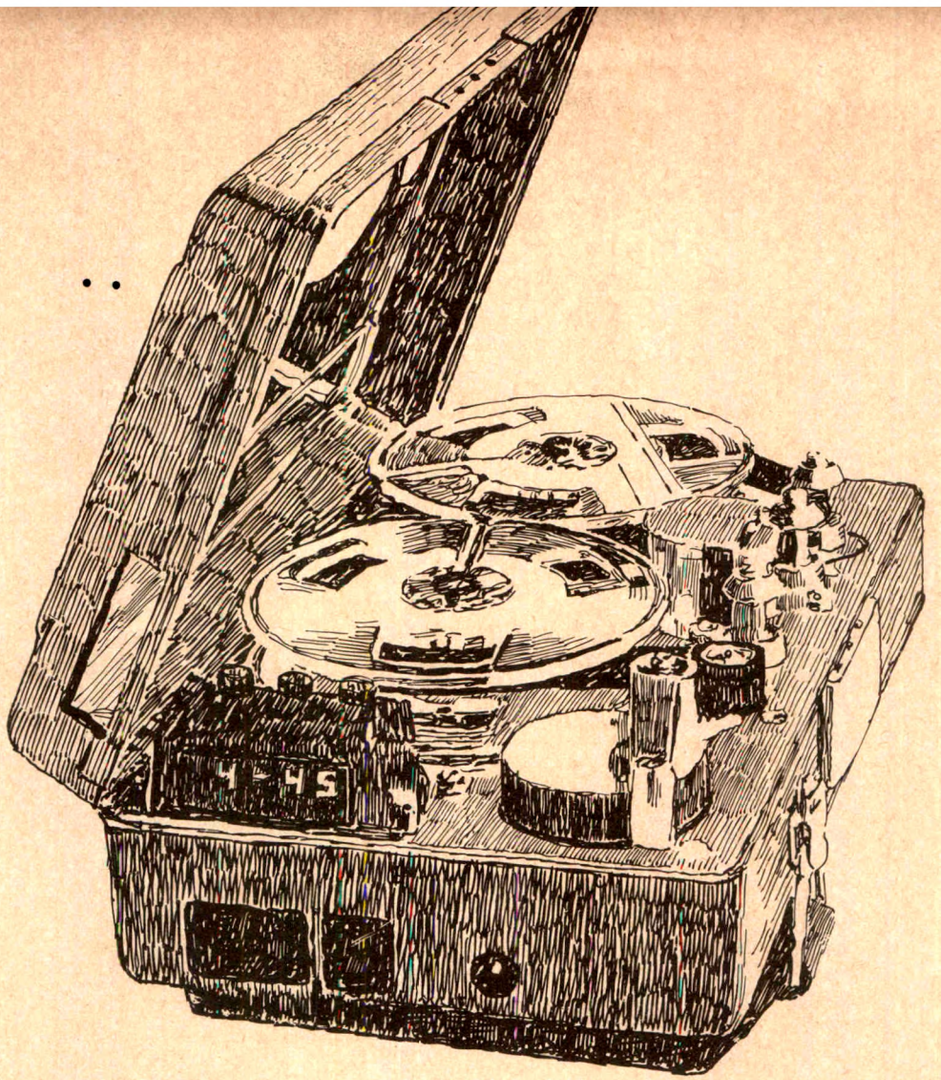
Ayerst® AYERST LABORATORIES New York, N.Y. 10017



It's no secret. We're giving it away.

We'll give you a new Avionics 445 Mini-Holter Recorder. No charge. Then you send the recordings to us. We'll send you a complete report.

Your dynamic cardiogram report will include a computerized quantitative analysis, a trend analysis of Heart Rate and ST segment levels, 2-channel real-time recordings of abnormalities and symptomatology—completely mounted in booklet form. In 24 hours it's in and out of our hands.

Our scanning system is designed to fit your system. It's easy, it's inexpensive—all you really need is the need.

Pacemaker reliability...

something you both get from CPI.

For the physician, this means less frequent replacement and fewer problems with the pacemaker once it is implanted. For the patient, it means a higher confidence level in his physician and greater optimism about his potential for a longer, more comfortable life after surgery.

CPI established its position of leadership among pacemaker manufacturers when it pioneered the research and development of lithium-powered pulse generators. Now, CPI is setting industry standards in pacemaker reliability. For example, CPI's failure rate is approximately .03% per month at the 90% confidence level compared to the failure rate of .15% per month at the 90% confidence level set by the Nuclear Regulatory Commission for nuclear-powered pacemakers. This includes all reported implants since CPI's first in 1972. Further, clinical data shows that CPI pulse generators have averaged more than 2.5 million pacing hours mean time between failures.* CPI has pacemakers implanted up to 57 months and to date has not experienced premature battery failure.

CPI is committed to maintaining the standards of excellence that made them the leader in lithium and reliability... standards that help CPI provide you with the highest quality pacemaker available. You can have every confidence in CPI pacemaking systems... and so can your patients.

...of the three major pacemaker companies, CPI is the leader in lithium and reliability.

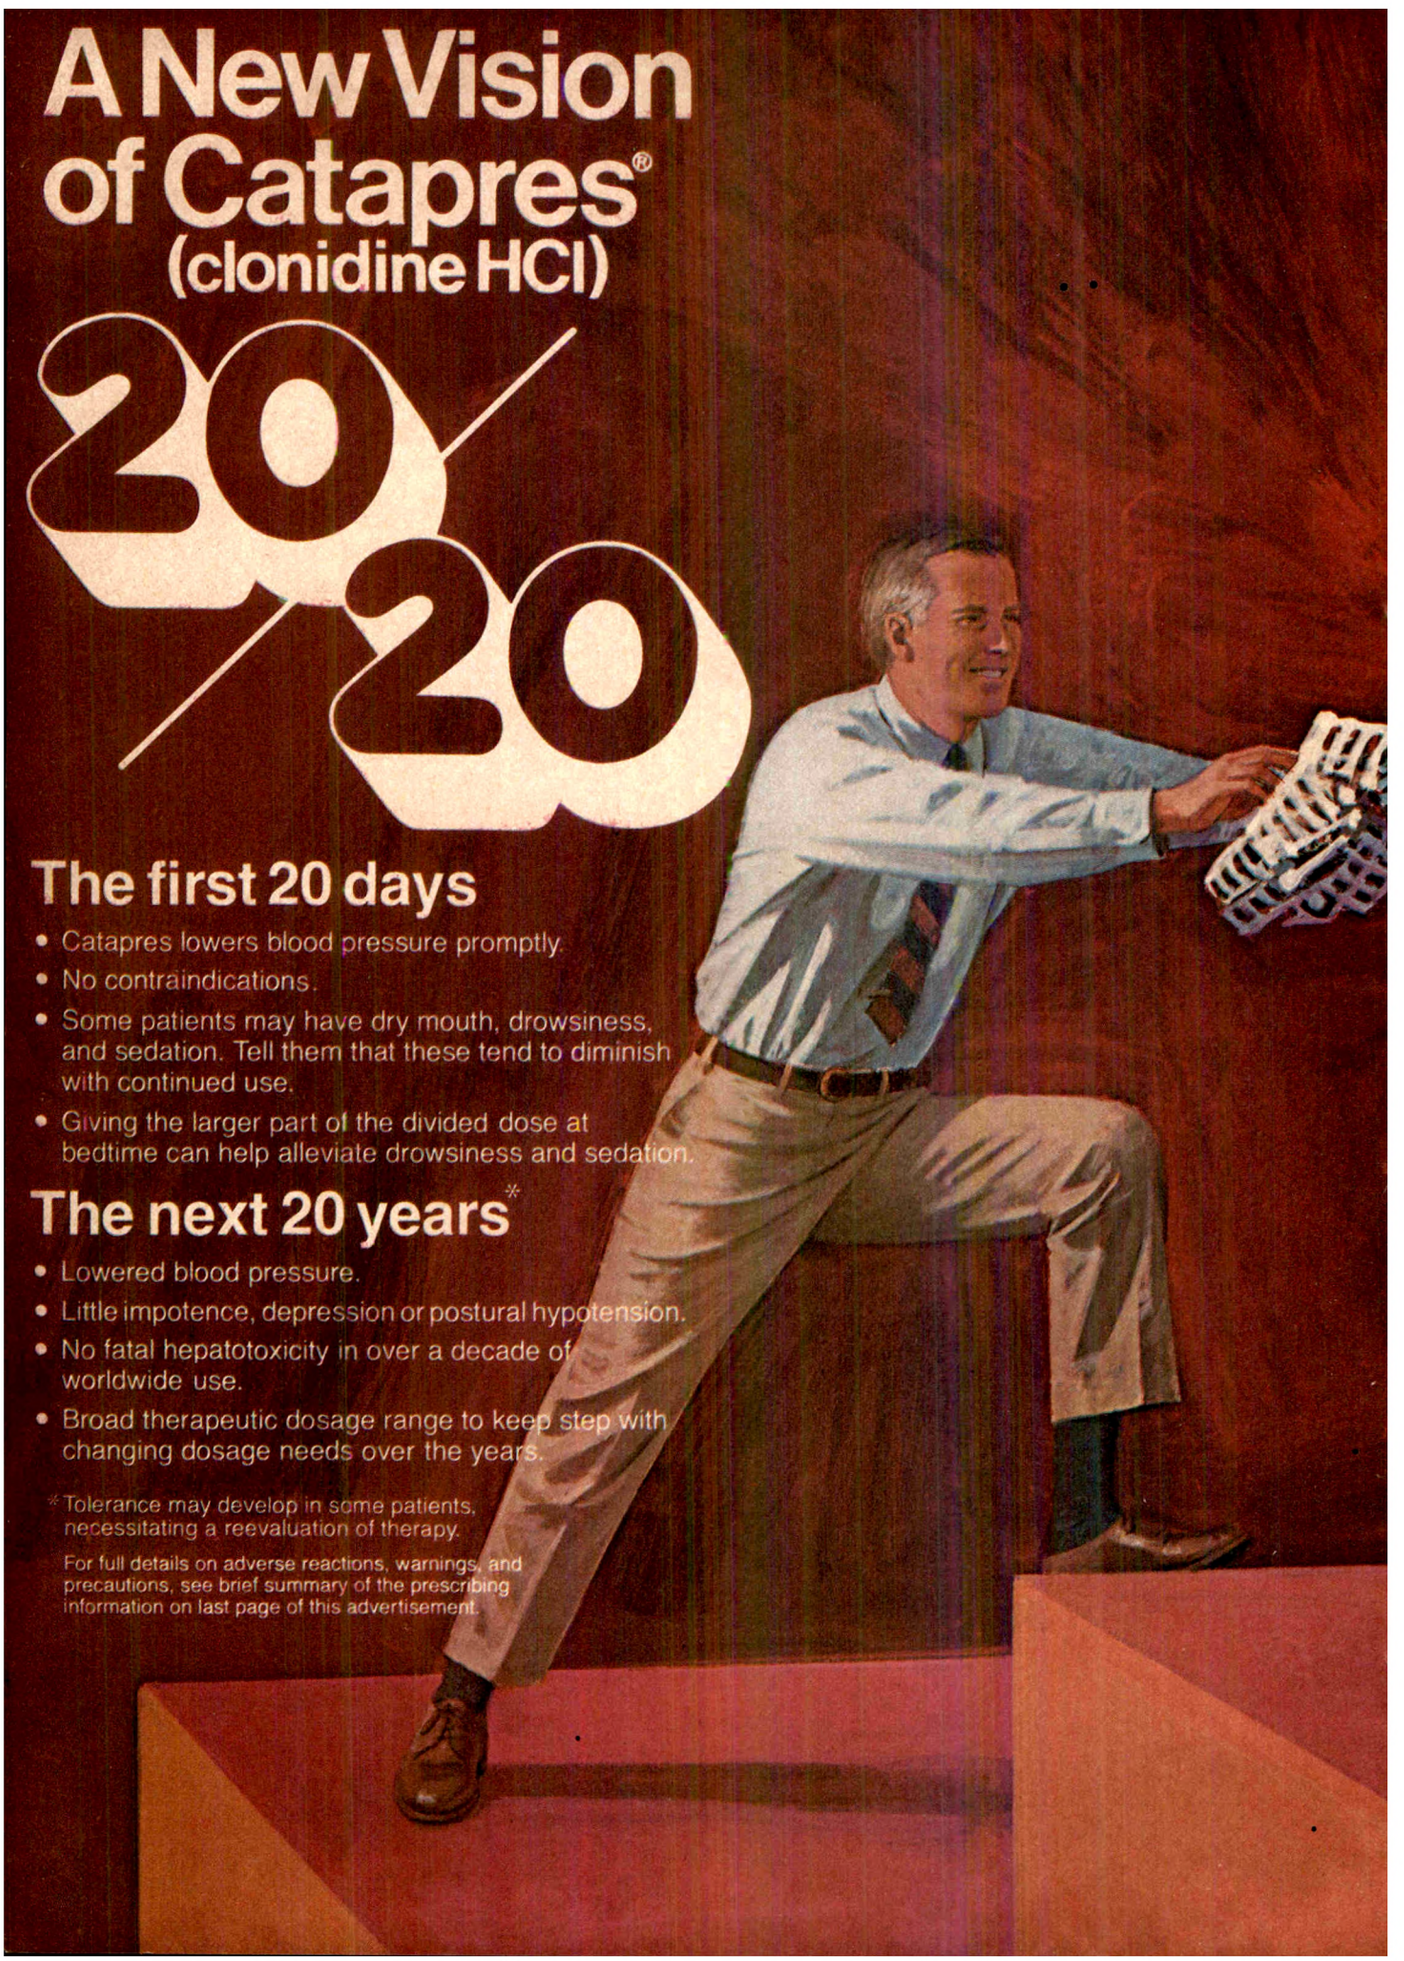
CPI—LEADER IN LITHIUM AND RELIABILITY.

A New Vision of Catapres® (clonidine HCl)

20/20



The first 20 days

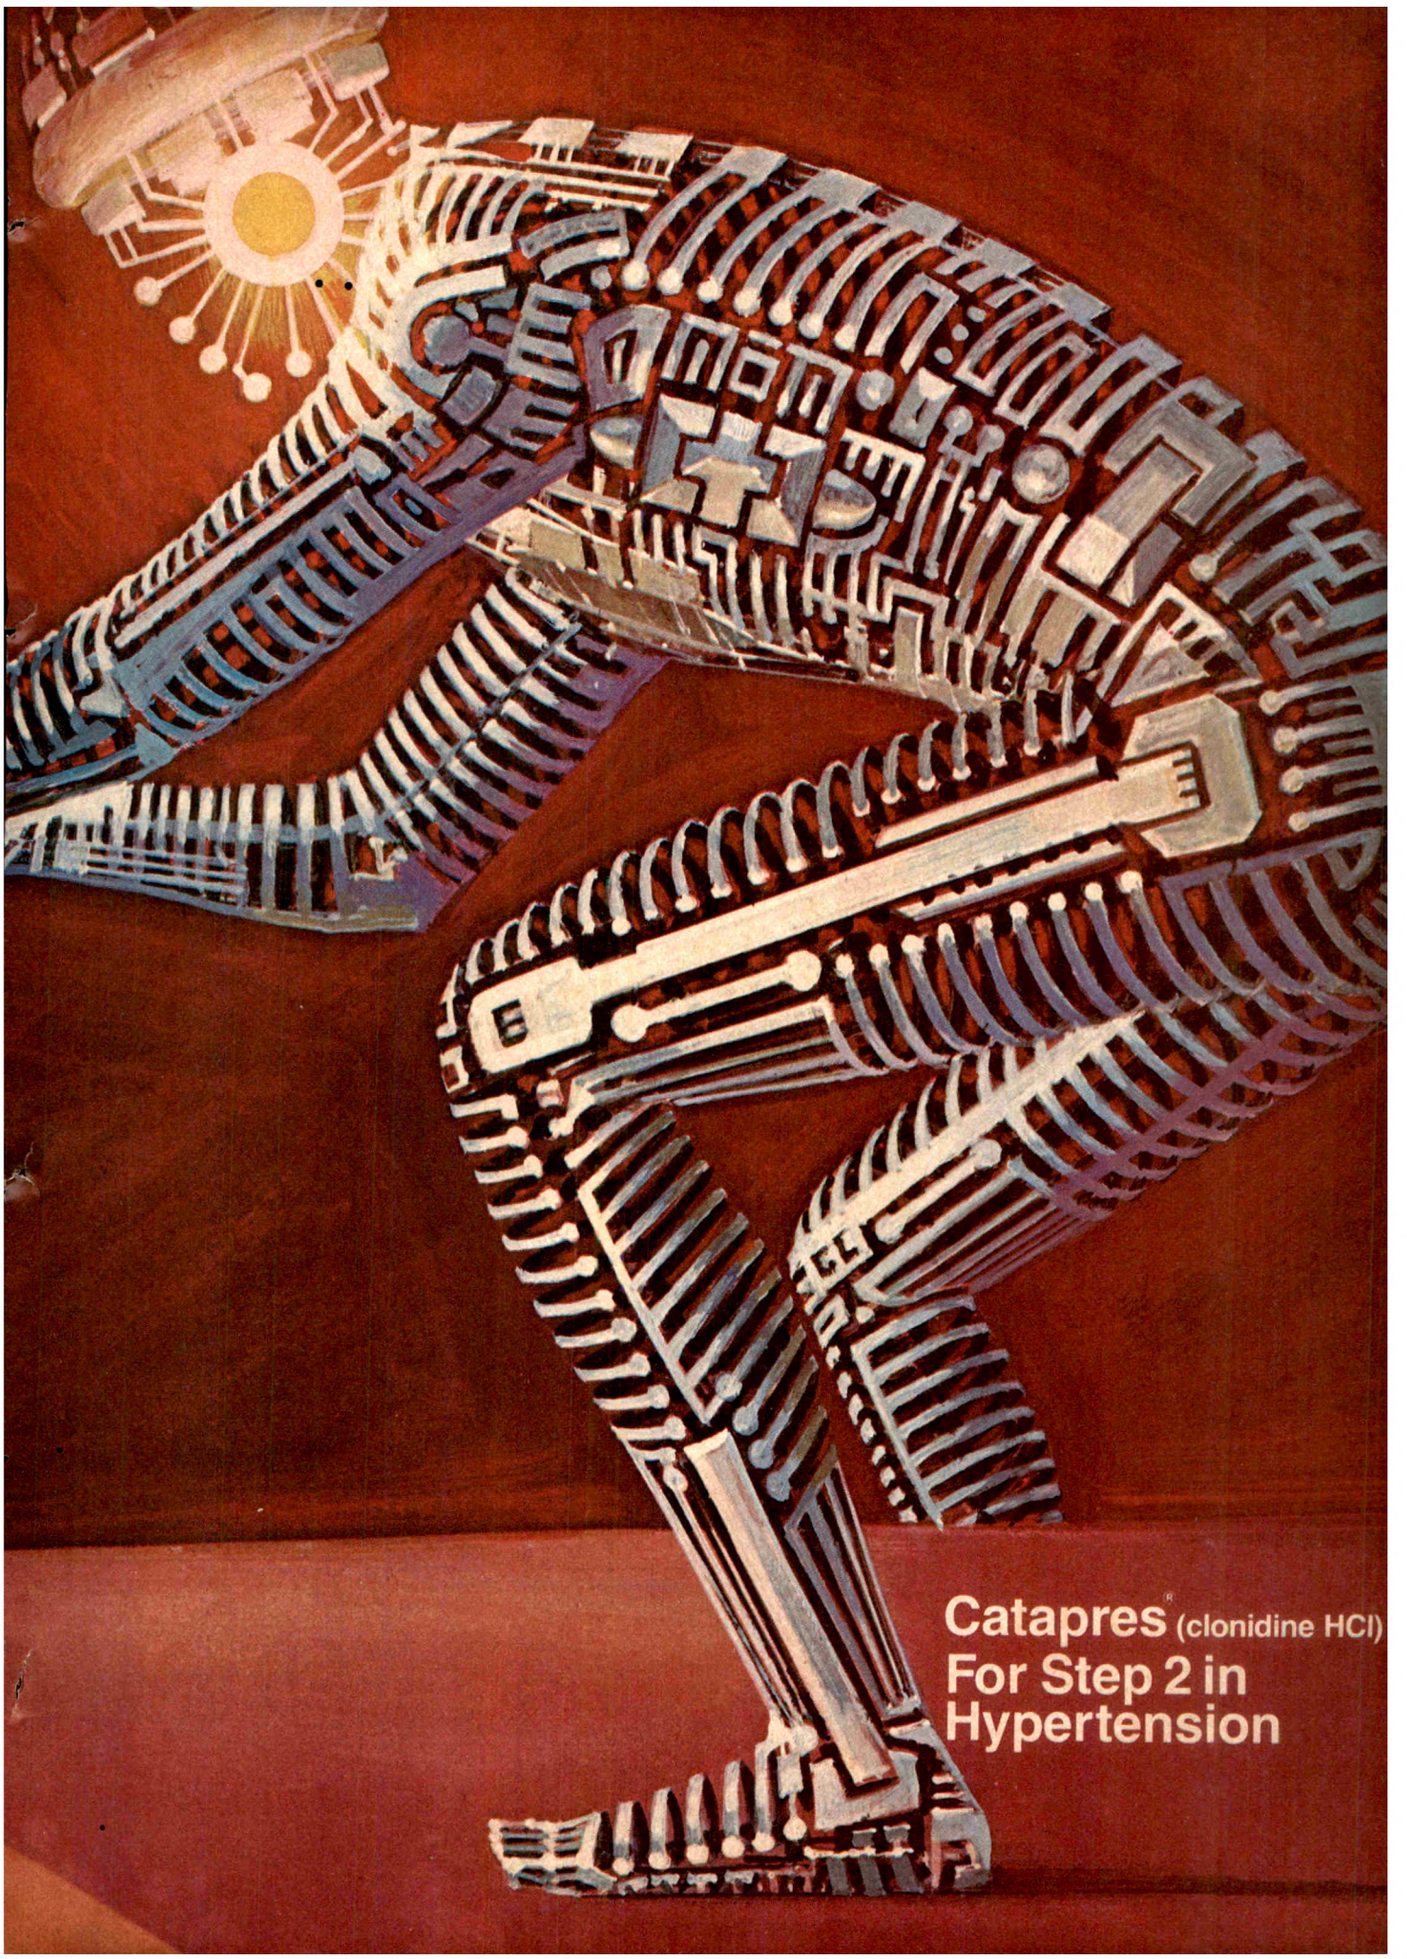
- Catapres lowers blood pressure promptly.
- No contraindications.
- Some patients may have dry mouth, drowsiness, and sedation. Tell them that these tend to diminish with continued use.
- Giving the larger part of the divided dose at bedtime can help alleviate drowsiness and sedation.

The next 20 years*

- Lowered blood pressure.
- Little impotence, depression or postural hypotension.
- No fatal hepatotoxicity in over a decade of worldwide use.
- Broad therapeutic dosage range to keep step with changing dosage needs over the years.

* Tolerance may develop in some patients, necessitating a reevaluation of therapy.

For full details on adverse reactions, warnings, and precautions, see brief summary of the prescribing information on last page of this advertisement.



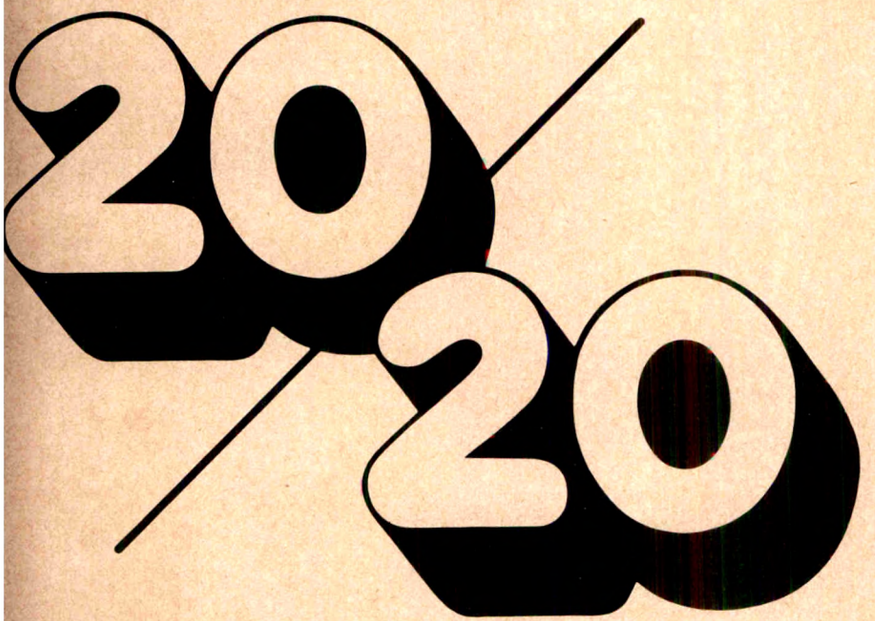
Catapres® (clonidine HCl)
For Step 2 in
Hypertension

HYPERTENSION

A New Vision of Catapres®

(clonidine HCl)

Tablets of 0.1 and 0.2 mg



What you do the first 20 days Can help him the next 20 years

Catapres®
(clonidine hydrochloride)
Tablets of 0.1 mg and 0.2 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encepha lopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established.) These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone, and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and menta depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000.

For complete details, please see full prescribing information.

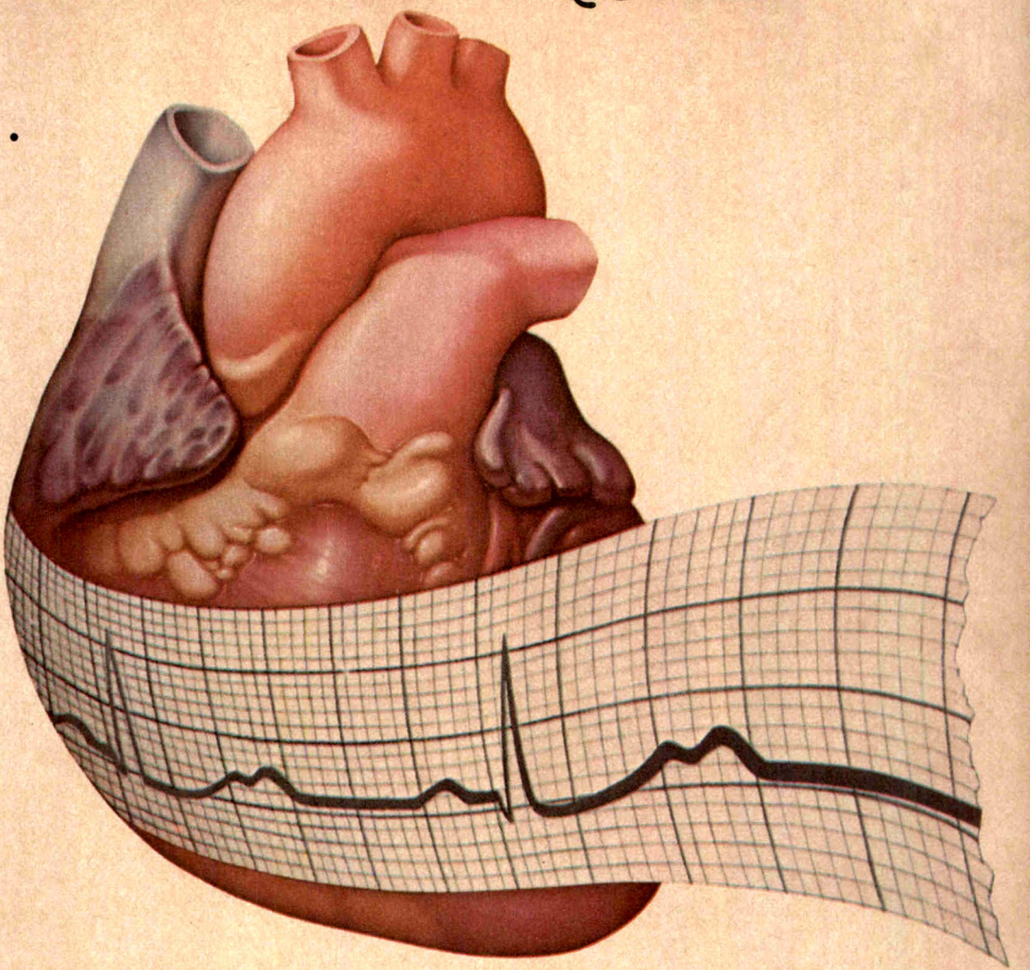
A42

WHEN THERAPEUTIC DOSES OF POTASSIUM ARE REQUIRED:



CONVENIENT AND ECONOMICAL

KAON-CL 20%®

(potassium chloride) LIQUID

40 mEq per 15 ml

Indications: KAON-CL 20% is indicated for the treatment of potassium depletion in patients with hypokalemia and metabolic alkalosis, and for the treatment of digitalis intoxication. During therapy serum potassium levels should be monitored and the dosage titrated to achieve the desired clinical and laboratory effects. KAON-CL 20% is also indicated for the prevention of potassium depletion when the dietary intake of potassium is inadequate for this purpose. The prophylactic administration of potassium ion may be indicated in patients receiving digitalis and diuretics for the treatment of congestive heart failure, hepatic cirrhosis with ascites, patients with hypertension on long-term diuretic therapy, hyperaldosteronism states with normal renal function, the nephrotic syndrome, and certain diarrheal states.

Contraindications: In patients with hyperkalemia, chronic renal failure, systemic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Warnings: Do not administer full strength. KAON-CL 20% will cause gastrointestinal irritation if administered undiluted.

In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: Nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effect is hyperkalemia (see Contraindications, Warnings and Overdosage).

Overdosage: If excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes. Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest.

How Supplied: Pints, gallons and 4 fl. oz.

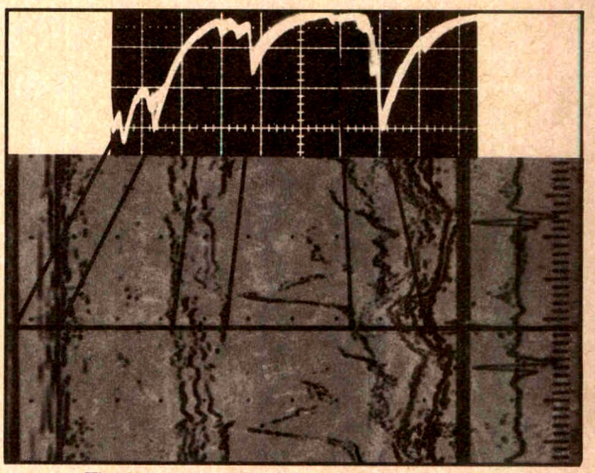
Automation solved one of their problems.

Let it solve one of yours.

Automatic Gain Compensation

Automatic Gain Compensation (AGC) circuitry has been designed to automatically analyze and determine the optimum display of each returning echo, so that heart structures are clearly delineated. As moving structures change depth and angle, the real-time flexibility of AGC permits the display to remain true and accurate throughout the examination. The result: more clinical information and an extremely high percentage of interpretable exams.

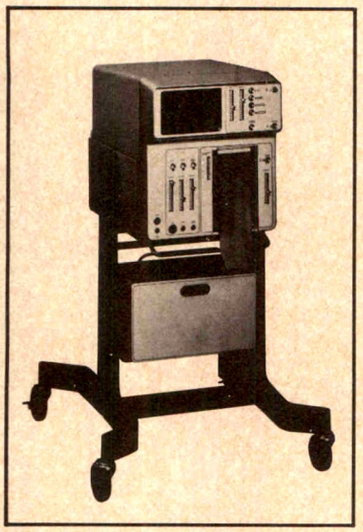


The interaction of AGC and echo information

Price Breakthrough
Incorporating new 1977 state of the art technology, the ECHOMATIC is extremely lightweight (approx. 50 lbs.) and is priced about 30% less than its next higher-priced competitor. Standard phono, carotid and ECG channels are included at this same price.

Service Support
A nationwide network of service offices is maintained to permit us to regularly meet our goal of on-site repair within 48 hours of your call. With over 30 service offices, our factory support staff, and the reliability we have built in, you can expect minimum downtime with the ECHOMATIC.

Basic Training Program
To assist in the establishment of your echocardiography service, the Metrix Teknika Echocardiography Basic Training Program has been prepared. This program includes 35mm slides, tape cassette and extensive textbook material.



☐ Please send the full story about the ECHOMATIC and Automatic Gain Compensation (AGC).

REFLECTION OF PROGRESS:

THE MEDTRONIC 5375 EXTERNAL PACEMAKER.

FROM THE COMPANY THAT HAS ALWAYS SET THE STANDARDS FOR EXTERNAL PACEMAKERS

From our long-standing tradition of providing products for the pacemaker patient has evolved the 5375. Engineering advancements allow the 5375 to provide safe, convenient operation for the physician, nurse and patient.

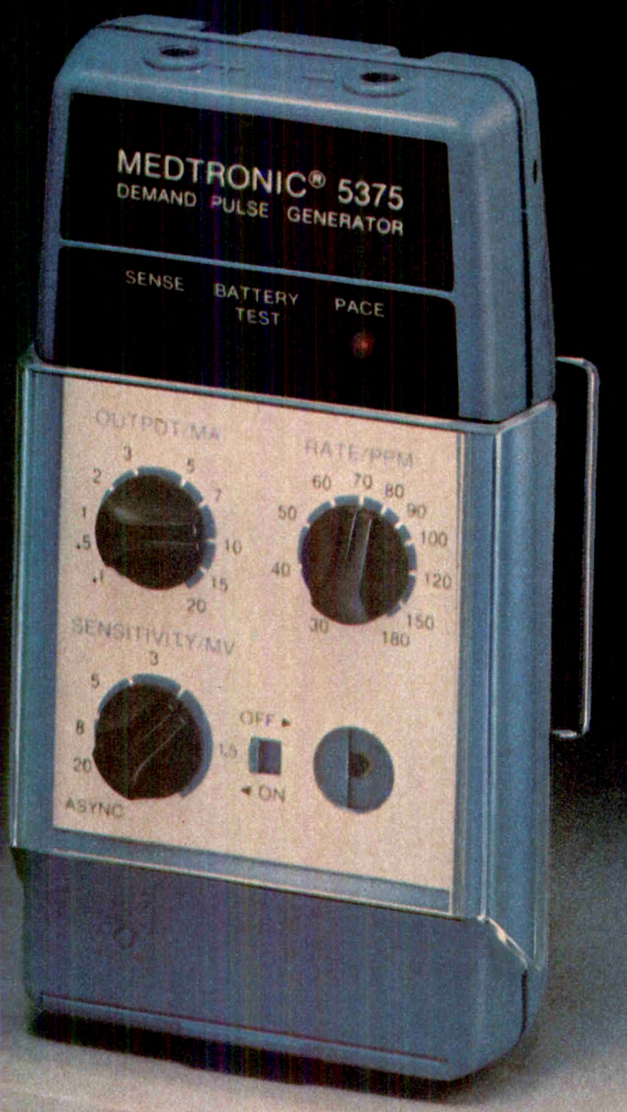
THE STANDARD OF SAFETY

5375 features provide protection against leakage current, EMI and inadvertent inhibition. Splash resistant terminal connections greatly reduce chances of contact with sources of dangerous leakage current — especially important on the busy CCU and ER service floors.

THE STANDARD OF CONVENIENCE

Cables connect by push button. Sliding transparent faceplate protects against accidental movement of controls. Retractable handles allow easy fastening of unit to patient's arm or waist. Indicator lights offer durable, visible verification of pacing, sensing and battery operation. And batteries can be changed quickly and easily, without tools, without interrupting pacing.

Evaluate the 5375. Contact Medtronic. We've been setting the standards for external pacemakers for more than 20 years.



Medtronic

Helping you help the pacemaker patient

MEDTRONIC 5375 EXTERNAL PACEMAKER PRODUCT INFORMATION

INTENDED USES
The Model 5375 External Demand Pulse Generator is intended for use in conjunction with a cardiac lead system for temporary demand or asynchronous pacing. The Model 5375 can be used where therapeutic, prophylactic or diagnostic cardiac pacing is indicated. It can also be used to estimate stimulation thresholds and the R-wave potentials sensed by the pacing lead system electrodes (see product labeling for details).

CONTRAINDICATIONS
There are no known contraindications to the use of external pacing as a means to temporarily pace the heart. The patient's age and medical condition, however, may dictate a particular external pulse generator and the lead system used by the physician.

WARNINGS
A cardiac lead system constitutes a direct, low resistance current path to the myocardium. Extreme caution must be taken to properly ground all line-powered equipment used in the vicinity of the patient to protect against ventricular fibrillation induced by leakage current.

Electrosurgical units should be used with caution in the vicinity of an external pacemaker system because of the danger of introducing extrinsic currents into the heart from the external pacemaker system which could cause fibrillation. When operating in the demand mode, the pulse generator output may revert to the asynchronous mode or inhibit the pulse generator in the presence of excessive levels of interference from equipment such as: electrosurgery units, diathermy equipment and some medical telemetry systems. Defibrillation discharges will probably not affect external pulse generators.

PRECAUTIONS
The physician should be aware that the Model 5375 can malfunction for reasons such as: random component failure, battery depletion and mishandling which cannot be predicted prior to failure. The pacing lead system may malfunction at any time due to lead system-related problems. Appropriate standby equipment should be available when the Model 5375 pulse generator is used.

POTENTIAL COMPLICATIONS
Potential complications associated with the use of an external pacemaker system are asystole following abrupt cessation of pacing and lead system-related problems such as: myocardial irritability, local tissue reaction, muscle and nerve stimulation, infection, erosion of the lead system through the skin, transvenous lead-related thrombosis and embolism, myocardial lead-related hemorrhage and cardiac tamponade.

In the past five years great strides have been made in clinical electrophysiology and the understanding of mechanisms of various cardiac arrhythmias. These advances have not only led to an improved diagnostic capability—but have also provided the basis for therapeutic innovations in management of cardiac arrhythmias with old and new antiarrhythmic drugs and cardiac pacing. This program has been designed to bring together leading authorities in cardiac anatomy, electrophysiology, electropharmacology, electrocardiography and pacing for an exchange of ideas and to review the current status. This program is geared for in-depth and high level discussions not only amongst the invited facuty but also the participating audience. This meeting should be valuable to both the academician and the practicing physician.

CLINICAL STUDIES

Identification of High Risk Subsets Of Acute Myocardial Infarction

Derived from the Myocardial Infarction Research Units Cooperative Study Data Bank

KARL T. WEBER, MD, FACC*
JOSEPH S. JANICKI, PhD*
RICHARD O. RUSSELL, MD, FACC†
CHARLES E. RACKLEY, MD, FACC†

Philadelphia, Pennsylvania
Birmingham, Alabama

To identify the patient at high risk after acute myocardial infarction data on 400 patients obtained from the Myocardial Infarction Research Units Cooperative Data Bank were examined. Patients were grouped according to clinical findings as follows: uncomplicated (class I, 81 patients); mild to moderate failure (class II, 150 patients); severe failure with pulmonary edema (class III, 17 patients); and severe failure with shock (class IV, 152 patients). Hemodynamic data including pulmonary capillary wedge pressure and cardiac output were available in all patients. High risk subsets within clinical classes I, II and IV were identifiable. In class I, nonsurvivors had significantly ($P < 0.05$) higher values for pulmonary capillary wedge pressure (16 mm Hg) and heart rate (96 beats/min); nonsurvivors in class II also had a significant ($P < 0.01$) elevation in pulmonary capillary wedge pressure (23 mm Hg); and in class IV the high risk subset was characterized ($P < 0.01$) by pulmonary capillary wedge pressure (21 mm Hg), heart rate (100 beats/min), cardiac index (1.6 liters/min per m^2), stroke index (14 cc/m^2) and stroke work index (12 g-m/m^2). Discriminant function analysis using pulmonary capillary wedge pressure and heart rate predicted mortality in classes I to III with 72 percent accuracy; a similar equation representing stroke work index, pulmonary capillary wedge pressure and cardiac index had an 83 percent rate of accuracy in class IV patients. Interclass comparison of the last three measurements indicated that the data differed significantly among classes, thus signifying a spectrum of ventricular impairment after infarction that was commensurate with the clinical presentation. However, in individual patients the clinical examination did not consistently reflect the degree of ventricular dysfunction. Thus, careful bedside examination together with hemodynamic monitoring of wedge pressure, cardiac output and heart rate serve to identify the high risk patient after acute myocardial infarction.

From the Cardiovascular-Pulmonary Division, Department of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania*; and the Cardiology Division,* Department of Medicine, University of Alabama, Birmingham, Alabama.†

Address for reprints: Karl T. Weber, MD, Cardiovascular-Pulmonary Division, Hospital of the University of Pennsylvania, 3600 Spruce Street, Philadelphia, Pennsylvania 19104.

Hospital survival after acute myocardial infarction correlates with the degree of accompanying left ventricular dysfunction.[1–10] The presence and severity of ventricular failure, indicators of immediate prognosis, are currently assessed with careful bedside examination. In addition,

measurements of pulmonary capillary wedge pressure and cardiac output obtained in the coronary care unit have provided complementary objective information. Specifically, these hemodynamic data have been used to identify accurately the severely compromised ventricle and the associated poor prognosis.[1–7] However, prognostic features of increased risk in patients with lesser degrees of impairment after myocardial infarction have not been identified. In their early studies Peel et al.[8] and Norris et al.[9] suggested that age, sex, location of infarct, history of previous infarction, presence of systemic hypotension and clinical or radiographic evidence of pulmonary congestion and failure would provide such information. Yet, except for findings indicating obvious impaired performance, the relative contribution of these historical and clinical factors as objective criteria for predicting survival has not been substantiated.[2–5] Thus there is an obvious need to develop reliable prognostic criteria in such patients. In this investigation we reasoned that such criteria could be developed if a sufficiently large pool of clinical and hemodynamic data, representing the entire spectrum of ventricular dysfunction after myocardial infarction, were available for discriminant function analysis. This objective was realized by examining the data base for 400 patients who had been followed up in the nine Myocardial Infarction Research Units (MIRU).

Methods

Patient selection: Data were reviewed from 475 patients of whom 400 underwent hemodynamic evaluation. The data included information on 387 patients obtained from the Cooperative MIRU Data Bank and on an additional 88 patients from the University of Alabama MIRU seen between 1970 and 1972. The diagnosis of acute myocardial infarction was based on appropriate historical and clinical observations in association with documented electrocardiographic evidence of infarction. The evolution of diagnostic Q waves and S-T segment or T wave changes, or both, with associated serial enzyme alterations was required. The location of the infarction was documented electrocardiographically and was reported as anterior, inferior or lateral in location. Patients with S-T segment changes alone without accompanying Q waves were considered separately.

Patients were evaluated during the acute phase (less than 36 hours) of their infarction. Historical data relating to the presence and duration of angina, congestive heart failure, previous myocardial infarction and hypertension were available in 388 of the 400 patients. The patients were first characterized by clinical criteria on admission. The classification of Killip and Kimball[10] was used to represent the clinical estimate of ventricular dysfunction existing after infarction. The categorization was as follows: (1) Class I: Patients without auscultatory evidence of failure (pulmonary rales or third sound ventricular gallop, or both) were judged to have an uncomplicated infarction (81 patients). (2) Class II: The presence of basilar rales or ventricular gallop sound, or both, was judged to represent moderate ventricular failure (150 patients). (3) Class III: Pulmonary edema was reported for 17 patients. (4) Class IV: The diagnosis of shock was made in 152 patients. The criteria for shock, according to MIRU protocol, included both a systolic blood pressure of 90 mm Hg or less (or less than 110 mm Hg in patients known to have had hypertension previously) and clinical evidence of depressed mentation, pallor, cold and clammy skin and oliguria. Systemic blood pressure values were confirmed with arterial catheterization data. Patients with secondary causes of shock, such as arrhythmia with heart rates of 60 beats/min or less or 150 beats/min or more were excluded. Finally, information on mortality was limited to those deaths considered of cardiac origin.

Hemodynamics: After clinical categorization right heart and arterial catheterization was performed without preferential selection. Informed consent was obtained in all patients. Left ventricular filling pressure was estimated using pulmonary capillary wedge pressure. Cardiac output was measured with the dye-dilution or thermodilution technique. These 400 patients who underwent hemodynamic evaluation did not represent sequential admissions to the respective units or all patients observed in each unit. Their inclusion here was governed solely by the fact that their clinical and hemodynamic data were complete and available for analysis from the Data Bank.

From the hemodynamic data, left ventricular stroke work index (SWI, g-m/m^2) was calculated using the formula: SWI = (MSP − PCW) · SI · 0.0136 where MSP is calculated mean ejection pressure[11] and PCW is capillary wedge pressure (both in mm Hg), SI is stroke index (cc/m^2) and 0.0136 the conversion factor to metric units. Peripheral vascular resistance (PVR) (mm Hg/liter per min per m^2 or units) was calculated from the formula: PVR = (MSP − RAM)/CI where RAM is right atrial mean pressure (mm Hg) and CI the cardiac index (liters/min per m^2). In patients not having a reported right atrial mean pressure, peripheral vascular resistance was estimated as MSP/CI.

Statistical analysis of the hemodynamic data between each clinical class. Nonsignificant (NS) and statistically different ($P < 0.05$ or < 0.01) pairings are identified. Abbreviations as in Table I.

Statistical analysis: In addition to the assessment of clinical and hemodynamic data, sets of hemodynamic variables from all classes were compared individually and collectively using discriminant function analyses[12] to predict mortality. This method was used to derive a function that consisted of a linear combination of any chosen number of variables modified by statistically determined coefficients. Such an analysis permits a description of the specific influence of various measurements on overall survival and thereby an expression of prognosis. The utility of such an expression in predicting mortality has been previously demonstrated.[5,13] In this study, the variables analyzed in varying combinations were cardiac index; pulmonary capillary wedge pressure; heart rate; mean, diastolic and systolic arterial pressures; mean right atrial pressure, and peripheral vascular resistance. Solving the derived discriminant function with the required variables then resulted in a prediction of mortality for that patient. Information on radiographic heart size was not included in the data profile.

Results

Clinical and hemodynamic data: In classes I, II and III the clinical (age, sex and infarct location) and historical (previous infarction, angina, heart failure or hypertension) data had no statistical bearing on clinical outcome. In class IV, however, this information was found with significant ($P < 0.05$) frequency in nonsurvivors.

Class I: Eighty-one patients without clinical evidence of heart failure were grouped as having an uncomplicated infarction. Anterior infarction and inferior infarction were each observed in 44 percent; the remaining 12 percent had either S-T segment changes alone (9 percent) or lateral infarction (3 percent). The overall mean age was 56 years with men outnumbering women 6 to 1. The overall mortality rate was 10 percent.

Wedge pressure, cardiac index, stroke index and stroke work index averaged 11 mm Hg, 2.9 liters/min per m^2, 31 cc/m^2 and 49 g-m/m^2, respectively (Table I). As will become evident the interclass comparison of such information as wedge pressure, cardiac index and stroke work (Table II) indicates that as a whole class I patients (those without clinical evidence of heart failure) had a significantly higher level of left ventricular performance than patients in the other three classes. Left ventricular filling pressure and heart rate were significantly ($P < 0.05$) higher in class I nonsurvivors (16 mm Hg and 96/min, respectively) than in survivors (10 mm Hg and 83/min, respectively) (Table III). The other hemodynamic data did not distinguish this high risk

‡ Patients with nonhypovolemic shock (right atrial mean pressure >5 mm Hg).

class I subset. The utility of this information in establishing prognosis by discriminant function is presented in a subsequent section (see later).

Class II: One hundred fifty patients were found to have a ventricular gallop sound or basilar rales, or both, and were therefore classified as having moderate heart failure. Fifty-nine percent had acute anterior and 38 percent had acute inferior infarction. Acute lateral infarction and isolated S-T segment changes were seen in 2 and 1 percent, respectively. The mean age was 58 years with an approximate male to female ratio of 4 to 1. The overall mortality rate was 11 percent.

The hemodynamic data for class II (Tables I and II) were consistent with a greater reduction of left ventricular performance than in class I ($P < 0.05$). Cardiac index, stroke index and wedge pressure averaged 2.5 liters/min per m^2, 26 cc/m^2 and 16 mm Hg, respectively. Mean cardiac index, stroke index and stroke work index in those class II patients who died averaged 2.3 liters/min per m^2, 25 cc/m^2 and 37 g-m/m^2, respectively. As in class I, mean wedge pressure in survivors was significantly lower ($P < 0.01$) than that of nonsurvivors (16 versus 23 mm Hg, respectively) (Table III). In addition, mean right atrial pressure was higher ($P < 0.01$) in nonsurvivors (12 mm Hg) than in patient survivors (7 mm Hg); however, mean heart rate was not significantly different. Arterial pressure, peripheral resistance, cardiac index, stroke index and stroke work index were of no value for the intraclass prediction of mortality. Class II patients demonstrated a greater degree of hemodynamic dysfunction than class I patients, but had less impairment than class III patients.

Class III: Pulmonary edema was reported for 17 patients. This limited number in all likelihood represents the inherent difficulty in obtaining adequate baseline hemodynamic information in patients with respiratory distress, instability and rapid fluctuations in clinical state. The incidence rate of anterior and inferior infarction was 79 and 14 percent, respectively; acute lateral infarction was seen in 7 percent. Men outnumbered women 2 to 1 and the average age was 65 years. The overall mortality rate for class III was 18 percent.

Mean values for cardiac index, stroke index and stroke work index in class III were all significantly lower ($P < 0.01$) (Tables I and III) than in class I. For the group, stroke index was reduced ($P < 0.05$) in comparison with class II whereas wedge pressure was higher than in class I or II. Nonsurvivors in this group could not be identified from hemodynamic criteria (Table III), but the small population sample prohibits meaningful statistical analyses and comparisons.

Class IV: By definition, patients in class IV had systemic hypotension and therefore arterial pressure in this group differed significantly from values in classes I, II and III. One hundred fifty-two patients constituted this group, which had an overall mortality rate of 70 percent. To determine whether any of these patients were volume-depleted a mean right atrial pressure of 5 mm Hg was arbitrarily chosen. Twenty-six patients judged to be hypovolemic on the basis of a mean right atrial pressure of 5 mm Hg or less were considered separately. Overall mortality for this hypovolemic subset was 48 percent. The remaining 126 patients with shock and a right atrial pressure greater than 5 mm Hg had a 75 percent mortality rate. These 126 patients are therefore considered to have primary shock and form the basis for all subsequent class IV analyses. Men outnumbered women 3 to 1 and the mean age was 59 years. Anterior infarction was seen in 57 percent and inferior infarction in 36 percent. S-T segment changes alone were reported in 5 percent and lateral infarction in 2 percent.

Hemodynamically, the patients with shock differed significantly ($P < 0.01$) from patients in classes I and II. Mean values for cardiac index, stroke index and stroke work index (1.8 liters/min per m^2, 18 cc/m^2 and 17 g-m/m^2, respectively) were all significantly lower whereas wedge pressure (20 mm Hg), heart rate and mean right atrial pressure were greater than the respective means observed in classes I and II. Within class IV, nonsurvivors could also be separated from survivors on the basis of these hemodynamic data (Table III). Specifically, cardiac index, stroke index and stroke work index were significantly lower and heart rate and wedge pressure higher ($P < 0.01$) in nonsurvivors. Class IV clearly represents the most profound functional impairment that exists after myocardial infarction.

Hemodynamic profile: The spectrum of ventricular dysfunction that exists after myocardial infarction within a given class or among classes could be represented by a comparison of cardiac index and left ventricular filling pressure or the three-dimensional display of stroke work index, cardiac index and filling pressure. For example, in Figure 1, cardiac index and filling pressure are presented for class IV with the additional considerations of infarct location and mortality. Patients with shock and a cardiac index of 2.0 liters/min per m^2 or less and wedge pressure of 15 mm Hg or greater had a 95 percent mortality rate. Patients in the other three hemodynamic quadrants had a substantially lower mortality rate. The respective mortality rates based on cardiac index (CI) and left ventricular filling pressure (LVFP) could be expressed as follows: CI less than 2.0 and LVFP less than 15, 55 percent; CI more than 2.0 and LVFP less than 15, 33 percent; and CI more than 2.0 and LVFP more than 15, 58 percent.

To characterize the hemodynamic profile for all 400 patients a series of averaged ventricular function curves (that is, stroke work versus filling pressure) calculated at several cardiac index levels was utilized. For each cardiac index level a curve was constructed by averaging work for three ranges of filling pressure (0 to 14, 15 to 25 and 26 to 40 mm Hg, respectively). The resultant work, cardiac index and filling pressure display is shown in Figure 2. The mean values ±1 standard deviation for each clinical class are shown in Table I. The expected biologic variability among the 400 patients accounts in part for the overlap among classes. However, the mean values for classes I, II and IV in which sample size was sufficient for statistically meaningful analysis differed ($P < 0.01$) from one another.

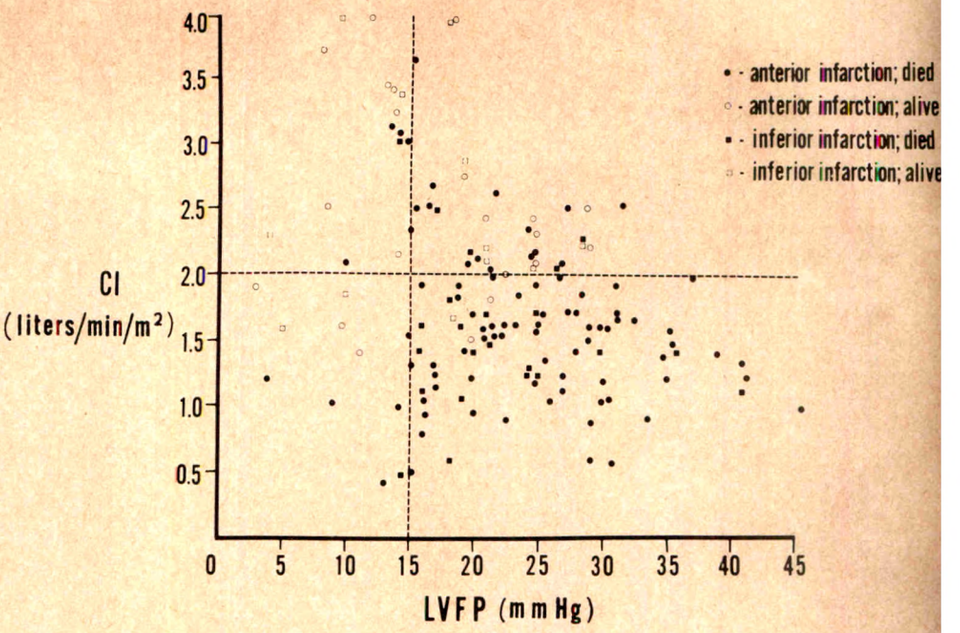

FIGURE 1. Class IV (shock) (152 patients). Identification of a high risk subset from the analysis of cardiac index (CI) and left ventricular filling pressures (LVFP). Infarct location and mortality are also represented.

Discriminant analysis: A discriminant function analysis (DF) can be used to weigh the influence of individual variables so as to predict mortality. A three variable discriminant analysis of stroke work index (SWI), cardiac index (CI) and wedge pressure (PCW) was developed for the 126 patients in shock. An 83 percent accuracy rate in predicting mortality was found. The resultant equation for these patients may be given as $DF_{1(Shock)} = 1.59 - 0.036SWI - 0.011CI + 0.023$ PCW where $DF_1 > 1.28$ indicates nonsurvival. Combining stroke work index, cardiac index and wedge pressure together with the infarct location did not improve prognostic accuracy. Other hemodynamic data, such as systolic, diastolic or mean arterial pressures, peripheral resistance and heart rate analyzed individually or in various combinations, were less useful in predicting mortality for class IV.

The observed mortality rate for classes I to III in our series ranged between 10 and 18 percent. In the individual patient, heart rate (HR) and wedge pressure (PCW) together provided an estimate of survival with a 72 percent accuracy rate. The resultant equation for the discriminant function (DF) using these two variables was as follows: $DF_{2(Failure)} = -0.568 + 0.018$ PCW $+ 0.005$ HR where DF_2 greater than 0.35 indicates nonsurvival. Moreover discriminant analysis using heart rate and wedge pressure together with age, infarct location, mean right atrial pressure, stroke index and stroke work or other hemodynamic data did not improve on the 72 percent accuracy rate obtained using heart rate and wedge pressure alone.

Discussion

Before we discuss the results of this investigation and its implications a number of comments are in order regarding the use of pooled data. The clinical and hemodynamic data base from which our study was derived represents retrospective information from the nine Myocardial Infarction Research Units. The appropriate historical and clinical definitions of acute infarction associated with electrocardiographic and enzymatic evidence of infarction were required. However, a common protocol dictating methodologic policy for hemodynamic data acquisition was not in effect. Thus cardiac output, for example, may have been measured with dye-dilution or thermodilution techniques. Information pertaining to specific techniques, reproducibility and the like may be obtained from an appropriate scientific publication of the individual units. We do not believe that such differences in technique would significantly hinder the interpretation of the information. Nevertheless, by its very nature certain constraints do exist with respect to the analysis of such pooled data. We have therefore made no attempt to single out similarities but rather only statistically significant differences. Moreover, this information obtained from a cross section of the U. S. medical centers does not represent sequential admissions. Thus it will not accurately reflect either the average experience of any given coronary care unit or the expected incidence of the various clinical categories of patients.

Clinical versus hemodynamic findings: In general, the scope of the clinical presentation appeared to follow the hemodynamic measurements of wedge pressure and cardiac index. Considered collectively, evidence of ventricular impairment or failure (that is, depressed cardiac output and elevated filling pressure) was accompanied by clinical findings of pulmonary rales or ventricular gallop sound, or both, for each clinical class. However, this agreement between clinical and hemodynamic observations was not consistent in the individual patient. This was particularly evident when

considering the high risk subset of classes I and II. Thus the degree of ventricular dysfunction in the individual patient and the prediction of hospital course after acute infarction could be more accurately assessed by complementing the clinical examination with hemodynamic monitoring. Clinical data on age, sex and infarct location were noncontributory in predicting mortality. Similarly, the presence or absence of historical information such as previous infarction, angina, failure or hypertension did not appear with distinguishing frequency in patients with an uncomplicated infarction or failure. However, these historical findings were present in the majority of nonsurvivors with shock.

Mortality rates for classes I and II: Role of left ventricular filling pressure: In general, the mortality rates observed in patients in classes I and II were in accord with the experience of others.[2–6,8–10,14,15] From this nationwide experience it is apparent that specific hemodynamic variables served to identify the high risk patient within each clinical class. Class I patients without auscultatory evidence of heart failure are considered to have a clinically "uncomplicated" infarction with minimal ventricular dysfunction. However, this is clearly not the case when complementary hemodynamic data are obtained. The range of filling pressure in these patients has been previously shown to be highly variable. For example, Hamosh and Cohn[3] observed a range of left ventricular end-diastolic pressure of 6 to 22 mm Hg (mean 15) in 14 patients without clinical evidence of failure and Wolk et al.[4] reported a mean of 16 ± 9 mm Hg for 23 similar patients. Additionally, filling pressure in our patients was closely related to early survival after myocardial infarction. Patients in class I not surviving hospitalization had significantly greater left ventricular filling pressures than their counterparts who survived. High risk patients with mild to moderate failure (class II) could also be distinguished by the level of filling pressure (23 mm Hg in nonsurvivors; 16 mm Hg in survivors). This observation represents a hitherto unstressed but very important observation in these class I and II patients. In addition, it emphasizes that the degree of myocardial impairment may be underestimated by the clinical examination. Heart rate also tended to be higher in nonsurvivors, a finding that reached statistical significance for class I.

Class III: Role of pulmonary edema: Because pulmonary edema (class III) was reported for only 17 patients, statistical conclusions on this group are limited and questionable. However, these patients differed hemodynamically from patients in classes I and II and had a higher mortality rate (18 percent). In 22 patients with pulmonary edema, Ramo et al.[1] reported that mean right atrial pressure, cardiac index and stroke index were 15 mm Hg, 1.9 liters/min per m^2 and 19 cc/m^2, respectively, and these values were significantly different from those of patients with lesser degrees of failure. However, a difference in such measurements between patients in classes III and IV could not be demonstrated. Sjogren[14] found that 15 of 40 patients (38 percent) who had frank pulmonary edema during the first 24 hours of their hospital stay died. Killip and Kimball[10] also reported a 38 percent mortality rate in 26 class III patients, whereas 17 percent of Scheinman's patients[15] with pulmonary edema after acute infarction expired.

Class IV: Role of stroke work index, cardiac index and wedge pressure in shock: Within the group with shock after acute mycardial infarction there is a subset at greater risk. These are the patients with a stroke work index of 20 g-m/m^2 or less, a cardiac index of 2.0 liters/min per m^2 or less and a wedge pressure of 15 mm Hg or greater. The observed mortality rate (96 percent) for this subset is consistent with previous observations[5]; however, these findings are only valid for patients with shock due to myocardial damage alone and do not include patients with other causes of hypotension, such as hypovolemia or arrhythmia.

Estimation of ventricular performance and contractile state after myocardial infarction: A hemodynamic profile of acute infarction was presented in 1973[5] for 79 patients followed up in the University of Alabama Myocardial Infarction Research Unit. This profile, which may be represented as the three-dimensional display of stroke work, cardiac output and filling pressure (Fig. 2) served also to describe the spectrum of left ventricular dysfunction for the 400 patients reported herein. Represented in this geometrical structure

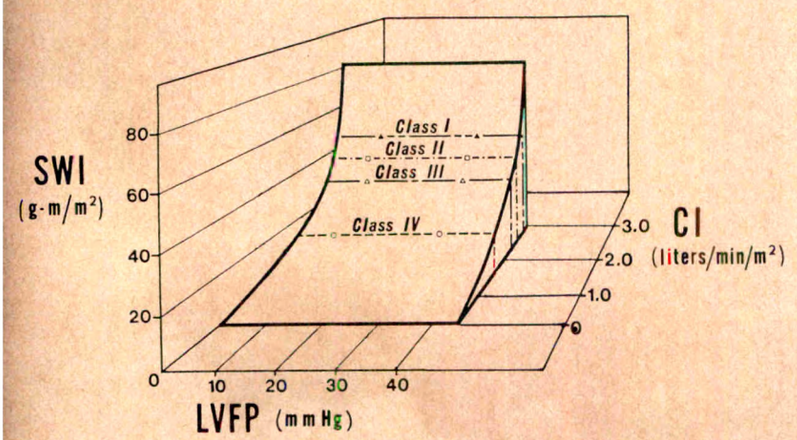

FIGURE 2. Hemodynamic profile of acute myocardial infarction based on stroke work index (SWI), cardiac index (CI) and left ventricular filling pressure (LVFP) presented for each clinical class.

are a series of ventricular function curves, a traditional estimate of pump performance relating to stroke work and filling pressure. On the basis of this information, the spectrum of stroke work index expressed with respect to the clinical classification could broadly be represented as follows: (1) uncomplicated infarction, greater than 40 g-m/m^2; (2) moderate failure, 30 to 40 g-m/m^2; (3) severe failure with pulmonary edema, 20 to 30 g-m/m^2, and (4) severe failure with shock, less than 20 g-m/m^2.

It is often assumed that myocardial contractile state can be assessed by determining the level of stroke work for any given series of filling volumes (or filling pressures). Unfortunately, in the individual patient this approach neglects the influence of arterial pressure on stroke volume as well as alterations in ventricular distensibility.[16] In the context of representing stroke work for each clinical class as we have here, it was assumed that the interplay of extrinsic and intrinsic factors regulating myocardial performance in any given heart had been assimilated. In physical terms ventricular work may be defined as the integral of the force-length loop. Because the ventricle shortens within the confines of its contractile state-dependent, maximal force-length relation,[16,17] a reduction in the slope of this relation will attenuate both the extent of wall shortening and work for any given condition of fiber length and load. Thus the progressive decline in stroke volume and work noted for classes I to IV, despite increments in filling pressure, suggests a continuous decline in contractile state that is reflected in the series of ventricular function curves. This spectrum of impairment probably represents the amount of accumulative muscle damage: That is, as the quantity of infarcted and ischemic myocardium increases there is a progressive reduction in contractile state whose functional limit is obtained for patients with shock.[5,18,19]

Clinical implications: Careful bedside examination together with measurement of heart rate and the hemodynamic determination of pulmonary capillary wedge pressure and cardiac output will identify the high risk subsets after acute myocardial infarction. It is in these patients that an aggressive, goal-oriented management program directed at reducing myocardial energy utilization must be instituted. The aim of this approach would be to control infarct size and reduce patient morbidity and mortality.

The high risk subsets among patients with acute myocardial infarction can be identified from the hemodynamic measurement of pulmonary capillary wedge pressure, cardiac output, stroke work and heart rate. Moreover it is possible to generate an expression of survival by discriminant function analysis for all patients on the basis of these data. This information will assist in the management of individual patients and will also permit evaluation and comparison of treatment programs and their influence on hospital survival.

Acknowledgment

Without the untiring efforts of the nine individual Myocardial Infarction Research Unit directors, their respective staff and Dr. R. A. Rosati, who collated all information for the Data Bank, this report would not have been possible. We gratefully acknowledge their contributions. The secretarial assistance of S. Pharaoh and M. Yachinsky is also deeply appreciated.

Coronary Anatomy and Arteriography in Patients With Unstable Angina Pectoris

HAROLD W. ALISON, MD
RICHARD O. RUSSELL, Jr., MD, FACC
JOHN A. MANTLE, MD
NICHOLAS T. KOUCHOUKOS, MD, FACC
ROGER E. MORASKI, MD
CHARLES E. RACKLEY, MD, FACC

Birmingham, Alabama

A prospective series of 188 patients with the syndrome of unstable angina pectoris undergoing coronary arteriography was reviewed to determine the spectrum of anatomic coronary artery disease, suitability for coronary revascularization and in-hospital morbidity and mortality. Thirty-two patients demonstrated normal to moderately diseased coronary arteries. None of these patients sustained myocardial infarction or died. Twenty patients (10.6 percent) had normal coronary arteriograms. Of the 156 patients having severe coronary artery disease (greater than 70 percent stenosis), 20 patients (13 percent) had left main coronary artery disease. One hundred forty-two patients (91 percent) were potential candidates for coronary surgery; 14 were not candidates because of distal vessel disease or poor left ventricular function. During cardiac angiography or in the subsequent hospital period 12 patients sustained a myocardial infarction and 7 of these died. Of these seven, six had left main coronary artery disease and one had three vessel disease. In three patients who died (1.9 percent of those with severe coronary artery disease) the death may have been related to cardiac catheterization because evidence of myocardial necrosis began within 24 hours of study. Thus, patients with the syndrome of unstable angina pectoris usually presented with severe coronary artery disease and were candidates for coronary revascularization. The anatomic severity of coronary artery disease appeared to be the most important factor contributing to myocardial infarction or death after cardiac catheterization. Mortality after catheterization was primarily associated with left main coronary artery disease.

Unstable angina pectoris is a clinical syndrome describing the patterns of ischemic chest pain interposed between acute myocardial infarction and chronic stable angina pectoris. Patients with this cardiac condition are at high risk for myocardial infarction and death.[1–39] However, some groups[6,14–16,18,30,31,34,38–40] have reported the short-term prognosis during the period of hospitalization to be benign. In an attempt to plan appropriate therapy for these patients, many physicians have recommended coronary arteriography as soon as feasible after exclusion of an acute myocardial infarction. Nevertheless, several difficulties face the clinician dealing with the syndrome of unstable angina pectoris. There are no uniform definitions or criteria for selection of patients. This problem is of critical importance because there are subgroups of unstable angina pectoris having greatly varying prognoses. Chahine[41] has discussed the difficulty of defining unstable angina pectoris with different prognoses. The clinical course of medically and surgically treated patients is still not clearly established. The risks of cardiac catheterization and left ventricular and coronary angiography are still controversial. In part, this results from lack of a clear definition of what constitutes a catheterization-related complication, that is, one occurring during catheterization or within a certain period after the procedure. As a means of examining

TABLE I

Anatomic Subgroups and Clinical Characteristics

Coronary Anatomy (no. of diseased vessels)	Cases (no.)	Male/Female Ratio	Mean Age (yr)	Angina Profile (Chronic/ At rest*/ STΔ's)	Electrocardiogram (Normal/ Abnormal [Scar])
Group A	156	131/25	53.5	116/153/86	31/125(61)
Severe CAD (1 v = 49, 2 v = 52, 3 v = 35)	136	115/21	53	98/135/81	29/107(53)
Left main CAD (0 v† = 3, 1 v† = 3, 2 v† = 5, 3 v† = 9)	20	16/4	58	18/18/5	2/18(8)
Group B	32				
Normal	20	15/5	48	15/20/1	12/8(1?)
Mild-moderate CAD	12	8/4	54	10/11/1	2/10(1)

* Pain at rest often did not occur after hospitalization and, when it did, an electrocardiogram was sometimes not recorded during an episode.
† Number of diseased vessels other than left main coronary artery.
CAD = coronary artery disease; 0 v = no vessel, 1 v = one vessel, 2 v = two vessels, 3 v = three vessels; STΔ's = S-T segment changes with angina at rest.

these problems a large prospective series of patients presenting with the syndrome of unstable angina pectoris was analyzed. This report reviews the spectrum of coronary arterial anatomy, suitability for coronary revascularization surgery and the in-hospital morbidity and mortality in these patients.

Methods

Selection of patients: During a 3 year period, 188 patients with the clinical syndrome of unstable angina pectoris underwent diagnostic angiography to evaluate coronary arterial anatomy and left ventricular function. All patients were evaluated clinically by one of the cardiology faculty. Unstable angina pectoris in this study was defined as (1) recent onset of effort angina, (2) changing pattern of effort angina (increasing frequency, intensity or duration), and (3) angina at rest. In addition, these various patterns of chest pain must have developed within 3 months of hospitalization and were not mutually exclusive. All patients with recent onset of effort angina also had angina at rest or a changing pattern of effort angina. Generally, ischemic symptoms persisted 5 or more minutes and were accompanied by transient ST-T wave changes in the electrocardiogram in patients with severe coronary artery disease. Electrocardiographic changes during chest pain were not essential for inclusion in the study. S-T segment changes were not considered diagnostic of ischemia unless they were 1 mm or greater.

Patients with serious noncardiac illnesses, significant nonischemic heart disease or acute myocardial infarction were excluded from analysis. Patients presenting with the syndrome of unstable angina but not seen by one of us were also excluded. Myocardial infarction was excluded after an observation period of at least 24 but usually 48 to 96 hours. During this time, evidence for myocardial necrosis included an abnormal rise and fall of serum levels of glutamic oxaloacetic transaminase (SGOT), creatine kinase (CK) and lactic acid dehydrogenase (LDH) with its isoenzymes; or evolutionary S-T segment or Q wave changes, or both, in serial electrocardiograms. CK isoenzyme analyses were not available at our institution during the period of this study.

Initial treatment: Patients were treated initially with bed rest, isosorbide dinitrate and nitroglycerin sublingually. If patients were taking propranolol, the dose was reduced to 80 to 160 mg/day; otherwise administration of the drug was not begun until after cardiac catheterization.

Angiography: After the initial observation period, coronary arteriography was performed using the Judkins or Sones technique.[42,43] Because systemic heparinization of patients undergoing coronary arteriography did not become routine until after this study was begun, 34 (18 percent) of the total patient population did not receive heparin during cardiac catheterization. Selective coronary cineangiograms filmed at a rate of 60 frames/sec and large roll films at 2 to 6 frames/sec in multiple projections were available for definition of coronary arterial anatomy. Left ventricular biplane angiograms were obtained at a rate of 6 frames/sec after ventricular injection of 50 to 60 ml of sodium and meglumine diatrozoates.[44]

Candidates for saphenous vein bypass grafting: Patients were considered potential candidates for surgery if 70 to 100 percent obstruction of the luminal diameter of one or more coronary arteries was present without diffuse distal vessel disease or poor left ventricular function. Ventricular function was considered poor primarily on the basis of an ejection fraction of less than 0.30 or generalized hypokinesia, or both, as documented with left ventricular angiography. Unsuitability for coronary revascularization was determined jointly by a cardiologist and a cardiac surgeon.

Classification of coronary anatomy: Disease in the lumen of the major coronary arteries was classified as follows: (1) absent (normal coronary arteries)—less than 25 percent stenosis; (2) mild to moderate coronary artery disease—25 to less than 70 percent stenosis; (3) severe coronary artery disease—70 to 100 percent stenosis, and (4) left main coronary artery disease—greater than 50 percent stenosis.

Results

Spectrum of Coronary Artery Disease

Subgrouping: On the basis of coronary anatomy, 188 patients presenting with the syndrome of unstable angina pectoris were classified into two major groups (Table I). The mean age of the patients was 53 years. One hundred fifty-four patients (82 percent) were men and 34 were women. Patients with severe coronary artery disease were classified in Group A, which consisted of 156 patients, including 20 with left main coronary artery disease and 136 with severe coronary artery disease without significant involvement of the left main

coronary artery. Group B was composed of 32 patients with normal or mildly to moderately diseased coronary arteries, including 20 with a normal coronary arteriogram and 12 with mild to moderate coronary artery disease.

Severe coronary artery disease without significant left main coronary involvement (Table I): The mean age of these 136 patients was 53 years; 115 were men and 21 were women. Excluding 2 patients with left bundle branch block, 53 patients (40 percent) had electrocardiographic evidence of an old myocardial infarction. Twenty-nine patients (21 percent) had a normal electrocardiogram. All but one of the patients had angina at rest. Ninety-eight patients (72 percent) had a history of chronic angina (chest pain for more than 3 months) and two had a questionable history of chronic angina. One hundred twelve patients had chest pain in the hospital and 98 had an electrocardiogram taken during episodes of pain. With the exclusion of 2 patients who had a marked intraventricular conduction abnormality, 81 patients (83 percent) of those having an electrocardiogram during chest pain were documented to have transient ischemic S-T segment changes. The 136 patients with severe coronary artery disease without disease of the left main coronary artery were further classified into those with 70 to 100 percent stenosis of one, two or three vessels; 49 (36 percent) had one vessel disease, 52 (38 percent) had two vessel disease and 35 (26 percent) had three vessel disease. Thus, approximately two thirds of these patients had multivessel disease.

Left main coronary artery disease: Twenty of the 156 patients (13 percent) had greater than 50 percent stenosis of the left main coronary artery and 18 of these 20 demonstrated 70 percent or greater stenosis in this artery. The mean age for this group was 58 years; 16 were men and 4 were women. Eight patients (40 percent) had electrocardiographic evidence of old myocardial infarction. Two patients had a normal electrocardiogram. Eighteen patients had a history of chronic angina and 18 had a history of angina at rest. Among the 10 patients who had chest pain in the hospital, 8 had an electrocardiogram during pain. In five of these eight transient ischemic S-T segment changes were recorded during episodes of chest pain. The patients were then classified according to the number of severely involved vessels in addition to the left main coronary artery. Only 3 of the 20 had severe disease limited to the left main coronary artery; 3 had single vessel, 5 had two vessel and 9 had three vessel coronary artery disease in addition to the left main stenosis. Thus, a large majority of patients with left main coronary artery disease also had severe involvement of the remaining coronary arteries.

Normal coronary arteriograms: Twenty (10.6 percent) of 188 patients with unstable angina pectoris had a normal coronary arteriogram. The mean age of these patients was 48 years; 15 were men and 5 were women. All of the patients presented with a history of angina at rest that usually was prolonged and responded poorly to nitrates. Twelve patients had a normal electrocardiogram and eight had an abnormal electrocardiogram that in one suggested a remote myocardial infarction. Of the 13 patients who had an electrocardiogram recorded during chest pain, one was thought to have had ischemic S-T segment depression. Eighteen patients had one or more major risk factors; in the remaining patient the presence of risk factors was not known.

Candidates for Saphenous Vein Bypass Grafting

The 156 patients with severe coronary artery disease were analyzed according to suitability for saphenous vein bypass grafting as determined from coronary anatomy and left ventricular function (Table II). One hundred forty-two of the 156 patients (91 percent) were considered potential surgical candidates because they had one or more graftable vessels and adequate left ventricular function. However, 44 patients (28 percent) had single vessel disease and surgery was often not advised by their primary physicians. The condition of 14 (9 percent) of the patients was considered inoperable because of diffuse distal vessel disease or poor left ventricular function, or both.

In-Hospital Morbidity and Mortality

Incidence of major complications: Major in-hospital complications of these patients with unstable angina pectoris were myocardial infarction and death. There were no deaths or myocardial infarctions as a result of an arrhythmia at the time of cardiac catheterization. No patient sustained a cerebrovascular accident. Twelve of the 156 patients (7.7 percent) with severe coronary artery disease (Group A) sustained an acute myocardial infarction; five patients survived and

TABLE II

Candidacy for Saphenous Vein Bypass Grafting in 156 Patients With Severe Coronary Artery Disease

	Patients	Percent
Candidates for grafting	142	91
Single vessel disease	44	28
Multivessel disease	98	63
Noncandidates for grafting	14	9
Severe distal vessel disease	8	. . .
Poor left ventricular function	4	. . .

TABLE III

In-Hospital Myocardial Infarction or Death, or Both

Anatomic Groups	Patients (no.) Total	AMI	Death
Group A	156	12 (7.7%)	7 (4.5%)
Severe CAD	136	6 (4.4%)	1 (0.7%)
Left main CAD	20	6 (30%)	6 (30%)
Group B	32	0	0
Normal	20	0	0
Mild-moderate CAD	12	0	0
Groups A + B	188	12 (6.4%)	7 (3.7%)

AMI = acute myocardial infarction; CAD = coronary artery disease.

seven died (Table III). No patient in Group B with normal to moderately diseased coronary arteries sustained an acute myocardial infarction or died.

Analysis of patients sustaining an acute myocardial infarction: In Table IV each of the patients sustaining an acute myocardial infarction in-hospital is analyzed according to severity of stenosis of major coronary arteries, onset of symptoms, survival and clinical characteristics. Of the seven patients who died, six had left main coronary artery disease and one had hypothyroidism and severe three vessel disease. Three patients had symptoms and evidence of myocardial infarction within hours of coronary angiography and died within 24 hours of the procedure. Two patients had a myocardial infarction after 24 hours and died within 48 hours. One patient had a myocardial infarction after 48 hours and died within 72 hours. The last patient had a myocardial infarction 11 days after cardiac catheterization and died on the 12th day. Each of the patients who died had prior stable angina for at least 2 years. Four of the seven patients had a history of a previous myocardial infarction with pathologic Q waves. One patient had a history of an old myocardial infarction with nonspecific ST-T wave abnormalities. Electrocardiograms in the two remaining patients also revealed nonspecific ST-T wave abnormalities.

Of the five patients surviving an acute myocardial infarction, three had symptoms and evidence of myocardial necrosis during or several hours after cardiac catheterization. One patient sustained a myocardial infarction 9 days after catheterization. All of these patients had a prior history of stable angina with recent onset of angina at rest and abnormal electrocardiograms. Three had a history of a previous myocardial infarction that was confirmed in two by pathologic Q waves; the third patient's electrocardiogram exhibited nondiagnostic ST-T wave abnormalities. Of the remaining two patients, one had left bundle branch block and the other had left ventricular hypertrophy. Thus, among 12 patients sustaining an acute myocardial infarction, symptoms and evidence of myocardial necrosis developed in 6 patients within 24 hours, in 3 patients from 24 to 48 hours and in 2 patients more than 72 hours after cardiac catheterization.

Discussion

In the spectrum of symptomatic coronary artery disease, the clinical syndrome of unstable angina pectoris is placed between stable angina pectoris and myocardial infarction. Fowler[45] proposed the term "unstable angina," but the condition has been variously labeled since its original description in 1937 by Sampson and Eliaser[1] and Feil.[2] Some of these designations include "preinfarctional angina,"[9] "acute coronary insufficiency,"[10] "impending myocardial infarction,"[3] "intermediate coronary syndrome,"[7] "status angiosus,"[12] "accelerated angina pectoris"[22] and "crescendo angina."

Studies of the natural history of unstable angina pectoris have indicated considerable variation in the incidence of myocardial infarction and death.[7,8,11–16,21–24,26–28,30–32,35–40] These discrepancies may be due to differences in definitions and criteria of selection of patients with unstable angina pectoris. In particular, the older reported studies suffer from a lack of angiographic documentation of the severity of coronary artery disease. Indeed, the natural history of angina pectoris has been shown by Bruschke,[46] Friesinger,[47] Reeves[48] and Oberman[49] and their co-workers to correlate more closely with coronary anatomy on angiography and left ventricular function than with clinical data or definitions alone. Our investigation provides information on coronary anatomy and left ventricular function in patients with unstable angina pectoris and its subgroups. Furthermore, these observations are related to in-hospital myocardial infarction and death and to suitability for coronary bypass surgery.

Unstable angina with normal coronary arteriogram: Of the patients presenting with the syndrome of

TABLE IV

Data on 12 Patients Who Had an In-Hospital Myocardial Infarction or Died, or Both

Case no.	Age (yr) & Sex	Coronary Stenosis*				Onset After Cath		Prior Angina	History of MI	ECG

12	60F	0	5	4	6	9 days	. . .	1 yr	No	LVH

* Grading of stenosis: 0 = absent; 1 = <25 percent; 2 = 25 to <50 percent; 3 = 50 to <70 percent; 4 = 70 to <90 percent; 5 = 90 to 99 percent; 6 = 100%.

† Did not receive systemic heparin.

Cath = cardiac catheterization; ECG = electrocardiogram; LAD = left anterior descending coronary artery; LBBB = left bundle branch block; LCx = left circumflex coronary artery; LM = left main coronary artery; LVH = left ventricular hypertrophy; MI = myocardial infarction; NDSTT = nondiagnostic ST-T wave abnormalities; RCA = right coronary artery.

unstable angina pectoris, 10.6 percent had normal coronary arteriograms. Similar findings have been reported in other studies.[19,23,36,39,50–52] Review of anginal pattern, electrocardiograms and risk factors for atherosclerosis did not distinguish the individual patients with normal coronary arteriograms from those presenting with unstable angina pectoris and severe coronary artery disease. However, as a group, the former had a less typical history for angina pectoris and were more likely to have an electrocardiogram that was normal or lacked evidence of a previous myocardial infarction.

Left main coronary artery disease and mortality: An additional 10.6 percent of the patients with unstable angina pectoris had left main coronary artery disease. This finding is in agreement with data from other recent studies.[22,35,53–55] Ten percent of our patients with left main coronary artery disease were thought to have died as a result of cardiac catheterization because they had symptoms or evidence of myocardial necrosis within 24 hours of the procedure. This mortality rate seems excessive when compared with other experiences.[22,50,53,54,56–58] Possible reasons for our higher mortality rate are a small number of patients (20) for statistical analysis, lack of routine heparinization, myxedema in one of the two fatal cases and occurrence of both deaths during the earlier years of experience with coronary arteriography when present techniques were not uniformly used.

Of the patients with severe coronary artery disease, 91 percent were considered potential candidates for saphenous vein bypass grafting on the basis of one or more bypassable vessels and adequate left ventricular function. Thirty-one percent of the surgical candidates had single vessel disease. The primary physician often elected to treat these patients medically. In a group of 65 patients undergoing surgical treatment for unstable angina pectoris at our institution, there were no hospital deaths.[59]

Myocardial infarction and death related to cardiac catheterization: The in-hospital risks of myocardial infarction and death are related to the severity of coronary artery disease. All patients experiencing a serious complication had 70 percent or greater stenosis of the major coronary vessels. Myocardial infarction and death were attributed to cardiac angiography only when these complications developed within 24 hours of the procedure. Thus, 6 of 188 patients (3.2 percent) presenting with unstable angina may have sustained a myocardial infarction as a result of cardiac angiography that in three cases culminated in death (1.6 percent). Because no emergency coronary bypass procedure was performed no catheterization-related infarction or death would be considered a complication of surgery. In the first 65 patients undergoing coronary revascularization, there was an interval of 10.4 ± 2 days (mean ± standard error of the mean) between coronary arteriography and bypass surgery. There were no in-hospital deaths.[59] Intraaortic balloon pumping was not used during the period of this study.

Characteristics of high risk subgroup with unstable angina: Patients who sustained a myocardial infarction or died in the hospital had unstable angina that usually met the criteria of an extremely high risk subgroup of patients with "preinfarctional angina" described by Gazes et al.[21] or a subgroup with the "intermediate syndrome" described by Bertolasi et al.[36,37] The high risk subgroup of Gazes et al. had a 43 percent 1 year mortality rate. The subgroup of Bertolasi et al. with the "intermediate syndrome" treated medically had a 35 percent mortality rate after a mean follow-up period of 8.3 months[36] and a 46 percent mortality rate after a mean follow-up period of 32 months.[37] The main clinical features of patients in these extremely high risk subgroups were (1) prolonged episodes of angina at rest usually continuing in the hospital and responding poorly to nitrates, (2) transitory ST-T wave changes in the electrocardiogram during episodes of chest pain, and (3) usually a history of stable angina or a previous myocardial infarction, or both.

Implications: Several pertinent facts are apparent from these data on patients presenting with the clinical syndrome of unstable angina pectoris and undergoing cardiac catheterization and angiography. The patients usually have severe coronary artery disease and are potential surgical candidates. A significant percent have left main coronary artery disease but, equally important, a significant percent have normal coronary arteries. There may be an increased risk of myocardial infarction and death from coronary and left ventricular angiography as judged from symptoms or evidence of myocardial necrosis occurring in the first 24 hours after cardiac catheterization. Anatomic severity of coronary artery disease is the most important factor predisposing to myocardial infarction and death. In-hospital death in patients with unstable angina undergoing coronary arteriography occurs primarily in those with disease of the left main coronary artery.

Tortuosity as an Index of the Age and Diameter Increase of Coronary Collateral Vessels in Patients After Acute Myocardial Infarction

GROVER M. HUTCHINS, MD
MARTIN M. MINER
BERNADINE H. BULKLEY, MD, FACC

Baltimore, Maryland

A possible correlation among increase in diameter, lengthening or tortuosity and age of bypassed obstruction was investigated in coronary arterial collateral vessels. In 35 autopsy patients with a myocardial infarct of known age, as determined from clinical history and pathologic demonstration of an infarct of consistent age in the distribution of an obstructed vessel, 140 collateral vessels were identified in postmortem arteriograms and measurements made of their diameter and tortuosity. Multivariable regression analyses showed that collateral diameter and tortuosity increase with greater time after the infarction. It is suggested that identification of tortuosity in a coronary vessel may provide an indication that it functions as a collateral channel and of the degree of its dilatation and the time it has been a collateral channel. The lengthening that produces tortuosity probably arises from the same relaxation of medial tension that induces dilatation as a result of increased blood flow.

Little is known about the morphology and time course of the development of the collateral circulation in human beings with occlusive coronary artery disease.[1,2] A major problem in the study of the development of human coronary arterial collateral vessels is the necessarily limited number of sequential observations that can be obtained in any one subject. The variability in collateral patterns among species makes studies of the time course of changes in caliber of the collateral channels in various animals of limited value in understanding the human situation.

We have noted while reviewing postmortem coronary arteriograms from patients with and without coronary atherosclerosis[3,4] and with coronary arterial occlusive lesions[5] that collateral vessels appeared not only to increase in diameter but also in length after myocardial infarction. Lengthening of such arteries, fixed at either end by their connections, produces a tortuosity of the vessel. The observation that collateral channels may be tortuous is not new. In 1762, William Hunter,[6] describing the features of the collateral vessels bypassing occluded arteries, stated: "Whatever distends, must at the same time, lengthen them, and thereby produce serpentine turns." In 1883, von Recklinghausen[7] noted that as collateral vessels carry more blood they become thicker and more tortuous. Although numerous studies have been performed on collateral vessels, especially coronary collateral vessels, in recent years little attention appears to have been given to tortuosity.

Although the age of infarction is not a precise index of age of coronary occlusion because most vessels have some narrowing before infarcts occur, it does provide an identifiable point when blood flow through the coronary artery was suddenly diminished and such a change should be a stimulus for collateral vessels. Using this general relation in this study,

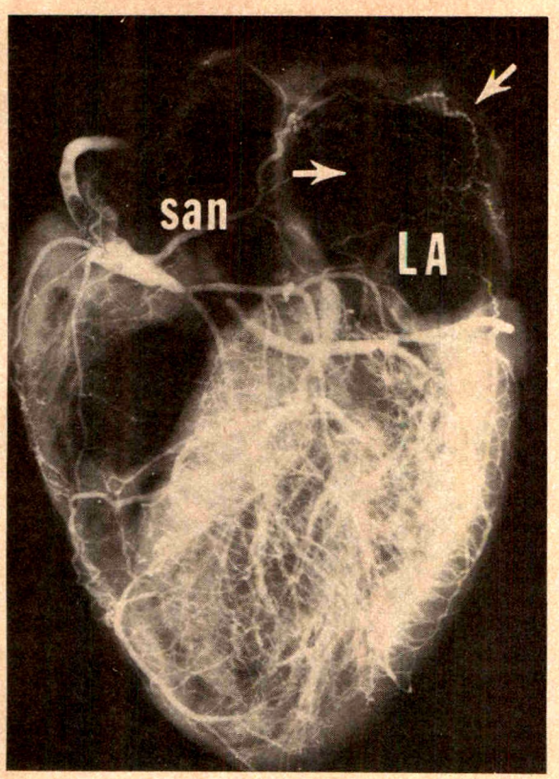

FIGURE 1. Postmortem coronary arteriogram of a patient with severe three vessel obstructive coronary atherosclerosis. The circulatory patterns are very complex, probably as a result of development of obstructive lesions of various ages. Note the dilated tortuous "corkscrew" collateral channels **(arrows)** traversing the left atrial (LA) wall. The sinoatrial nodal artery (san) is supplying blood to the distal right coronary and left circumflex arteries through the collateral channels.

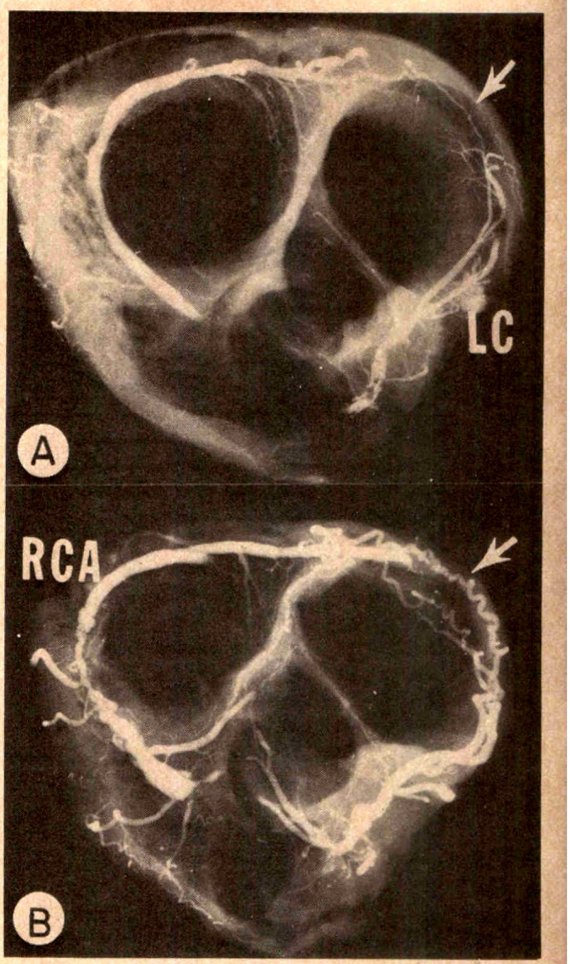

FIGURE 2. Collateral vessels **(arrows)** joining the left circumflex (LC and right coronary arteries (RCA). In these two hearts, the collatera vessels lie parallel to the plane of the radiograph and were suitable fo the measurements made in this study. **A,** the distal left circumfle coronary artery is filled from the right coronary artery. The myocardia infarct produced by coronary occlusion was 3 1/2 weeks of age. Th collateral channel is small in caliber and only slightly tortuous. **B,** th right coronary arterial obstruction had caused a myocardial infarct 1 years before death. The collateral channels filling the distal right cor onary artery from the left circumflex branch are large and markedl tortuous.

we have identified collateral bypass channels in the coronary vasculature of patients with occlusive coronary arterial lesions that produce myocardial infarcts of known age. The diameter and tortuosity of the collateral vessels were measured and compared with the patient's age, heart weight and age of occlusion for which the collateral channel was a bypass. The results show that tortuosity increases with the interval after myocardial infarction, the latter reflecting in part the time a vessel functions as a collateral channel.

Materials and Methods

Patients from the autopsy files of The Johns Hopkins Hospital were included in this study if they met the following criteria: (1) Their heart had been studied after coronary arteriography and fixation in distension.[8] (2) There was a total occlusion or significant (greater than 75%) obstruction of the luminal cross-sectional area of a major coronary artery with an associated myocardial infarct of known clinical age that was confirmed by pathologic study. Precise age of infarction was determined from a definite clinical history plus a pathologic demonstration of a myocardial infarct of consistent age as determined from gross and histologic features.[5] (3) One or more collateral vessels through which the coronary artery distal to the occlusion was being filled could be visualized in the plane of the postmortem arteriograms (Fig. 1 and 2).[1] Review of radiographs in multiple views and in stereoscopic projection allowed resolution of overlapping vessels. Collateral channels that ran obliquely to the plane of the radiograph were not included in the study.

Pathologic study: Coronary arteriography was performed in hearts obtained at autopsy by injection of a gelatin-pigment-barium mass with added formalin at pressures of 100 to 150 mm Hg controlled by manometer. The injection mass used is viscous and usually fills arterioles but not capillaries.[9] After completion of injection, hearts were fixed in distension with formalin at 20 to 40 cm water pressure introduced into the chambers through cannulas tied into the major vessels. Sets of stereoscopic radiographs were prepared on the intact heart and its transverse sections. The hearts were studied grossly and histologically for the presence of myocardial lesions and obstructive lesions of the coronary arteries. The

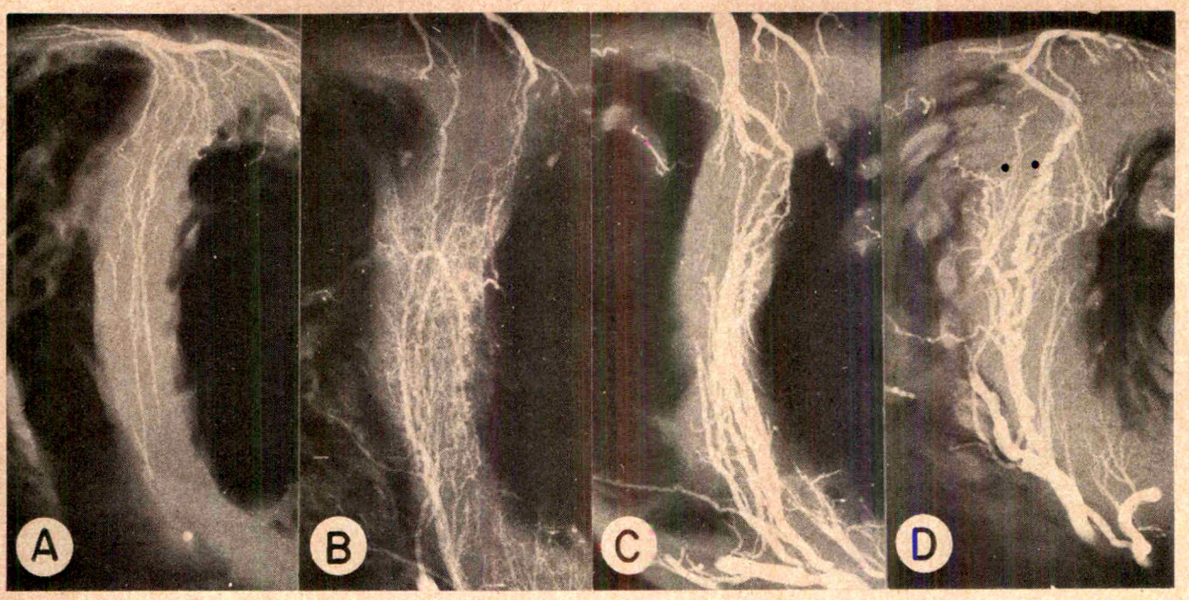

FIGURE 3. Series of radiographs of the interventricular septum of four hearts showing collateral channels bypassing coronary arterial obstructions of increasing age. Tortuosity (length) and dilatation increase with time. Numerous collateral vessels may be present at some stages but a few channels appear to become the preferred channel of flow. The most marked tortuosity is present in the mid part of the collateral. The radiographs are all oriented as in Figure 2 with the anterior interventricular septum toward the bottom and the left ventricle on the right side. In **A** and **C,** occlusions of the left anterior descending coronary artery had produced myocardial infarcts 3 days and 8 years, respectively, before death. The septal branches of the left anterior descending coronary artery are filled through collateral channels from the septal branches of the right posterior descending coronary artery. In **B** and **D,** proximal right coronary occlusions had produced infarcts in that vessel 9 days and 14 years, respectively, before death. The septal branches of the right posterior descending coronary artery are filled through collateral channels from the septal branches of the left anterior descending coronary artery.

pathologic findings were correlated with the clinical information in each case.

The diameter of collateral vessels was measured on the radiographs using an optical device with a scale calibrated to 0.1 mm. The diameter was determined from measurement of the mid portion of each collateral vessel and a representative diameter agreed upon by consensus among the observers[10] was ascertained. There was little intraobserver variability. The tortuosity of each collateral vessel was determined and expressed as cycles per centimeter by measuring the distance traveled, counting the number of wave cycles in that distance and dividing the number of cycles by the distance traveled. The cycles were counted from peak to peak. Cycle number was chosen and the amplitude of the waves and the three-dimensional excursions of the vessel were disregarded because of the difficulty and inaccuracy of determinations of each vessel length.

Statistical analysis: Data were obtained from measurements of collateral vessels, the patient's age, heart weight and the age of the coronary arterial occlusion associated with the collateral circulation as determined from the clinical history of the myocardial infarct confirmed with pathologic study. The facilities of The Johns Hopkins University Computer Center were used to carry out multivariable regression analysis using Biomedical Computer Program BMD02R.[11]

Results

Among the 980 autopsy patients whose heart had been studied after coronary arteriography and fixation in distension there were 35 hearts with 140 collateral vessels that had the proper orientation on the arteriograms for performing the measurements made in this study. The patients ranged in age from 35 to 86 years (average 65). The period of survival after the myocardial infarct, of which the causative coronary arterial obstruction was the subject of study, ranged from 2 days to 16 years. The heart weights ranged from 320 to 960 g (average 530).

In the 35 hearts 21 of the obstructive lesions being bypassed by the collateral vessels were total occlusions. The remaining 14 coronary lesions were obstructions of 75 to 99 percent of the luminal cross-sectional area. Percent luminal narrowing was estimated visually by comparing transverse sections of coronary arteries with a standard chart of measured reductions of luminal area. The 140 collateral channels identified ranged from 0.7 to 8.2 cm in linear distance from point of origin to termination. The diameter of the collateral vessels ranged from 0.2 to 1.6 mm.

Sequence of changes in collateral flow: The impression was gained from review of the arteriograms that in the early stages after acute myocardial infarction a number of channels dilate, function as collateral vessels and become tortuous. With passage of time a few collateral channels appear to be selected as preferential channels of flow and undergo further dilatation and tortuosity. The apparent sequence of changes in collateral flow through the vascular bed of the interventricular septum is illustrated in Figure 3. Inspection of angiograms also shows that in the entire course of the collateral channel between two larger arteries the greatest tortuosity occurs in its mid portion. The mid part of the collateral vessel is the portion that would undergo the greatest dilatation because the proximal

and distal ends would be larger vessels arising from the supplying and supplied arteries.

Relations among collateral tortuosity, heart weight, age of infarction, patient's age and collateral diameter: Relations were sought among collateral tortuosity, age of infarction, heart weight, patient's age and collateral diameter. The logarithmic values of heart weight and age of occlusion were chosen to simplify graphic representation of the data (Table I). Correlation coefficients of these variables are shown in Table II. An equation predicting tortuosity of the collateral vessel from heart weight, age of infarction, collateral diameter and patient's age and equations predicting age of infarction and collateral diameter from the other variables were calculated using multivariate regression analysis. The program[9] makes predictive formulas by choosing from up to 99 variables in the sequence of their F values for inclusion. It begins by fitting a linear regression to the data and then adds single terms to the simple regression, obtaining a multivariate correlation coefficient for each step. Only statistically significant ($P < 0.05$) variables are entered into the equation as determined by the F value to enter. All variables were assigned a free status, allowing the program freedom to choose only those of significance for entrance into the formulas.

The formulas (Table III) show that collateral tortuosity may be predicted by age of infarction and diameter of collateral vessel. The older the infarct, the more tortuous the collateral channels. The larger the vessel, the less the tortuosity and the fewer cycles per centimeter it will have. The predictive formula obtained for logarithmic age of infarction illustrated a correlation with collateral caliber and tortuosity. Collateral vessels bypassing infarcts and presumably older occlusions are more tortuous and of larger caliber. The diameter of the collateral vessel is predicted from the age of the infarct with which it is associated, except that the caliber will be less the greater the number of cycles per centimeter found. The reduction of tortuosity expressed as cycles per centimeter in larger vessels simply reflects their lesser ability to accommodate reversals of direction within a given net distance traveled.

Discussion

Mode of formation and growth of collateral vessels: With the onset of occlusion of an epicardial coronary artery, those channels in communication between the distal nonperfused artery and adjacent arteries will have a pressure gradient favoring flow into the vessel distal to the obstruction, as shown in animal experiments.[1,2] It has been suggested that the dilatation of a vessel that occurs with an increase in flow is a result of increase in the shear stress on the endothelium.[12] This endothelial shear stress may induce local relaxation of medial smooth muscle and dilate the vessel. Dilatation continues until the drag on the endothelium returns to its control value. Once shear stress is diminished, the vessel wall regains its normal state of tension. Subsequently complete anatomic reorganization around the dilated caliber occurs, as indicated experimentally in dogs by an increase in mitotic activity of both the endothelial and smooth muscle cells in the coronary collateral channels.[13] Similar observations after experimental vascular interruption in the collateral fields of the rat mesentery[14] have shown that the most constant and progressive changes were increased diameter and tortuosity. It seems likely that a similar postocclusive dilatation and lengthening of the collateral beds stimulates the proliferation of collateral vessels in human beings as well. In man, however, unlike dogs and other experimental animals, the native collateral vessels

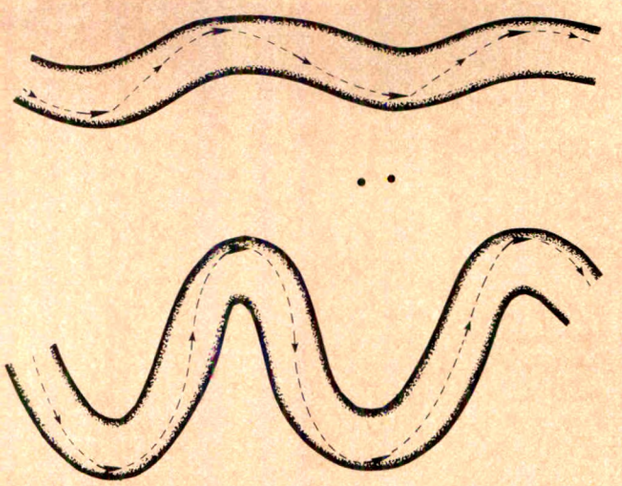

FIGURE 5. Diagram of the shift in the axial stream of most rapid flow as a result of increased tortuosity. As a result of the change in direction of flow at the peaks of the curves the flow impinges on the outer wall and tends to elongate the intervening straight segments between the bends.

do not appear to be substantial,[1] and actual vascular growth in response to arterial occlusion is of even greater significance.

Correlation of age of infarction and tortuosity and caliber of collateral vessels: The relation between age of infarction and the tortuosity and caliber of collaterals found in our study is shown diagrammatically in Figure 4. If, as suggested, the dilatation of collateral vessels is caused by relaxation of the medial smooth muscle as a direct consequence of increased flow related to occlusion, then the concomitant increase in length of the vessel must also result from proliferation of vessel wall. The increased length is seen as tortuosity because the ends of the vessels are fixed. The development of tortuosity may initially be an accentuation of deviations from a perfectly straight course. As the vessel bends, the axial stream deviates from the mid line (Fig. 5) and, as it impinges on first one wall and then another, would tend to lengthen the intervening segment of relaxed dilating vessel. The constraints of the surrounding tissue, and diverging course of branch vessels would constrain the excursions and force the vessel to acquire new cycles as well as to lengthen the existing ones.

Limitations of study: Although we believe it essential to study collateral vessels, which are species-variable, in patients with atherosclerosis, there are some inherent limitations to this approach to human collateral channels. Because it is impossible to determine the time course of the development of coronary arterial narrowings, which undoubtedly occur over a long period of time, we have used the age of infarction as a readily identifiable event, confirmable at autopsy, when coronary flow was suddenly and drastically impaired. Because this latter event should be a stimulus for collateral development, the data collected in our study have been interpreted as though collateral vessels began to function with the onset of the clinically datable occlusion that caused a myocardial infarct. It is probable that some collateral development was already present and would have been influenced by the duration and degree of obstruction in the coronary arteries preceding the onset of the clinical infarction. Another factor that we were not able to take into account is the distribution and severity of atherosclerosis in the entire coronary arterial bed, which may also influence the development of collateral vessels. For example, the complex pattern of collateral filling shown in the heart in Figure 1 is probably attributable to the severe three vessel disease with obstructive lesions of various ages.

Vascular reactivity of collateral vessels: Despite these limitations, the age of infarction does appear to vary directly with collateral size and tortuosity. Furthermore, the time course of collateral development identified here is compatible with clinical observations at angiography. In our study new vessels comparable in caliber with smaller epicardial coronary arteries formed within 6 months, and this finding is compatible with the reports of Fam and McGregor[15] that the greatest improvement in collateral function after administration of nitroglycerin occurred in patients with ischemic symptoms for more than 6 months. Vascular remodeling is probably of importance in the development of nitroglycerin responsiveness. It has been shown that collateral vessels in patients without coronary disease are largely unresponsive to nitroglycerin.[16] The "natural" collateral vessels have a very thin muscular coat as well as a small caliber and the increase in the smooth muscle component of these vessels is probably an important aspect of acquired responsiveness to nitroglycerin. It remains to be determined whether collateral tortuosity as a morphologic marker readily identifiable at the time of coronary angiography correlates with the ability of collateral vessels to respond to vasodilators.

Diameter and tortuosity of collateral vessel as an angiographic index of age of coronary occlusion: In our postmortem angiographic study it appears that the age of the coronary occlusion associated with infarction can roughly be estimated when vessels of determined diameter and tortuosity are fitted to the graph

in Figure 4. The greater the collateral tortuosity, the older the age of infarction. Angiographic visualization of intercoronary collateral circulation has been used as an indirect sign of significant coronary arterial luminal narrowing, even if the coronary lesion is not readily apparent.[17] Our findings suggest that, in a similar fashion, the diameter and tortuosity of the collateral vessel may be a rough but useful angiographic index of age of vascular occlusion.

Clinical implications of a collateral tortuosity index: The importance of collateral vessels to the preservation of myocardium in patients with occlusive atherosclerotic disease is still uncertain and the subject of some controversy.[1] Although collateral vessels may take time to develop and acquire dimensions of value in human beings, and thus are of limited use in the setting of acute infarction, it is difficult to deny at least a potential value of a well developed collateral system to the long-term survivor of acute coronary occlusion. Whether the course of survivors of acute myocardial infarction in terms of reinfarction, late arrhythmias or sudden death is influenced by the degree of collateral proliferation or its time course of development are important issues to resolve, especially if interventions become available that can selectively enhance such collateral growth. A tortuosity index may be of use in such determinations.

In conclusion, the growth of collateral vessels, like the growth of normal vessels, is by both dilatation and lengthening. Increased length is appropriate for the growing body but in the collateral vessel, which is constrained by relatively fixed points of origin and termination, the excess length is accommodated by increasing tortuosity. The extent to which a collateral channel of a given size is tortuous is an indication of the time it has functioned as a bypass for an obstructed vessel.

Angiographic Evaluation of the Natural History of Normal Coronary Arteries and Mild Coronary Atherosclerosis

BAUDOUIN MARCHANDISE, MD
MARTIAL G. BOURASSA, MD, FACC
BERNARD R. CHAITMAN, MD, FACC
JACQUES LESPERANCE, MD

Montreal, Quebec, Canada

Between September 1966 and September 1976, a group of 48 patients with normal coronary arteries or nonsignificant coronary atherosclerosis documented in a first coronary arteriogram underwent a second angiogram because of persistent or recurrent chest pain. The interval between studies was 13 to 108 months (mean 42 months). The indication for the first angiogram was typical or atypical anginal pain. The patients were separated into two groups according to the results of the first angiogram. Group I included 22 patients, 9 men and 13 women, with normal coronary arteries (mean age 49 years, range 28 to 62). Group II included 26 patients, 18 men and 8 women, with coronary stenosis of less than 50 percent of intraluminal diameter (mean age 49 years, range 38 to 63). The second angiogram revealed normal coronary arteries in all 22 patients in Group I but showed progression of disease in 7 (27 percent) of the 26 patients in group II. The coronary arterial narrowings were greater than 50 percent in four patients and greater than 70 percent in only two patients. The clinical course, coronary risk factors and interval between angiograms were not useful predictors of progression of disease. The data suggest that coronary artery disease is unlikely to develop in adults with normal coronary arteries and that roughly 75 percent of adults with nonsignificant atherosclerosis will not show progression of disease over a 3 to 4 year period.

Previous reports[1,2] have shown that at least one third of patients undergoing coronary arteriography for the evaluation of chest pain have normal coronary arteries or mild nonobstructive atherosclerosis. Whereas the natural history of patients with obstructive coronary disease has been widely reported,[3–5] little has been written about the course of patients with normal coronary arteries or nonsignificant atherosclerosis. Their clinical prognosis is generally believed to be benign[6,7] although many remain symptomatic years after their initial coronary arteriogram.[6] It is often not clear whether the persistence of symptoms is related to the development or the progression of coronary disease. Knowledge of the rate of progression of coronary atherosclerosis is important both for the long-term management of this large group of patients and for better insight into the natural history of coronary disease in general. Therefore, in this study we evaluated angiographic developments in patients with normal coronary arteries or minimal nonobstructive coronary disease.

Material and Methods

Between September 1966 and September 1976, a total of 8,630 patients had coronary arteriograms at the Montreal Heart Institute. Of these, 2,025 (23 percent) had normal coronary arteries and 838 (10 percent) had nonobstructive coronary disease (less than 50 percent stenosis of intraluminal diameter). Among these, 48 patients were studied who met the following criteria: (1) two examinations performed at intervals of more than 12 months; and (2) coronary arteriograms of good technical quality to allow adequate comparison between studies.

TABLE I

Patient Material

	Group I*	Group II*
Patients (no.)	22	26
Associated cardiac disease (no. of patients)	13	8
Men (no. and percent)	9 (41%)	18 (70%)
Age (yr) (average and range)	49 (28–62)	49 (38–63)
Interval between studies (mo) (average and range)	52 (13–108)	37 (14–86)

* Group I = normal coronary arteries; Group II = coronary stenosis of less than 50 percent.

Patients with associated cardiac lesions who required sequential studies were not excluded.

The average interval between examinations was 42 (13 to 108) months. The first coronary arteriogram was usually obtained to evaluate typical or atypical chest pain. The second angiogram was later required because of persistent or recurrent anginal pain or because of the development of a significant cardiac event.

Patients: The patients were separated into two groups according to the results of the first coronary arteriogram (Table I). Group I consisted of 22 patients with normal coronary arteries. There were 9 men and 13 women with a mean age of 49 (28 to 62) years. Group II contained 26 patients with less than 50 percent coronary stenosis. There were 18 men and 8 women with a mean age of 49 (38 to 63) years. The time interval between studies was approximately 4 1/2 years in group I and 3 years in group II. Thirteen patients in group I and eight patients in group II had associated cardiac lesions such as cardiac valve disease or cardiomyopathy. In addition, two patients in group I had mitral valve prolapse and one had Prinzmetal's angina. Two patients each in groups I and II had an intercurrent myocardial infarction.

Patients in group II were then classified into two subgroups according to whether the coronary lesions evident in the second angiogram remained unchanged (group IIa: nonprogressive atherosclerosis, 19 patients) or increased (group IIb: progressive atherosclerosis, 7 patients).

Clinical data: In all patients, clinical data between studies and atherosclerotic risk factors were recorded. Typical angina was noted when pain of constrictive or oppressive character, localized in the precordium, was precipitated by exertion and relieved by rest. Atypical pain consisted of thoracic pain or discomfort that was in part characteristic of typical angina.

TABLE II

Coronary Anatomy in Group II (coronary stenosis of less than 50 percent)

	Cases (no.)
Degree of stenosis	
≤25%	11
<50%	15
Site of lesion	
Left anterior descending coronary artery	20
Left circumflex coronary artery	12
Right coronary artery	17
Number of arteries diseased	
One	9
Two or three	17

A family history of coronary artery disease was noted when angina or a coronary event occurred before age 50 in one or more first degree relatives. Smoking was defined as the use of at least 10 cigarettes a day for at least 5 years. High blood pressure was considered present when the diastolic blood pressure was greater than 100 mm Hg on three successive occasions. Blood lipid abnormalities were defined as a serum cholesterol level greater than 250 mg/100 ml or serum triglyceride values greater than 180 mg/100 ml, or both. Diabetes was defined as a persistent elevation of blood glucose level requiring administration of either insulin or orally given hypoglycemic agents.

Coronary arteriography: The technique used at this institution has previously been described.[8] The angiographic films were interpreted successively by an experienced cardiovascular radiologist. Angiographic progression of disease was recorded when there was a new stenosis of 25 percent or more of the intraluminal diameter of the artery or if a preexisting stenosis increased to 25 percent or more.

Results

Normal Coronary Arteries

Coronary atherosclerosis did not develop in any of the 22 patients in group I even though 2 patients had a well documented myocardial infarction. The interval between examinations averaged 4 1/2 years in the total group and exceeded 4 years in 11 patients.

Less than 50 Percent Coronary Stenosis

Initial angiograms: Table II shows the distribution and severity of lesions in patients in group II. Eleven had stenosis equal to or less than 25 percent and 15 had stenosis of more than 25 percent but less than 50 percent. The left anterior descending coronary artery was the most commonly diseased artery. Nine patients had plaques limited to a single coronary artery and 17 had plaques in more than one artery.

Follow-up angiograms: Seven of the 26 patients (27 percent) in group II had progression of disease after an average interval of 3 years. Atherosclerosis progressed in 12 arteries of the seven patients (Table III). Five of the 12 arteries manifested progression to more than 50 percent stenosis and two showed progression to complete occlusion (Fig. 1).

Table IV lists the arteriographic findings in the patients who had progression of disease at the time of their second arteriogram, which was performed an average of 46 months after the first (group IIb). Of five patients restudied for persistent atypical angina three had progression to stenosis of less than 50 percent of the in-

traluminal diameter and two manifested stenosis of more than 50 percent. Significant obstructive disease developed in the two patients with atypical angina who later manifested typical angina. Stenosis of 70 percent or more of the intraluminal diameter developed in only two patients.

Of the two patients in group II with documented myocardial infarction before the repeat coronary angiograms, one showed no progression of disease and the second (Case 7) had the most extensive progression of disease in the study.

Role of coronary risk factors: The presence of coronary atherosclerosis in group II patients was more common in men than in women (difference not significant) and in smokers ($P < 0.01$). No other risk factor allowed discrimination between the presence or absence of coronary disease. Progression of disease was more frequent in patients younger than 45 years ($P < 0.025$). None of the coronary risk factors assessed allowed us

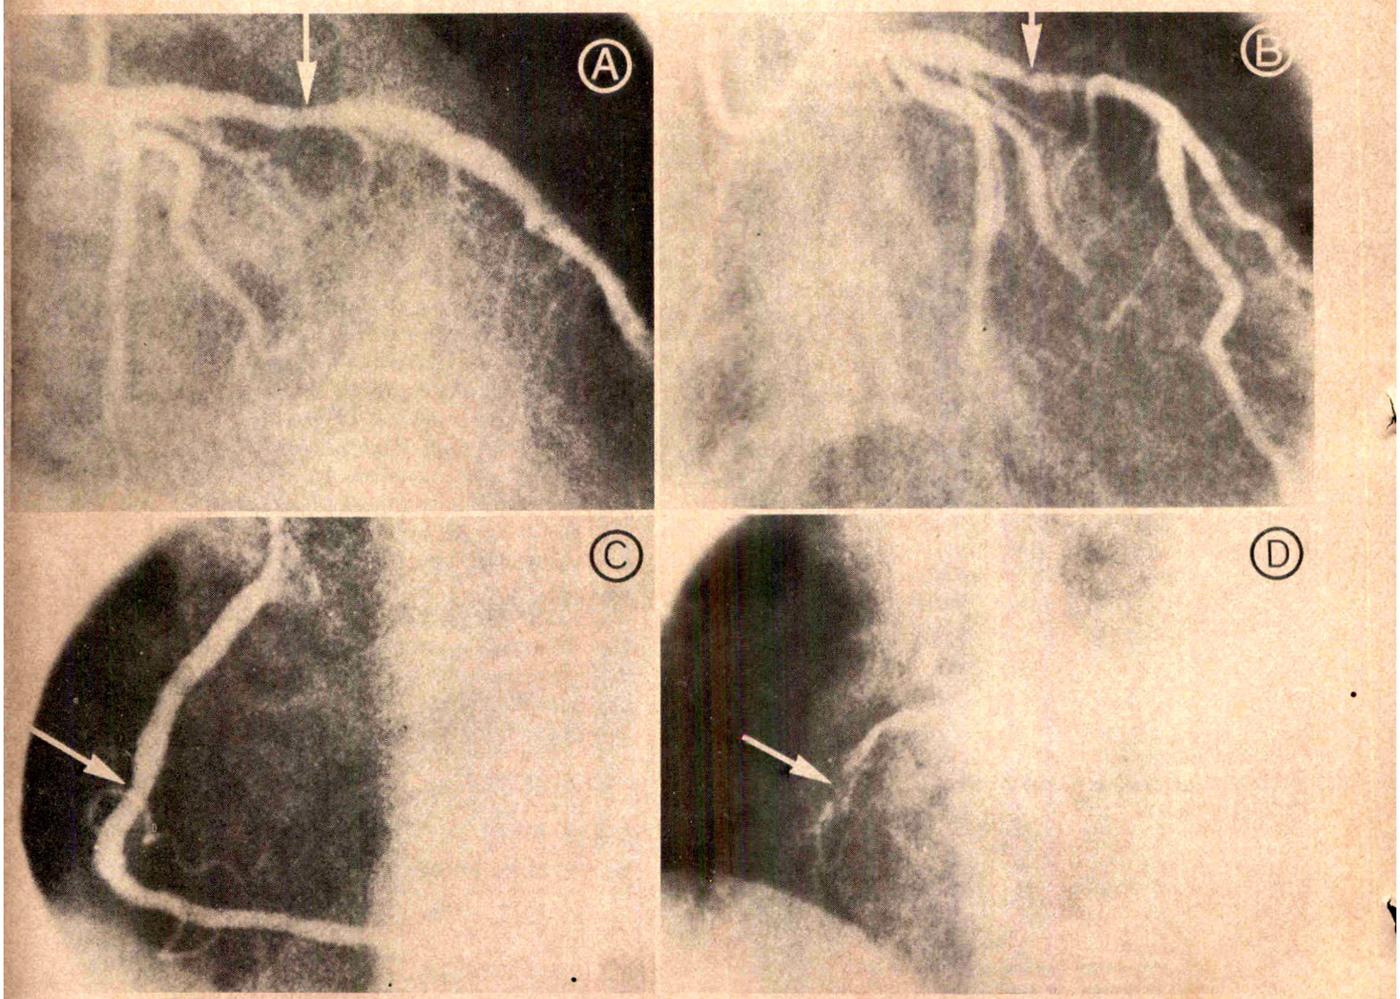

FIGURE 1. Case 5 (Table IV). The coronary angiogram shows progression of disease 6 years after the initial arteriogram. A 30 percent stenosis in the left anterior descending coronary artery (**A**) has progressed to 60 percent (**B**); a 25 percent stenosis in the left circumflex artery (not seen in this projection) remains unchanged. A 30 percent stenosis in the right coronary artery (**C**) has progressed to complete obstruction (**D**).

to predict which patients were more susceptible to progression of coronary disease (Table V).

Discussion

Obstructive coronary disease: The natural history of obstructive coronary disease has been widely reported.[4,5,9–13] Sequential coronary arteriograms in patients with severe obstructive coronary disease have shown that progression of disease can be frequent, rapid and highly unpredictable.[9–13] It was observed to occur within 1 to 2 years in 52 to 76 percent of patients studied for a change in symptoms. Rösch et al.[13] reported that after an average interval of 26 months, 33 percent of coronary obstructions were worse and disease progressed in an average of two arterial sites per patient. Subsequent progression was independent of overall severity of initial disease or prior disease at the site of progression and occurred frequently in previously normal vessels.[9] Data on the influence of clinical symptoms and coronary risk factors on progression of disease have been variable.

It has been shown that the clinical course and prognosis of coronary disease are related more to the severity of coronary atherosclerosis assessed angiographically than to any other factor.[3–5] Impaired ventricular function independently affects yearly mortality.

Normal coronary arteries: For obvious reasons, much less is known of the angiographic follow-up and prognosis of patients with normal coronary arteries or minimal nonsignificant coronary atherosclerosis. Gensini et al.[12] reported that 44 of 46 patients with normal coronary arteries did not manifest evidence of coronary disease an average of 52 months after the initial arteriogram although their average age was nearly 50 years. The exceptions were two diabetic men with hypertension. In both patients, a single vessel was involved and the lesion was less than 75 percent. Kimbiris et al.[11] reviewed data on 12 patients with normal coronary arteries. After an interval of 33 months, the second radiologic examination reaffirmed the presence of normal coronary arteries in all patients. Rösch et al.[13] reported on 11 patients with valve disease and normal coronary arteries. Follow-up angiography showed normal findings in nine patients after a mean interval between studies of 39 months. In two patients, four stenoses were found on follow-up studies performed at intervals of 32 and 55 months, respectively. These stenoses were of minor degree (less than 50 percent). Finally, Bruschke et al.[14] described serial angiograms in six patients with normal coronary arteries who were restudied because of persistent symptoms. After an interval of 10 to 84 months, two patients manifested new stenosis: one had a lesion of less than 30 percent and the other had occlusion of the left anterior descending coronary artery 25 months after the initial study.

Our results demonstrate no development of coronary disease in 22 patients with normal coronary arteries after a minimal interval of 13 months and an average interval of 52 months. The combined data from these studies suggest that middle-aged adult men and women with normal coronary arteries rarely manifest subsequent coronary atherosclerosis.

It is generally believed that coronary disease begins at a relatively early age in the presence of a genetic predisposition and of factors that favor its development.[15,16] It has been suggested that the atherosclerotic process begins histologically during the first months of life.[17] Thickenings of internal vascular layers of the coronary vessels observed during childhood in some populations can be related to subsequent development of coronary atherosclerosis.[18] The nondevelopment of coronary atherosclerosis by the fourth and fifth decades of life warrants against its future presentation. However, one cannot rule out the possibility that the rare patient with later narrowing already had mild intimal changes not detected in the first coronary arteriogram.

Nonobstructive coronary disease: There are few data on the angiographic evolution of mild nonobstructive coronary atherosclerosis. Bruschke et al.[14] reported that patients with this condition have an excellent 5 year prognosis. The incidence rate of presumed cardiac death after 5 years of follow-up was 2 percent in 101 patients with stenosis of less than 30 percent, a

rate lower than that observed for an average population matched for age and sex. The incidence rate of presumed cardiac death in 57 patients with an intraluminal narrowing of more than 30 but less than 50 percent was 5.3 percent after 5 years, slightly more than that observed in the average population. In 14 patients with minimal lesions (less than 50 percent stenosis) who had serial angiograms because of persistent symptoms, 9 showed progression of disease after an average interval of 4 years; 7 patients manifested stenoses of more than 50 percent.

In our series of 26 patients with minimal lesions, 27 percent showed progression of coronary disease on restudy after an average interval of 3 years. However, only four patients (15 percent) had significant coronary disease (greater than 50 percent stenosis) and only two (8 percent) had stenosis of more than 70 percent. This small incidence of progression in a population restudied for worsening or persistent symptoms explains the excellent prognosis of these patients. This low rate of progression in middle-aged adults compared with that in patients with significant obstructive coronary lesions is probably related to the pathophysiology of coronary disease. The process tends to begin early in life and to evolve in episodes, at times not showing a progressive character.[19]

The duration, character and evolution of symptoms were not helpful in separating patients with and without coronary atherosclerosis or those whose atherosclerosis showed signs of progression.[9]

Implications: Our study, like most retrospective studies, dealt with a selected group of symptomatic patients. Thus, our conclusions may not be applicable to unselected asymptomatic men and women. Sequential coronary arteriograms from childhood to middle age in asymptomatic persons would clarify the timing of development of coronary disease, but these studies cannot now be justified.

Incidence and Significance of Decreases in Systolic Blood Pressure During Graded Treadmill Exercise Testing

STEPHEN N. MORRIS, MD, FACC
JOHN F. PHILLIPS, MD, FACC
JOHN W. JORDAN, MD
PAUL L. McHENRY, MD, FACC

Indianapolis, Indiana

The incidence of decreases in peak systolic blood pressure during treadmill exercise was investigated in 460 patients with definite or suspected coronary heart disease. All patients were studied with coronary cineangiography. Exercise was continued to one of the following end points: chest pain, 85 to 90 percent of the patient's age-predicted maximal heart rate, ventricular tachycardia or a sustained decrease of 10 mm Hg or more below the peak level of systolic blood pressure. Twenty-two patients with 75 percent or greater stenosis of one or more major coronary arteries manifested a decrease in systolic pressure 10 mm Hg or more during exercise. These included 15 (17 percent) of 88 patients with three vessel, 7 (7 percent) of 101 with two vessel and 0 of 90 with single vessel disease. The decrease in pressure was reproducible in the seven patients who underwent a second exercise test before alteration of therapy; this decrease was abolished in the six patients who exercised again after coronary bypass graft surgery.

A decrease in systolic pressure of 10 mm Hg or more also occurred during exercise testing in 3 of 23 patients with noncoronary organic heart disease; all 3 had an obstructive cardiomyopathy that had not been suspected clinically. Only 1 of 158 subjects with chest pain and no demonstrable heart disease had a decrease in systolic blood pressure with exercise. Declines in blood pressure were not observed during 650 maximal exercise tests performed on 560 clinically normal men.

In conclusion, if one excludes subjects with cardiomyopathy or significant heart valve disease, a sustained exercise-induced decrease in peak systolic blood pressure of 10 mm Hg or more is a highly specific sign of multiple vessel coronary artery disease. This phenomenon is best explained by acute left ventricular pump failure secondary to extensive myocardial ischemia.

In normal subjects exercise produces an increase in systolic blood pressure, and this increase is usually accompanied by a decrease in the diastolic blood pressure with a widening of the pulse pressure.[1,2] A decrease in systolic blood pressure below resting levels has been observed during treadmill exercise testing in some patients with severe valve, hypertensive or coronary heart disease[3]; a decrease in systolic pressure below resting levels at the onset of treadmill exercise-induced angina has been reported as a reliable sign of severe multiple vessel coronary artery disease.[4] However, Baker et al.[5] reported that a decreasing systolic blood pressure may be observed during graded exercise in the absence of significant coronary artery disease, especially in women. Other study results[6,7] have suggested that a reduction in systolic pressure may be a normal physiologic response during prolonged strenuous exercise. Thus, there are conflicting reports regarding the significance of decreasing systolic blood pressure during graded exercise testing. Furthermore, it is not known how great a decrease in systolic blood pressure is necessary

to be of potential diagnostic aid when evaluating patients with suspected coronary artery disease.

This report deals with the findings of a prospectively designed study of the blood pressure responses during treadmill exercise testing of 460 patients with known or suspected coronary heart disease. During the time of this study we also evaluated the blood pressure responses of 560 normal male members of the Indiana State Police Force who underwent a total of 650 maximal treadmill exercise tests.

Material and Methods

Cases: A total of 1,020 persons from two patient populations were evaluated by treadmill exercise testing. Group I consisted of 560 clinically healthy male members of the Indiana State Police Force who underwent periodic maximal exercise testing during the study period as part of a continuing cardiovascular evaluation program being conducted at the Indiana University Medical Center.[8] Group II consisted of 460 consecutive patients who underwent both treadmill exercise testing and coronary cineangiographic studies at our institution between July 1, 1973 and September 30, 1976 because of known or suspected coronary artery disease. Our modified Balke multistage exercise protocol and our electrocardiographic recording techniques have previously been described.[8,9]

Blood pressure recordings: All exercise blood pressure levels were measured by the same observer during each individual exercise test. However, three of us participated in the supervision of the exercise tests reported in this study, and serial testing of the same patient was occasionally performed by a different physician. The blood pressure recordings were made with a Tycos cuff adapted to a Baumanometer sphygmomanometer and a standard stethoscope with the diaphragm placed over the right brachial artery. Blood pressures were recorded in the subjects in Group I during sitting and standing rest and during the last minute of each 3 minute stage of exercise. Blood pressures in the patients in Group II were recorded at least once per minute during each 3 minute stage of exercise. During exercise all blood pressure recordings were made with the subject's hand resting on a side rail and his arm flexed slightly at the elbow. This technique reduces the amount of mechanical or arm movement artifacts and assures accurate and reproducible blood pressure measurements. Whenever a decrease was observed in the systolic pressure, the blood pressure recordings were repeated one or more times at approximately 15 second intervals to confirm the accuracy of the reading and to demonstrate that the decrease was sustained. By study protocol design, a decrease in systolic blood pressure of 10 mm Hg or more that was sustained during two or more consecutive determinations was considered an end point for the exercise test.

Coronary cineangiographic studies: In the patients in Group II these studies were performed utilizing the Judkins transfemoral approach.[10] Each coronary artery was filmed in multiple projections using 35 mm cineangiography. All coronary cineangiograms were reviewed and interpreted by three of us, and arteries unanimously graded as having a 75 percent or greater luminal narrowing were considered significantly narrowed. The presence and extent of left ventricular wall motion abnormalities were estimated using a left ventriculogram filmed in the right anterior oblique position. Left ventricular end-diastolic pressure was measured in the resting state before the left ventricular and coronary cineangiographic injections.

Exercise protocol: *The subjects in Group I* underwent a thorough history, physical and laboratory examination before exercise testing.[8] All men with definite or suspected heart disease were excluded from this study. Also excluded were subjects with persistent systolic blood pressure at rest exceeding 160 mm Hg or diastolic pressure exceeding 96 mm Hg. The end point of exercise for these highly motivated subjects was a self-determined maximal effort; all subjects attained an exercise heart rate exceeding 90 percent of their age-predicted maximal rate.[11]

The exercise end points for the patients in Group II were one of the following: (1) chest pain, (2) an exercise heart rate of 85 to 90 percent of the patient's age-predicted maximal rate, (3) ventricular tachycardia, or (4) a decrease in systolic blood pressure of 10 mm Hg or more sustained during repeat blood pressure determinations. In patients who experienced chest pain during exercise, the test was terminated shortly after the onset of pain if a diagnosis of coronary heart disease was already established or if the S-T segment response was interpreted as abnormal by the monitoring physician (1.0 mm or more of horizontal or downsloping S-T depression). If the S-T segment response remained normal or equivocal at the time of exercise-induced chest pain and a diagnosis of coronary heart disease was not established, the test was sometimes continued in an effort to elicit an abnormal S-T segment re-

TABLE I

Prevalence of Exercise-Induced Decreases in Systolic Blood Pressure (EDBP) in the Study Populations

§ Includes 19 patients with cardiomyopathy. The three patients with exercise-induced decreases in systolic blood pressure were the only ones in this study group with obstructive cardiomyopathy.

sponse. However, the patient's chest pain was never allowed to exceed the intensity of that he experienced during his usual daily activities.

All exercise electrocardiograms were recorded on magnetic tape. Upon completion of the exercise test the S-T segment changes were quantitated using previously described computer techniques.[9] In patients with a normal baseline ST-T segment, the computed S-T response was considered abnormal if the S-T depression was 1.0 mm or greater and the algebraic sum of the S-T depression in millimeters and the S-T slope in millivolts/second was less than zero.[9] These computed values were used to compare the incidence of abnormal S-T segment responses in patients with and without exercise-induced declines in systolic blood pressure.

Results

Group I (normal subjects): The 560 clinically normal subjects in Group I underwent a total of 650 maximal exercise tests during the study period. None of these subjects demonstrated a decrease in systolic blood pressure during exercise (Table I).

Group II (known or suspected coronary artery disease): The patients in this group were divided into three subgroups according to their final clinical diagnosis (Table I). Group IIA consisted of 159 patients who were evaluated for symptoms of chest pain but found to have no coronary artery stenosis exceeding a 50 percent luminal narrowing by coronary cineangiography; the majority (91 percent) demonstrated no coronary artery disease or only minor luminal irregularities. In one patient, a 41 year old man with essential hypertension, systolic pressure decreased 24 mm Hg during exercise. He had no chest pain and at the time of the exercise test he was taking propranolol (40 mg four times a day), methyldopa (250 mg three times a day) and long-acting nitrates (Nitrobid®, 6.5 mg three times a day). Group IIB consisted of 279 patients who demonstrated a 75 percent or greater stenosis of one or more of the three major coronary arteries on coronary cineangiography. In this subgroup there were 22 patients (7.9 percent) who demonstrated a decrease in systolic blood pressure of 10 mm Hg or more during exercise. Group IIC consisted of 22 patients with noncoronary organic heart disease; 16 had nonobstructive cardiomyopathy, three had obstructive cardiomyopathy, two had aortic insufficiency and one had a partial absence of the pericardium. Three of these patients demonstrated a decrease in systolic blood pressure during exercise and all three had an obstructive cardiomyopathy.

Patients with exercise-induced decline in systolic blood pressure: A total of 39 exercise tests were performed in these 26 patients. All of the repeat exercise tests were performed in the 22 patients with coronary artery disease in Group IIB. The Group IIB patients demonstrated a mean decline in systolic blood pressure of 23 mm Hg during their initial exercise test (Table II). The systolic blood pressure level during exercise dropped below that recorded during standing rest in only 9 of the 22 patients. Sixteen of these 22 patients had angina before the decrease in blood pressure; the limiting symptoms in the remaining 6 were dyspnea in 3, leg fatigue in 2 and giddiness in 1.

A second exercise test was obtained in 7 of the 22 patients with coronary disease who demonstrated a decrease in systolic blood pressure during their initial test (Group IIB, Table II). The repeat tests were performed without intervening alterations in therapy and after time intervals ranging from 2 weeks to 17 months (the interval was 2 to 5 weeks in all but one patient). The decrease in systolic blood pressure during exercise was reproducible in all seven patients.

The most dramatic and abrupt decreases in systolic pressure were observed in the three patients with obstructive cardiomyopathy (Group IIC, Table II). These patients were being evaluated because of chest pain of uncertain origin and they did not have heart murmurs at rest or pathologic Q waves in the resting electrocardiogram. Prominent systolic murmurs were observed immediately after exercise, and a diagnosis of obstructive cardiomyopathy was subsequently confirmed with echocardiography and left heart catheterization.

Effect of surgery: Saphenous vein coronary bypass graft surgery was subsequently performed in 12 of the 22 patients with coronary artery disease (Group IIB). To date we have repeated the exercise test in 6 of the 12 patients postoperatively including 4 patients who demonstrated a decrease in systolic blood pressure during repeat exercise testing before surgery (Table II).

TABLE II

Magnitude and Reproducibility of Exercise-Induced Decrease in Systolic Blood Pressure (EDBP) in 26 Patients During 39 Exercise Tests

	Patients (no.)	With TMET (no.)	With EDBP (no.)	Mean and Range of EDBP (mm Hg)	With EDBP Below Standing BP at Rest (no.)
Group IIA	1	1	1	24	1
Group IIB	22				
First TMET	. . .	22	22	23 (10–46)	9
Repeat TMET	. . .	7	7	20 (10–34)	2
Repeat TMET after CABG	. . .	6*	0	. . .	. . .
Group IIC	3	3	3	39 (20–56)	2

* Four of these patients were in the subgroup of seven patients who had a second or repeat treadmill test. All four had a reproducible exercise-induced decrease in systolic blood pressure before surgery.

BP = blood pressure; CABG = coronary bypass graft surgery; TMET = treadmill exercise test.

All six of the patients demonstrated an increase in the peak systolic blood pressure attained during repeat exercise testing after surgery (Fig. 1). The mean increment in systolic pressure was 29 mm Hg (range 4 to 68). Two of the six patients still experienced angina during the postoperative exercise test, but every patient was able to exercise for a longer period than before surgery (mean duration 308 seconds preoperatively versus 638 seconds postoperatively).

Clinical characteristics of patients with a decrease in systolic blood pressure during exercise (Table III): The 22 patients with coronary artery disease and exercise-induced decreases in systolic blood pressure were, as a group, 4.4 years older than the 257 patients who did not have a decrease in systolic blood pressure during exercise. This age difference between the two subgroups was not statistically significant. All 22 patients were men (22 of 242). There were 37 women in the study group with significant coronary artery disease. The absence of a decrease in systolic blood pressure in women compared with men (0 of 37 versus 22 of 242) was not quite significant at the 0.05 level. This apparent sex difference was most likely due to a predominance of single vessel disease in the women and to a much greater prevalence of triple vessel disease in the men. No significant differences were observed between the two subgroups (those with and without a decrease in systolic blood pressure) in the frequency of computer-quantitated S-T segment abnormalities with exercise, the presence of ventricular premature complexes, the prevalence of previous myocardial infarction, evidence of akinesia or dyskinesia in the left ventriculogram or the level of mean left ventricular end-diastolic pressure (Table III).

The coronary arteriographic findings in the 22 patients with coronary artery disease and exercise-induced decreases in systolic blood pressure are summarized in Table IV. Three patients had significant stenosis of the left main coronary artery, and an additional 14 patients had a 75 percent or greater stenosis of the luminal diameter of both the left anterior descending and left circumflex coronary arteries. Therefore, 17 of the 22 patients had lesions that have been regarded by some investigators[4] as equivalent to a left main stem coronary artery stenosis. Fifteen (68 percent) of the patients had significant three vessel coronary disease. The remaining seven patients had at least two major coronary arteries with a 75 percent or greater stenosis and four of these patients also had a 50 percent stenosis of the third major coronary artery.

The prevalence rate of exercise-induced decreases in systolic blood pressure in the 279 patients with coronary

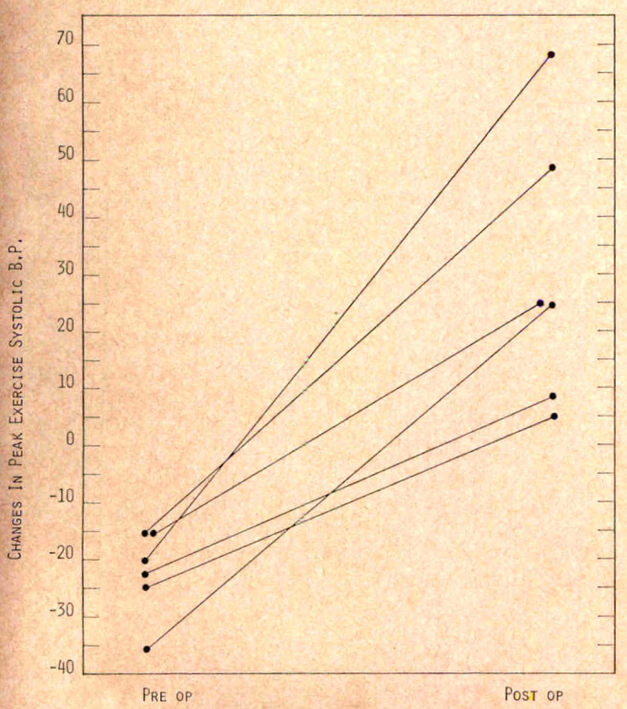

FIGURE 1. Effect of coronary bypass surgery in six patients. Preoperatively (PRE OP) these six patients had a mean decrease of 23 mm Hg from peak exercise systolic blood pressure level (B.P.). Postoperatively (POST OP) each patient attained a higher peak systolic blood pressure level than on the preoperative exercise test, with a mean increment of 29 mm Hg.

TABLE III

Characteristics of 279 Patients With Significant Coronary Artery Disease

	22 With EDBP	257 Without EDBP	*P* Value
Mean age (yr)	55.2	50.8	NS
Sex (no.)			
Male	22	220	
Female	0	37	NS
S-T depression with exercise testing*	88% (15/17)	78% (142/183)	NS
VPC	55% (12/22)	49% (126/257)	NS
Previous documented myocardial infarction	46% (10/22)	49% (125/357)	NS
Akinesia or dyskinesia on left ventriculography	32% (7/22)	39% (98/254)†	NS
Mean LVEDP (mm Hg)	11.7	11.2	NS

* Includes only patients with a normal baseline ST-T segment.
† A left ventriculogram was not obtained in three patients.
EDBP = exercise-induced decrease in systolic blood pressure; LVEDP = left ventricular end-diastolic blood pressure; NS = not significant; *P* = probability; VPC = ventricular premature complexes at rest or with treadmill exercise.

TABLE IV

Coronary Arteriographic Findings in 22 Patients (Group IIB)

	Patients (no.)
≥75% stenosis of:	
Left main coronary artery	3
Left anterior descending artery (LAD)	19
Left circumflex artery (LC)	18
Right coronary artery (RCA)	19
LAD and LC	17
LAD and RCA	16
2 major vessels	7
3 major vessels	15

artery disease was 7.9 percent, but this varied considerably within our study population depending on the number of coronary vessels involved (Table V). None of the 90 patients with single vessel disease manifested a decrease in systolic blood pressure during exercise whereas 7 percent (7 of 101) of the patients with two vessel disease and 17 percent (15 of 88) of those with three vessel disease demonstrated an abnormal systolic blood pressure response during exercise. Thus, a decrease in systolic blood pressure during exercise was observed in 11.6 percent (22 of 189) of patients with cineangiographic evidence of multiple vessel coronary artery disease. The prevalence rate of abnormal blood pressure responses in patients with left main coronary artery disease was 17 percent (3 of 18), which was the same as that observed in patients with significant three vessel disease. All three patients with significant left main coronary artery stenosis and an abnormal blood pressure response during exercise also had a 75 percent or greater stenosis of the right coronary artery.

TABLE V

Correlation of Severity of Coronary Artery Disease and Frequency of Exercise-Induced Decrease in Systolic Blood Pressure (EDBP) in 279 Patients

	Patients (no.)	With EDBP	
		no.	%
Single vessel with ≥75% stenosis	90	0	0
Two vessels with ≥75% stenosis	101	7	7
Three vessels with ≥75% stenosis	88	15	17

Discussion

Incidence and clinical significance of exercise-induced drop in systolic blood pressure: Our results reaffirm the clinical value of accurate blood pressure recordings during graded exercise testing. Previous reports[3,4] dealing with the exercise blood pressure responses of patients with heart disease have considered flat systolic blood pressure responses or a reduction in systolic blood pressure below resting levels to be abnormal. Our results show that a sustained and reproducible decrease in peak systolic blood pressure during exercise as small as 10 mm Hg is clinically significant. This observation holds true even when the initial expected increment in systolic blood pressure occurs during exercise. In patients with coronary artery disease a decrease of this magnitude in systolic blood pressure is highly suggestive of significant multiple vessel involvement. In our study population, 11.6 percent (22 of 189) of the patients with coronary cinenagiographic findings of advanced two or three vessel coronary artery disease demonstrated an abnormal decrease in blood pressure during exercise. Of the 88 patients who had triple vessel disease, 15 (17 percent) had an abnormal blood pressure response. Abnormal decreases in systolic blood pressure were not observed in healthy subjects or in patients with single vessel coronary artery disease.

The 22 study patients with exercise-induced decreases in systolic blood pressure were all identified on exercise tests performed before coronary cineangiography, and therefore there was no retrospective influence on their selection. None of the patients had orthostatic hypotension, hypovolemia, obstructive heart valve disease or evidence of congestive heart failure, and none had cardiac arrhythmia at the time of the exercise blood pressure determinations. Although one can question the accuracy of brachial arterial cuff pressure measurements taken during exercise, the reproducibility of an exercise-induced decrease in systolic blood pressure in all seven subjects undergoing a second exercise test and the absence of this finding in 560 normal men during maximal treadmill testing confirms that the blood pressure can be recorded during exercise with a high degree of reliability.

Causes of exercise-induced fall in systolic blood pressure: The decrease in the peak systolic blood pressure during exercise in patients with multiple vessel coronary artery disease is best explained by acute left ventricular pump failure secondary to extensive myocardial ischemia. This hypothesis is supported by an absence of abnormal blood pressure responses in our 90 patients with single vessel coronary disease, in whom less myocardium is at risk of ischemic compromise, and by the restoration of a normal blood pressure response to exercise in patients with multiple vessel disease after coronary artery bypass graft surgery. Because a decline in systolic blood pressure during exercise is primarily dependent upon the area of myocardium rendered ischemic, it is possible that some subjects with single vessel coronary artery disease will eventually be shown to manifest this abnormality. This could especially be the case when a maximal exercise protocol is used because the area of exercise-induced ischemia may be more extensive under these circumstances.

The abnormal blood pressure responses observed in the three patients with obstructive cardiomyopathy can best be attributed to an accentuation of the left ventricular outflow tract obstruction during treadmill testing. This is most likely due to a combination of an upright posture and the increase in circulating catecholamines that accompanies exercise.[12]

The explanation for the single patient with a "false positive" decrease in blood pressure among the 159 patients with chest discomfort and normal coronary arteriograms is less obvious. This patient was the only person in the study who was tested while receiving a combination of propranolol, methyldopa and long-acting nitrates. This drug combination has the potential for reducing maximal cardiac output while simultaneously augmenting the peripheral vasodilatation that accompanies exercise.[13–15] Therefore, certain pharmacologic agents may obliterate the adaptive mechanisms normally operative during exercise to maintain the systolic blood pressure.

Role of thermoregulatory mechanisms: Prolonged exhaustive exercise has been shown to cause a decrease in systolic blood pressure even in normal subjects.[6,7] This response is thought to be mediated through sympathetic vasodilatation of skin vasculature in order to

dissipate the heat load generated by the prolonged muscular work. As a larger percentage of the cardiac output is shifted to the skin for cooling purposes, the total peripheral vascular resistance decreases. If cardiac output is already near maximal, both the systolic and mean arterial blood pressures may decrease. This thermoregulatory or so-called "cardiovascular drift" phase of exercise[7] occurs only with vigorous exertion maintained over a prolonged period. This phenomenon was not observed by Saltin and Sternberg[6] using an exercise protocol including 15 minutes of warm-up followed by a maximal work load that would exhaust the subjects in another 6 minutes. With our modified Balke treadmill exercise protocol[8] none of the patients with an exercise-induced decline in systolic blood pressure walked more than 12 minutes (mean 4.9 minutes, range 2 to 12 minutes). Thus it is highly unlikely that the decrease in systolic pressure observed in the 22 patients was initiated by thermoregulatory mechanisms.

Our patient population was predominantly male but we did not observe an abnormal blood pressure response in any of the 37 women with coronary artery disease or in any of the 70 women who had chest pain but who were free of significant coronary artery disease on coronary cineangiography. Thus our results failed to confirm the finding of Baker et al.,[5] who reported that exercise-induced hypotension occurs more frequently in women and is often not associated with coronary artery disease.

Clinical implications: Our results show that a decrease in systolic blood pressure of 10 mm Hg or more below peak values during treadmill exercise is a reliable indicator of multiple vessel coronary artery disease provided the following conditions are met: (1) the decrease in pressure is sustained during one or more repeat determinations obtained at 15 to 20 second intervals after the initial recording; (2) there is no coexistent cardiomyopathy, heart valve disease, hypovolemia, orthostatic hypotension or evidence of congestive heart failure at rest; (3) there are no cardiac arrhythmias at the time of blood pressure recording; (4) the patient is not receiving a combination of pharmacologic agents that would significantly reduce cardiac output or augment the vasodilatation accompanying exercise, or both; and (5) exercise is at least 1 minute in duration. This latter condition is designed to exclude "false positive" decreases in systolic pressure in very anxious subjects whose pressure may decrease early in the first stage of exercise as they begin to relax. It is not necessary for the final systolic blood pressure to drop below that recorded at standing rest. Also, some subjects had normal exercise S-T segments (two patients) or did not experience angina (six patients). Therefore, when the criteria listed are fulfilled, we believe that an exercise-induced decrease of 10 mm Hg or more below peak systolic blood pressure is a useful, highly specific and easily elicited sign of severe compromise of the coronary circulation.

Significance of Chest Pain During Treadmill Exercise: Correlation With Coronary Events

JOHN P. COLE, MD
MYRVIN H. ELLESTAD, MD, FACC

Long Beach, California

A follow-up study of 1,402 patients with a positive maximal treadmill stress test was made to evaluate the significance of angina during the test. Life tables were constructed and evaluated for significance of age, sex and work load at onset of angina. Coronary events (myocardial infarction, progression of angina and coronary death) were twice as frequent in subjects with angina and S-T segment depression as in those without angina. The increased incidence in 4 years held for all coronary events and was still doubled at 7 years for progression of angina and coronary death. The incidence of coronary events was more than twice as great when the angina was induced by a light work load (4 metabolic equivalents = METS) as when it was induced by a heavy work load (8 to 9 METS). Men aged 41 to 50 years having angina during exercise testing had a 3-fold greater incidence of coronary events and a 4-fold greater incidence of myocardial infarction compared with their counterparts who had S-T segment depression alone.

In this study, angina during exercise testing identified 85 percent of true positive tests for coronary artery disease, whereas S-T depression alone identified only 64 percent of such tests. Thus, angina during exercise testing increases the sensitivity of the test and identifies cohorts of subjects at high risk for subsequent coronary events.

A number of variables in stress testing have previously been assessed in an attempt to identify patients with significant coronary artery disease.[1] The significance of angina during stress testing has not previously been elucidated. This study was designed to evaluate the presence of angina during maximal treadmill stress testing and its correlation with coronary events. The prognostic significance of stress testing was historically established by the follow-up study of Robb and Marks[2] on subjects given Master's two-step test reported in 1967 and supplemented for maximal treadmill testing by Ellestad and Wan in 1975.[1]

Material and Methods

Follow-up information, collected from referring doctors' records, was obtained on 1,402 patients who had a positive maximal treadmill stress test in this medical center between January 1, 1965 and July 1, 1976. A treadmill questionnaire was filled out by referring physicians or doctors' aides, and a trained research clerk reviewed the records for the following data: (1) presence, severity and progression of angina; (2) incidence and date of myocardial infarction; and (3) date and cause of death. All information was computerized and filed on disc in a CDC 3300 computer. The output provided the number of patients in each cohort, the number lost to follow-up, standard deviation of the mean and the cumulative percent of events at each interval. The vertical lines at each interval in the life tables indicate 2 standard deviations. When these limits do not overlap, the groups are significantly different ($P > 0.01$) by chi square analysis.

Protocol: Stress testing was performed according to the Memorial Hospital protocol.[3] The test was terminated if the patient reached the predictive maximal

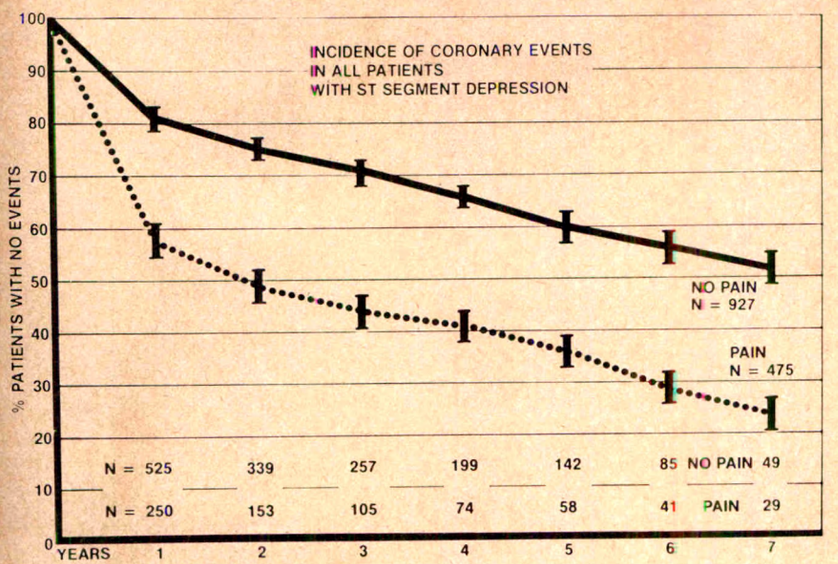

FIGURE 1. Life table illustrating the incidence of coronary events according to the presence or absence of chest pain during treadmill stress testing in all subjects with significant S-T segment depression. N = number of patients.

heart rate (as predicted by Åstrand et al),[4,5] or had worsening anginal pain (grade 3+), evidence of ischemia in the electrocardiogram, arrhythmias, progressively decreasing pulse or blood pressure or overwhelming fatigue. For the purpose of this study, the definition of chest pain was limited to symptoms reported by the patient and classified as characteristic of angina by the physician monitoring the test. During the test the patient was repeatedly questioned about the presence or absence of pain, its location, distribution and severity. He was asked to compare it with previous symptoms and was observed for clinical findings that might confirm or rule out the likelihood of coronary ischemia. The time course, site of pain and relation to breathing and position were especially noted.

Patients: The subjects had been referred for confirmation of suspected coronary artery disease, for quantitation of the degree of known coronary artery disease or for a routine screening test as part of an annual physical examination. Chest pain was the cause of referral of 72 percent of patients (67 percent of men and 93 percent of women). Surgically treated patients were excluded from the follow-up study.

Life tables were constructed according to the method of Cutler and Ederer.[6] The follow-up interval ranged from 6 months to 7 years.

Criteria for a positive test were at least 1.0 mm S-T segment horizontal or downsloping depression or 1.5 mm upsloping depression 0.08 second from the J point.

Results

The annual incidence of all coronary events over a 4 year period in these patients with a positive treadmill test was twice as great in patients who had S-T segment depression and chest pain during the test as in those who were free of angina during testing (Fig. 1 and 2). At

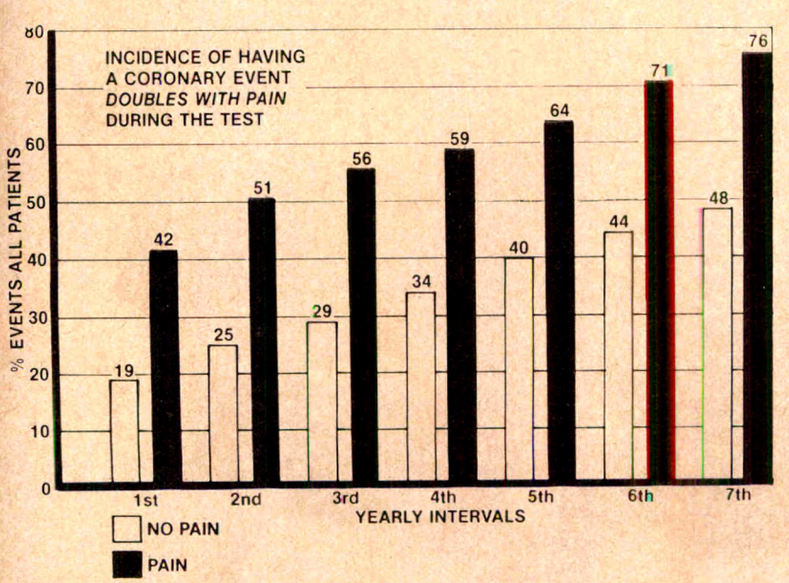

FIGURE 2. Bar graph demonstrating that the coronary events double at yearly intervals in all subjects with chest pain in addition to S-T segment depression during exercise testing.

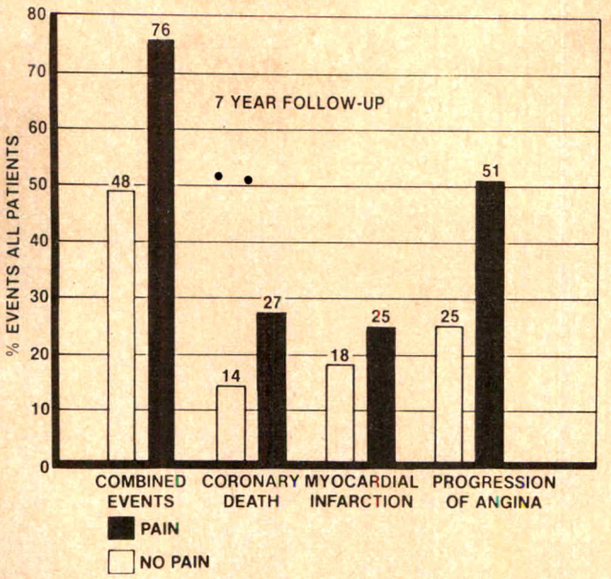

FIGURE 3. Bar graph at a 7 year follow-up period depicting the incidence of separate and combined coronary events according to the presence or absence of chest pain during exercise testing in all subjects.

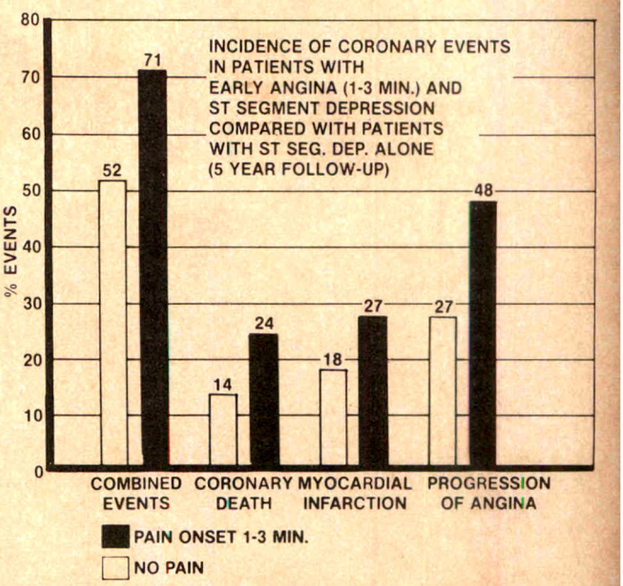

FIGURE 4. Bar graph illustrating the incidence of separate and combined coronary events at 5 year follow-up in subjects with or without chest pain during the first 3 minutes (MIN.) of exercise testing.ST SEG. DEP. = S-T segment depression.

7 years, the incidence rate of coronary events rose to 76 percent in patients with pain and to 48 percent in those free of pain during the test (Fig. 3). Coronary death and progression of angina also doubled over a 7 year period in patients with angina during the abnormal treadmill test.

Onset of angina: Coronary events were twice as frequent in patients with early onset of anginal pain at a light work load (1 to 3 minutes of testing, 4 metabolic equivalents = METS) of exercise testing as in those with pain at a heavy work load (7 minutes of testing, 8 to 9 METS), a load very near the peak capacity of most subjects. Subjects with angina induced at a light work load (1 to 3 minutes) demonstrated slightly more than double the incidence of coronary events found in subjects with angina induced by a heavy work load (Fig. 4 to 6).

Age and sex: Men aged 41 to 50 years with treadmill-induced angina had a tripled incidence of coronary

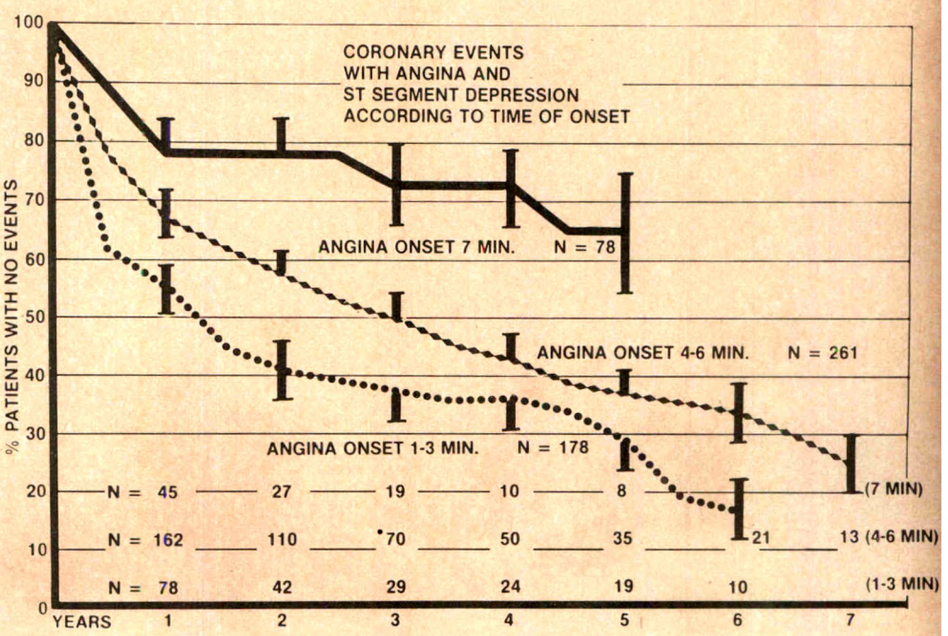

FIGURE 5. Life table comparing the incidence of coronary events in relation to angina induced by a light, moderate and heavy work load during exercise testing. MIN = minutes; N = number of patients.

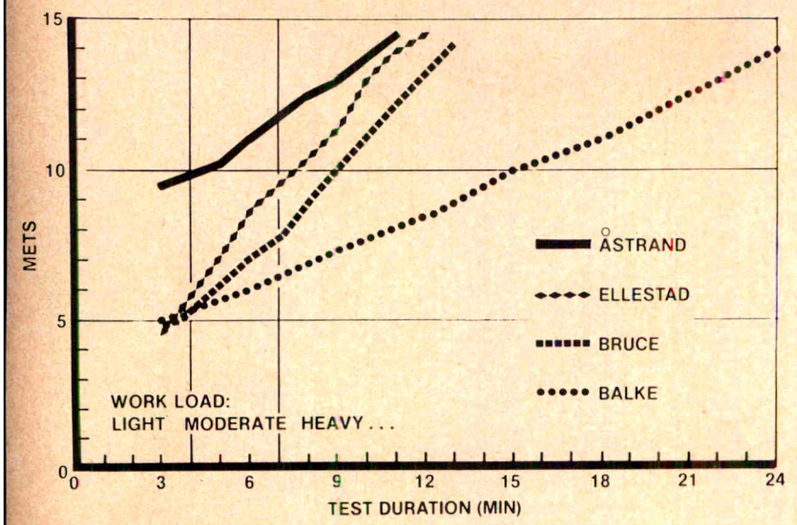

FIGURE 6. Comparison of four exercise protocols according to metabolic equivalents (METS) of the actual work load. MIN. = minutes.

events compared with their counterparts without angina (Fig. 7 and 8). These men with angina during the positive test had an 18 percent incidence rate of myocardial infarction during the 5 year period compared with a 4 percent incidence rate in the men without angina (Fig. 9). Thus, men aged 41 to 50 years having angina during the test had a more than quadrupled incidence of myocardial infarction compared with their counterparts who were free of pain during the test; the incidence of other coronary events (coronary death and progression of angina) doubled for the men in this age group who had pain during the test.

The questionnaire disclosed a history of chest pain in 93 percent of the women studied, compared with only 67 percent of the men; however, in women the occurrence of pain during the test was not correlated with an increased incidence of coronary events after 3 years. Thus, chest pain during the abnormal treadmill test was a less useful prognosticator of future coronary events in women than in men (Fig. 10).

Angiographic correlations: Coronary artery disease was considered angiographically significant when there was 50 percent or greater narrowing of the luminal diameter of a diseased vessel. Angiography, performed in 295 patients, revealed that an abnormal treadmill test for ischemia had a 64 percent true positive rate for significant coronary artery disease. This true positive rate increased to 85 percent (91 percent in men, 17 percent in women) among the 197 patients who had angina during the abnormal stress test. At a light work load (4 METS), the time of onset of S-T segment depression has unique significance in evaluating the severity of

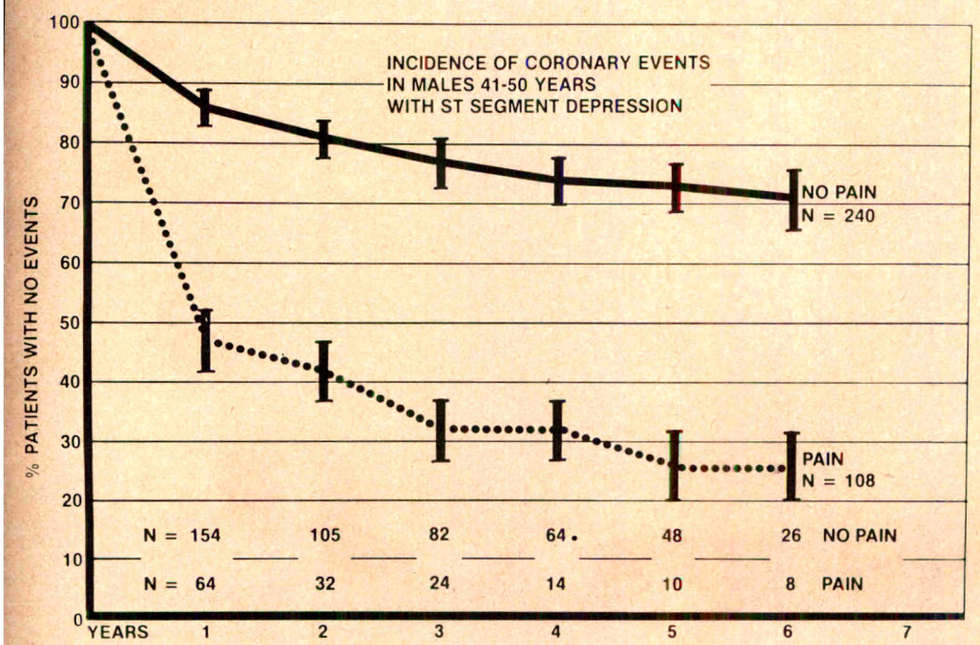

FIGURE 7. Life table illustrating the incidence of coronary events in men aged 41 to 50 years according to the presence or absence of chest pain during exercise testing with significant S-T segment depression. N = number of patients.

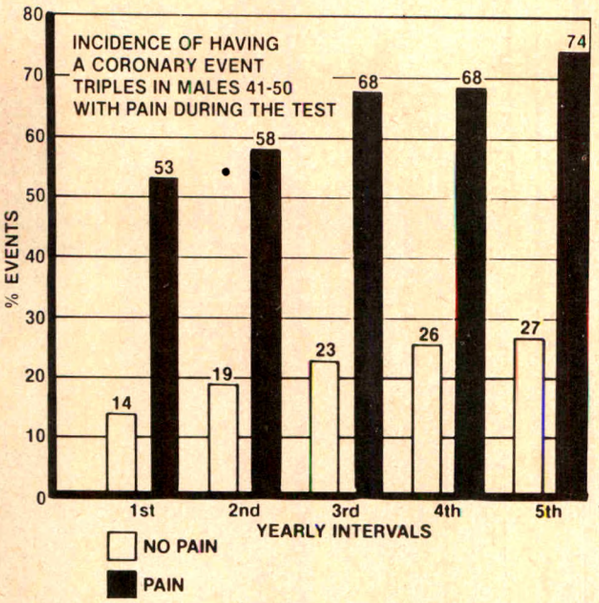

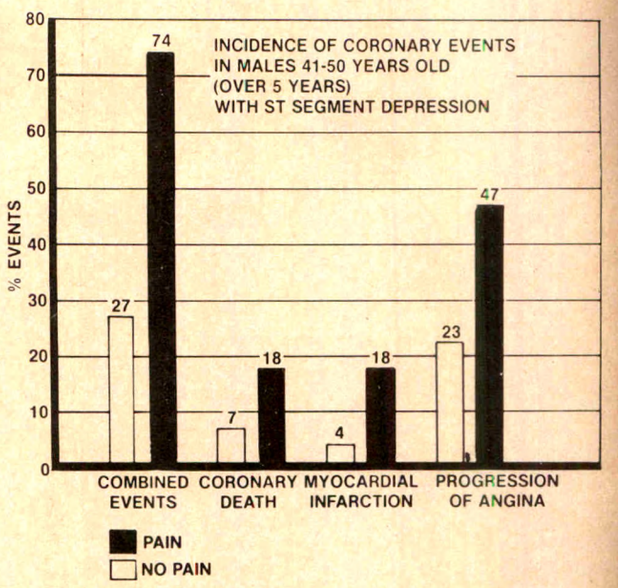

FIGURE 8 (left). Bar graph demonstrating that in men aged 41 to 50 years the incidence of coronary events triples when pain occurs during exercise testing.

FIGURE 9 (right). Bar graph depicting the incidence of separate and combined coronary events at 5 years in men aged 41 to 50 years according to the presence or absence of chest pain during exercise testing.

disease, as previously reported by Ellestad.[8] In our study, subjects with both S-T depression and pain at a light work load tended to have more coronary events than those with S-T depression and no pain. Angina occurring early in the protocol had more significance than asymptomatic S-T depression. When angina occurred during a heavy work load (8 to 9 METS), the incidence of coronary events was essentially the same as with positive tests for ischemia (Fig. 1 and 5).

Discussion

Predictive value of angina during exercise testing: In our subjects with a positive test by electrocardiogram, the presence of angina predicted a large inci-

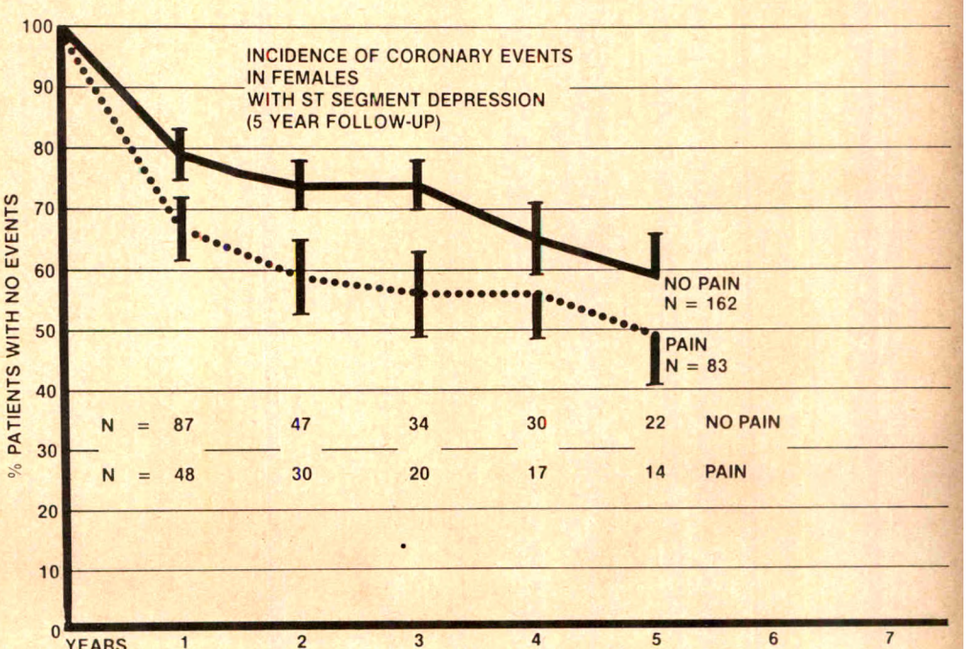

FIGURE 10. Life table illustrating the incidence of coronary events at 5 years in all women according to the presence or absence of chest pain with significant S-T segment depression during exercise testing. N = number of patients.

dence of later coronary events. Men aged 41 to 50 years with angina during a positive stress test had a 3- and 4-fold greater incidence of coronary events than similarly aged men without exercise-induced angina. These middle-aged men with exercise-induced pain may require more careful attention to control of risk factors and management of disease. Angina during exercise testing was a less accurate indicator of coronary disease in women. The examiner identified chest pain as angina on the basis of the patient's description, its duration, location, response to nitroglycerin and other factors that are partly subjective. Although chest pain is more likely to be of noncoronary origin in women than in men, our results suggest that our ability to categorize it is of less significance in women. Myocardial ischemia of noncoronary origin is also more common in women than in men.

All patients in our study who had angina during a positive exercise test had a doubled incidence of coronary events. Angina during exercise testing increased the sensitivity rate for angiographic coronary disease to 85 percent of all subjects with an abnormal stress test for ischemia. Weiner et al.[7] reported 91 percent true positive results for coronary artery disease when subjects had pain during exercise testing. The difference in results in their study may well be due to inherent differences in patient selectivity since our study, by design, included many subjects known or highly likely to have advanced coronary artery disease as well as many believed to be perfectly normal.

As noted in the life table figures, the majority of coronary events occurred during the first year of follow-up study. Therefore, we believe that exercise testing is a valuable aid in determining the risk of a subsequent coronary event in symptomatic patients and those highly likely to have ischemia. The possibility that asymptomatic subjects would manifest S-T segment depression and angina during exercise is remote, although it cannot be excluded. We believe that the patients in our study would be representative of a patient population referred to a moderate to large community hospital for exercise testing to evaluate suspected ischemia. Surgical patients were excluded and the types of treatment were not taken into consideration.

Other factors influencing evaluation of the stress test: Although the study was constructed to evaluate the contribution of angina to the evaluation of treadmill data, other clinical factors are also important. It must be emphasized that a considerable number of subjects with severe coronary disease do not have pain on testing. The time of onset of S-T segment depression, the magnitude of S-T depression, S-T segment contours, achieved heart rate response, blood pressure response and age have also been shown to have significance in predicting the outcome of patients with exercise-induced S-T segment depression. These and other clinical findings should be evaluated when determining the significance of a stress test.

Clinical implications: The presence of chest pain during treadmill testing increases the sensitivity of the test more accurately than its absence. Life table data demonstrate that the presence of anginal pain during the test identifies a cohort of high risk patients in terms of subsequent coronary events such as progression of angina, myocardial infarction and death. This study has unique significance in patients with anginal pain of early onset manifested at light to moderate work loads as compared with patients with pain at higher work loads. It also has more significance in younger than older subjects.

Acknowledgment

We are especially grateful to the attending physicians of Memorial Hospital Medical Center who helped us obtain follow-up data on the subjects tested, and to Lee Richard, our computer programmer, who made it possible to analyze the data in a meaningful way. We also thank John Manning, who helped us assemble the data and prepare the tables, and Fritzie Cohn for the preparation of the manuscript.

Plasma Norepinephrine in Congestive Heart Failure

JAMES A. THOMAS, MD*
BERNARD H. MARKS, MD†

Detroit, Michigan

Resting plasma concentrations of norepinephrine, dopamine-beta-hydroxylase enzyme activity and peripheral blood lymphocyte beta adrenergic receptor sensitivity to isoproterenol as reflected in cyclic 3′,5′-adenosine monophosphate (cAMP) generation were studied in patients with congestive heart failure due to atherosclerotic heart disease or to congestive cardiomyopathy or hypertensive cardiovascular disease. Systolic time intervals were also measured in nonhypertensive patients and correlated with the plasma norepinephrine concentration. Control patients were hospital employees without a previous history of heart disease or hypertension, and were matched for age to eliminate the effect of increasing age on the plasma norepinephrine concentration.

The results of this study clearly demonstrate that the plasma norepinephrine concentration is directly related to the degree of left ventricular dysfunction in patients with congestive heart failure. When the systolic time intervals were correlated with the plasma norepinephrine levels, a significant prolongation of the preejection period was observed with progressively increasing plasma concentrations of norepinephrine. The reverse was true for the left ventricular ejection time, which demonstrated a significant inverse relation with the plasma norepinephrine concentration. The ratio of the preejection period to the left ventricular ejection time, which is a reflection of left ventricular function, significantly increased with increasing levels of plasma norepinephrine. In addition, plasma lymphocytes from patients with the greatest degree of left ventricular dysfunction failed to generate normal amounts of cAMP after beta adrenergic receptor stimulation with isoproterenol. It is suggested that beta adrenergic receptors are desensitized in these patients and that this desensitization contributes to the observed alterations in myocardial contractility.

The role of the sympathetic nervous system remains poorly understood in both compensated and decompensated congestive heart failure, although an augmentation of sympathetic nervous activity in heart failure has previously been described.[1] An increase in impulse traffic in sympathetic nerves leads to the release of the endogenous neurotransmitter norepinephrine and its synthetic enzyme dopamine-beta-hydroxylase, and it has been proposed that the release of the latter enzyme might be used clinically to reflect changes in overall sympathetic nervous activity.[2] Release of norepinephrine is followed by the stimulation of adrenergic receptors, either in the heart or in other sympathetic beds throughout the body. This sequence of events is capable of increasing both contractility and the frequency of contractions of cardiac muscle[3] and is also capable of producing many extracardiac manifestations. These are reflected in a reduction of cutaneous blood flow,[4] the presence of venoconstriction,[5–7] elevation of renal vascular resistance[8] and augmentation of plasma catecholamines during exercise[9] associated with an increase in the urinary excretion of catecholamines.[1]

The augmentation in plasma norepinephrine concentration in patients with congestive failure during exercise was originally reported by Chidsey et al.[9] and was interpreted as an indication of an increased sympathetic outflow, providing an important cardiovascular supportive mechanism in these patients. Associated with this increased noradrenergic activity was an apparently normal adrenal medullary catecholamine release process, reflected in normal plasma and urinary levels of epinephrine.[1,9] This implied that sympathetic beds other than the adrenal medulla were responsible for this augmentation of noradrenergic activity. Many investigators[10–13] have reported a depletion of myocardial norepinephrine in congestive failure, both in human subjects and in experimental animal models. The mechanism of this depletion of the cardiac sympathetic neurotransmitter has not yet been elucidated. It remains to be established whether prolonged increases in cardiac sympathetic activity could lead to an exhaustion of the noradrenergic stores of the heart.[1] It is clear, however, that cardiac sympathetic nerves release norepinephrine and dopamine-beta-hydroxylase from their nerve terminals and that norepinephrine interacts with cardiac beta receptors, which are the sites for the modulation of intracell biochemical events that utilize cyclic 3′,5′-adenosine monophosphate (cAMP) as the second messenger.[14]

The search for an appropriate human in vitro model with which to study the beta adrenergic-cAMP relation led Scott[15] to demonstrate the stimulation of adenylate cyclase from human lymphocytes by epinephrine in broken cell preparations. Parker et al.[16] then studied peripheral blood lymphocytes from patients with bronchial asthma in search of possible alterations in cyclic 3′,5′-cAMP metabolism. Cells from asthmatic patients, at the time that the asthmatic condition was most severe, were found to have a highly significant decrease in their cAMP response to beta adrenergic agents as compared to normal control cells. These same cells, however, had an unaltered response to stimulants that activate adenylate cyclase by mechanisms other than through the beta receptor, thus demonstrating that the defect in catecholamine responsiveness was at the level of the beta adrenergic receptor.

The present study was undertaken to reinvestigate the functional activity of the sympathetic nervous sys-

* On methyldopa.
† Died.
Adm = admission; ASHD = atherosclerotic heart disease; B = black; BP = blood pressure (mm Hg) on admission; CCM = congestive cardiomyopathy; Dis = discharge; DBH = dopamine-beta-hydroxylase (nanomole/ml per hour); F = female; HR = heart rate (beats/min) on admission; HCVD = hypertensive cardiovascular disease; NE = norepinephrine (ng/ml); NYHA Class = New York Heart Association functional class; SEM = standard error of the mean; W = white.

tem, and its relation to compensated and decompensated heart failure. Plasma norepinephrine and dopamine-beta-hydroxylase levels were measured to assess sympathetic neuronal activity. The ability of peripheral blood lymphocytes to generate cAMP in the presence of beta receptor agonists was tested as a reflection of beta adrenergic receptor sensitivity. Systolic time interval measurements were used as a noninvasive technique for estimating changes in cardiac contractility and were correlated with the plasma catecholamine levels. The results of this study suggest that plasma levels of norepinephrine correlate very well with the functional cardiac status of patients with congestive heart failure. In addition, grossly elevated levels of plasma norepinephrine occur with chronic cardiac decompensation, and this may be associated with the development of desensitization of cardiac beta adrenergic receptors.

Study Subjects

Nineteen patients were included in this study. Six patients had atherosclerotic heart disease, and five patients were diagnosed as having congestive cardiomyopathy. Eight patients had hypertensive cardiovascular disease, and six of these patients were taking at least 750 mg/day of methyldopa (Table I). This medication was being taken at the time of admission to the study, and was continued throughout the observation period. All patients received a digitalis preparation (digoxin), a diuretic agent (furosemide or hydrochlorothiazide) and a potassium supplement both before entry into the study and during the course of the observation period. The functional cardiac status at the time of admission of each patient, as described by the New York Heart Association Criteria Committe,[17] ranged from slightly compromised to severely compromised (Class II–IV).

The physiologic cardiac diagnosis of left ventricular failure required one or more of the following criteria: (1) radiologic evidence of a sudden increase in left ventricular size, (2) a ventricular third sound or summation gallop sound over the left ventricle in the absence of mitral regurgitation, (3) angiocardiographic evidence of a dilated left ventricle and a cardiac output below 2.7 liters/min per m^2, or (4) manifestations of pulmonary congestion or pulmonary edema in the presence of a large left ventricle.

Patients in the study ranged in age from 26 to 75 years, with a mean age of 50.1. Ten of the patients were women, and nine were men. Control patients were hospital employees without any prior history of hypertension or heart disease. Control patients were matched for age to eliminate the effect of increasing age on the plasma norepinephrine concentration.[18]

Protocol: Blood was obtained from an antecubital vein while the subjects were supine and at rest for at least 5 minutes; indwelling catheters were not utilized. Blood specimens for norepinephrine and dopamine-beta-hydroxylase measurements and lymphocyte purification, were obtained from patients at the time of admission to the study, and every third morning between 7:00 and 8:00 AM with the patient at rest. Measurements of the blood pressure, heart rate and systolic time intervals were simultaneously obtained with the subject at rest and in the supine position. Systolic time interval measurements were taken as close to the day of admission as possible. Repeat measurements of time intervals were performed randomly throughout the hospital course. In all cases, systolic time interval measurements were always taken on the same morning during which a plasma specimen was obtained for the measurement of norepinephrine and dopamine-beta-hydroxylase. Measurements were terminated when the patients demonstrated improvement in clinical signs and symptoms of congestive heart failure for 96 or more hours, had demonstrated a constant body weight or necessitated a change in the therapeutic regimen. At least 7 days of hospitalization was required for patient inclusion in this study.

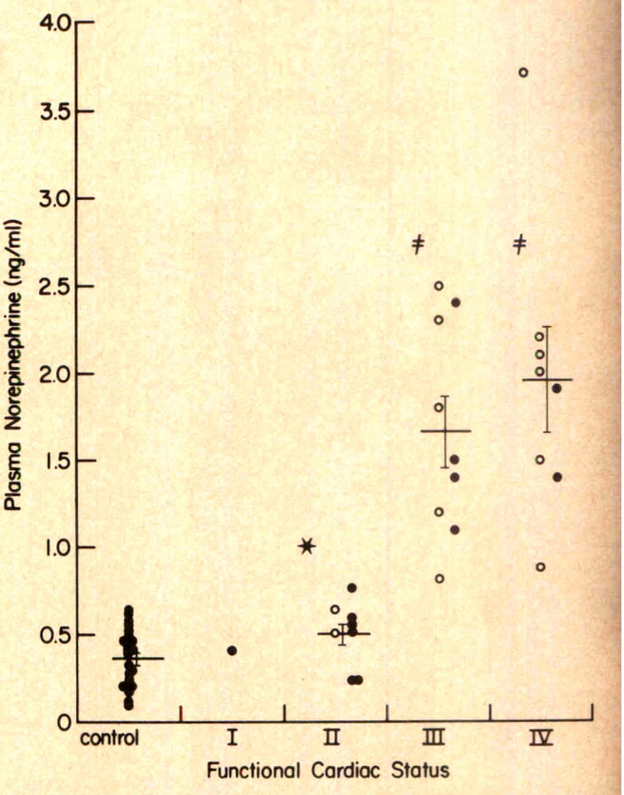

FIGURE 1. Functional cardiac status (New York Heart Association class) versus plasma norepinephrine concentrations in control subjects and in patients with congestive heart failure. **Open circles** represent admission values and **closed circles** represent discharge values for concentrations of plasma norepinephrine (no. = 13 for each group). Control values are as indicated (no. = 23). The mean ± standard error of the mean is indicated by the **solid bar** for each functional class. * = probability value (P) <0.001 compared with patients in classes III and IV; ≠ = P <0.001 compared with control period.

Methods

Plasma norepinephrine concentration was measured by the method of Henry et al.[19] Blood specimens were collected in heparinized tubes, and immediately placed on ice. The plasma was separated by centrifugation at 4° C within 30 minutes of obtaining the specimen. The plasma was then frozen and stored at −70 °C until the time of analysis. The isotopic enzymatic method involves the conversion of norepinephrine to ^{3}H-epinephrine, by the transfer of a ^{3}H-methyl group from ^{3}H-S-adenosylmethionine to the primary amine group of norepinephrine. The reaction is catalyzed by the enzyme phenylethanolamine-N-methyltransferase, and concentrations are reported in nanograms (ng) per milliliter (ml). Furosemide, digoxin and hydrochlorothiazide added to the assay mixture in concentrations equal to maintenance blood levels had no effect on the measurement of plasma norepinephrine concentration. In the case of methyldopa, concentrations from 5 to 20 μg/ml produced an apparent in-

crease above control levels in the measurable norepinephrine from 0.32 to 0.94 ng/ml, respectively.

Dopamine-beta-hydroxylase was measured with the radioisotopic method of Weinshilboum and Axelrod[20]; one unit of hydroxylase enzyme activity represents the formation of 1 nmol of phenylethanolamine product per milliliter of plasma per hour.

Lymphocytes were purified from whole blood on a Ficoll-Hypaque gradient at 4° C as described by Böyum.[21] Purified cells were washed and resuspended in Krebs-Henseleit buffer at pH 7.4. Cells were then incubated in the presence of 5 millimolar isoproterenol for either zero or 10 minutes at 37° C as described by Parker and Smith,[16] and the incubation was terminated by the addition of trichloroacetic acid to a final concentration of 7 percent. After ether extraction, the level of cyclic 3′,5′-adenosine-monophosphate (cAMP) was determined by radioimmunoassay as described by Steiner et al.[22] Results are expressed as picomoles (pM) cAMP/10^6 cells.

The durations of the phases of left ventricular systole were measured from simultaneous recordings of the electrocardiogram, phonocardiogram and carotid arterial pulse tracing as previously described by Weissler et al.[23] The following phases were measured directly: (1) the total electromechanical systolic interval (Q-S_2), (2) the left ventricular ejection time interval (LVET), and (3) the interval between the first and second heart sounds (S_1-S_2). The preejection period (PEP) interval was calculated from these measurements. The rate-corrected systolic time intervals are also reported.

Data were analyzed with use of Student's *t* test for individual and group differences and paired data analysis, and by the method of least squares for calculating regression coefficients as described by Delaunois.[24]

Results

Plasma norepinephrine concentration and degree of cardiac failure: Identifying data for all patients included in this study are summarized in Table I. Patients are represented in three groups on the basis of their functional cardiac status on admission. The plasma norepinephrine concentrations exhibit a progressive increase as patients demonstrate continued left ventricular functional deterioration. Although all three groups had plasma norepinephrine levels that were significantly different from the control value at the time of admission, plasma concentrations of patients in classes III and IV remained significantly elevated above control level at the end of the observation period ($P < 0.001$ for cardiac status III and IV, respectively). This finding is also presented graphically in Figure 1, but this figure includes only patients not treated with methyldopa. Whether at the beginning or the end of the observation period, the plasma norepinephrine level was found to correlate directly with the functional cardiac status and reflected the degree of cardiac decompensation.

Plasma dopamine-beta-hydroxylase enzymatic activity: No significant differences in this activity were observed in any of the patients in the study, although

BP = blood pressure (mm Hg); DBH = dopamine-beta-hydroxylase (nanomol/ml per hour); HR = heart rate (beats/min); LVET = left ventricular ejection time (msec); LVETI = left ventricular ejection time index; MAP = mean arterial pressure (mm Hg); NE = norepinephrine (ng/ml); PEP = preejection period (msec); PEPI = preejection period index; Q-S_2 = total electromechanical systole (msec); Q-S_2I = total electromechanical systolic index.

those patients exhibiting a more severe degree of cardiac decompensation tended to have lower admission values of dopamine-beta-hydroxylase enzymatic activity (Table I).

Systolic time intervals: Measurements for the control subjects and for patients with heart failure are summarized in Tables II, III and IV. Values are reported only for patients not receiving methyldopa. The values for plasma norepinephrine concentration, blood pressure and heart rate represent measurements made the same morning as the systolic time intervals. The data of patients with heart failure are grouped in Table III according to the functional cardiac status of the patient at the time the measurement was performed and include the mean values of each systolic interval for each functional status. A regression matrix of the systolic intervals as a function of plasma norepinephrine concentration and heart rate both before and after rate correction is seen in Table IV.

Analysis of the data in Tables II and III reveals a highly significant inverse relation between the duration of the electromechanical systolic interval ($Q\text{-}S_2$) and the heart rate in both control subjects and in patients with heart failure ($r = -0.79$, $P < 0.001$; $r = 0.81$, $P < 0.001$, respectively. See also Table IV). This is in agreement with previously published data of Lombard and Cope[25] and of Weissler et al.[23] Patients with heart failure had a significantly shorter $Q\text{-}S_2$ interval than the control subjects ($P < 0.001$) and also had a proportional increase in their heart rate. This decrease in the $Q\text{-}S_2$ interval with respect to the heart rate was caused by a significant decrease in the left ventricular ejection time, and although the latter was inversely related to the heart rate, the interval in patients with cardiac decompensation was markedly decreased compared with that in control subjects for any given heart rate ($P < 0.001$).

The relation between the preejection period and the heart rate for patients with failure and for control subjects is shown in Figure 2. Whereas neither of these regression lines demonstrate a significant correlation, the slopes have opposite absolute signs and are significantly different from each other when compared by Student's t test ($P < 0.005$). It would therefore appear that the effect of increasing heart rate on the preejection period in patients with heart failure is a tendency toward prolongation, an effect opposite from that observed in subjects with normal left ventricular function.

	Q-S_2I		LVETI		PEPI			
	Control	CHF	Control	CHF	Control	CHF		
NE vs	0.11	−0.17	0.15	−0.54[3]	−0.04	0.56[1,3]		

[1] $P < 0.01$ compared with control; [2] $P < 0.001$ compared with control; [3] significant correlation ($P < 0.05$); [4] significant correlation ($P < 0.01$); [5] significant correlation ($P < 0.001$).

CHF = congestive heart failure; HR = heart rate; LVET = left ventricular ejection time; LVETI = left ventricular ejection time index; NE = norepinephrine; PEP = preejection period; PEPI = preejection period index; Q-S_2 = total electromechanical systole; Q-S_2I = total electromechanical systolic index.

Relations between the systolic time intervals and the plasma norepinephrine concentration are depicted in Figures 3 and 4 and Table IV, with Figure 3 depicting intervals that have been corrected for rate. In control subjects, no correlation is noted between the plasma norepinephrine concentration and the Q-S_2, left ventricular ejection time and preejection period with or without rate correction (Table IV). The Q-S_2 interval in patients with left ventricular dysfunction was inversely related to the plasma norepinephrine concentration ($P < 0.001$) as a result of a marked shortening of the left ventricular ejection time (Fig. 3A). This finding is consistent with a progressive reduction in stroke volume in the presence of increasingly higher levels of circulating catecholamine in patients with cardiac decompensation. The opposite effect was noted with respect to the preejection period (Fig. 3B). A prolongation of the preejection period was observed in association with elevated plasma norepinephrine levels in heart failure ($r = 0.50$, $P < 0.05$), an effect that was similar to the regression of PEP on heart rate (Fig. 2). A comparison of the preejection period (PEP) and left ventricular ejection time (LVET) before and after correction for heart rate (Table IV) demonstrated that the statistical significance of the respective positive and inverse correlations was maintained.

An analysis of changes in the ratio of the PEP/LVET intervals with respect to the plasma norepinephrine concentration is seen in Figure 4. The positive correlation ($r = 0.67$) is significant and demonstrates a highly significant difference from the control value ($P < 0.001$). In addition, those patients in functional classes I and II had a plasma norepinephrine concentration of less than 0.70 ng/ml, which would not be considered outside the range of normal values for this laboratory. On the other hand, patients in classes III and IV having the

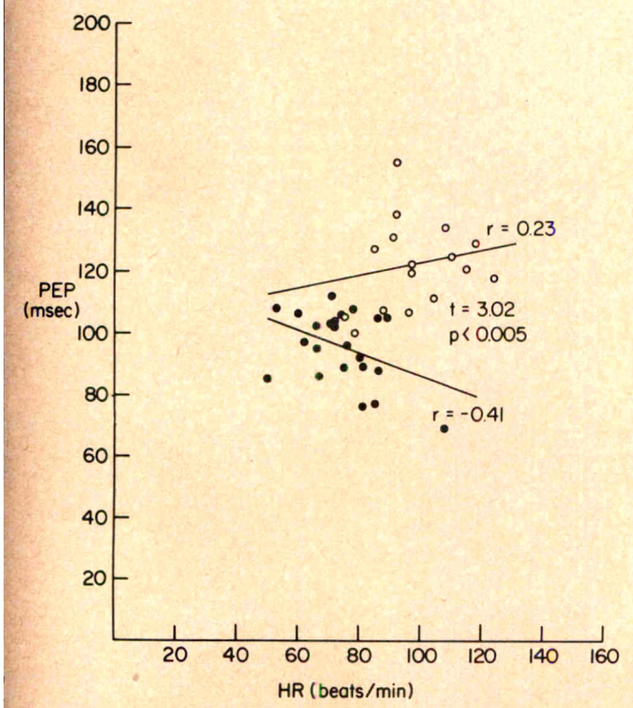

FIGURE 2. Preejection period (PEP) as a function of heart rate (HR) in control subjects and in patients with congestive heart failure. Control subjects represented by **closed circles** (no. = 23), patients with failure by **open circles** (no. = 16). The correlation coefficients (r) for each regression line are not significant. A comparison of the slopes of the two lines by Student's *t* test (t) is highly significant ($P < 0.005$).

TABLE V

Cyclic 3′,5′-adenosine monophosphate (cAMP) Generation After Exposure to 5 millimolar Isoproterenol in Lymphocytes From Normal Subjects and Patients With Functional Class III and IV Heart Failure

Incubation Time (min)	Cases (no.)	Lymphocyte cAMP (pM/10^6 cells ± SEM) 0 Minutes	10 Minutes
Control	21	1.24 ± 0.28	17.72 ± 1.43
CHF (class III + IV)	17	0.78 ± 0.18†	5.89 ± 0.94*

* $P < 0.001$ compared with control.

† $P > 0.1$ compared with control.

CHF = congestive heart failure; pM = picomoles; SEM = standard error of the mean.

highest PEP/LVET ratios, also had the highest plasma norepinephrine concentrations.

Relation between mean arterial pressure and plasma norepinephrine level (Fig. 5): In patients with left ventricular dysfunction, the mean arterial pressure was inversely related to plasma norepinephrine ($r = -0.59$, $P < 0.05$). However, there was no significant relation between the mean arterial pressure and the plasma norepinephrine level in the control group. Our data support the hypothesis that prolongation of the preejection period in these patients is not the result of norepinephrine-induced increases in afterload but reflects the reduction of left ventricular contractility.

Beta adrenergic receptor mediated generation of cAMP in lymphocytes: The values from both control subjects and patients with heart failure are shown in Table V. A highly significant decrease in the amount of cAMP generated after incubation of lymphocytes with 5 millimolar isoproterenol for 10 minutes is observed in the heart failure group ($P < 0.001$).

Discussion

Our results demonstrate that plasma levels of norepinephrine are elevated in resting patients with incipient and frank left ventricular decompensation. This finding is in agreement with earlier reports that plasma and urinary levels of norepinephrine were elevated in patients with congestive heart failure both at rest and during exercise,[1,9] and also elevated in various experimental animal models of right and left ventricular

The correlation coefficient (r) of the regression line for the patients with failure is indicated and is significant ($P < 0.05$). **B,** relation between the rate-corrected preejection period (PEPI) and plasma norepinephrine concentration (NE). Patients with heart failure are represented by **open circles** (no. = 16), control subjects by **closed circles** (no. = 23). The regression line along with the correlation coefficient (r) and its significance (p) is indicated. For both left ventricular ejection time and preejection period regression on plasma norepinephrine, the slopes are opposite for patients and control subjects (see Table V).

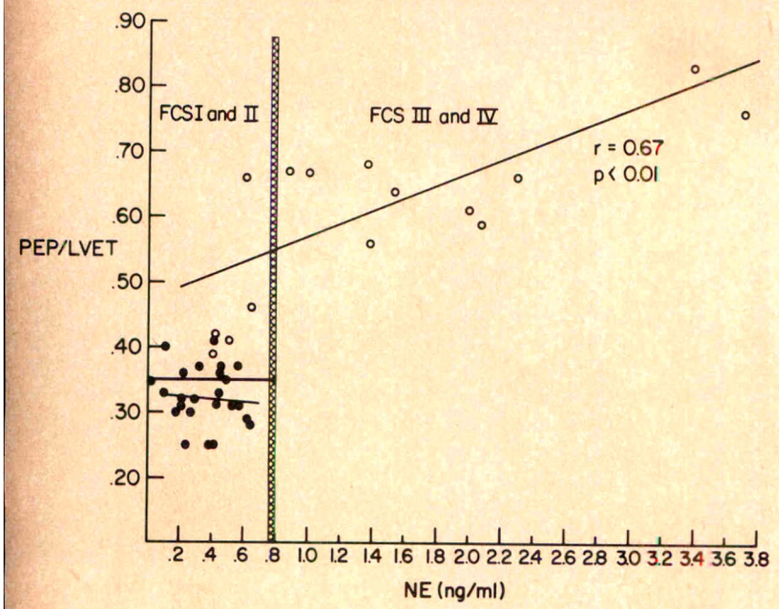

FIGURE 4. Regression of plasma norepinephrine concentration (NE) on the ratio of preejection period to left ventricular ejection time (PEP/LVET). Control subjects (**closed circles,** no. = 23) and patients (**closed circles,** no. = 16) with functional cardiac status (FCS) designations I and II are represented to the left of the **vertical cross-hatched line,** patients in functional classes III and IV to the right. The **solid horizontal line** (PEP/LVET = 0.35) represents the population mean for this laboratory. The regression line and correlation coefficient (r) for the patients with heart failure is indicated ($P < 0.01$).

failure.[26] However, Chidsey et al.[1] also reported that in patients with heart failure there was no statistically significant correlation between the magnitude of the urinary norepinephrine excretion and the severity of the heart failure although the excretion of norepinephrine tended to be greater in the most severely incapacitated patients. This difference between our findings and those of Chidsey et al.[1] appears to reflect the increased sensitivity of measuring plasma norepinephrine concentration with the enzymatic isotopic method of Henry et al.[19] as opposed to measuring urinary norepinephrine excretion. Plasma norepinephrine concentrations would appear to approximate more closely than urinary catecholamine excretion values the minute to minute changes of sympathetic neural activity, thus providing a more accurate tool for monitoring sympathetic activity.

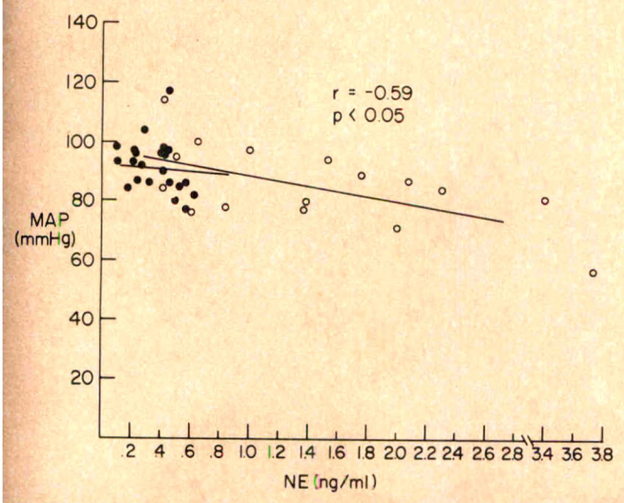

FIGURE 5. Relation between mean arterial pressure (MAP) and plasma norepinephrine concentration (NE). Control subjects are depicted by **closed circles** (no. = 23), patients with heart failure by **open circles** (no. = 16). The regression line and its correlation coefficient (r) are shown ($r = -0.59$, $P < 0.05$).

Plasma norepinephrine concentration and functional cardiac status: Our data demonstrate that the elevation of plasma norepinephrine levels correlates with the degree of clinical decompensation. This conclusion is based on the following observations: (1) patients in functional classes III and IV had significantly higher plasma norepinephrine concentrations on admission to this study than patients in functional class II; (2) patients with class II designations at the time of discharge from the study had significantly lower plasma levels of norepinephrine than patients in class III or IV; and (3) patients demonstrating either marginal or no change in their clinical condition also demonstrated minimal change in their plasma level of norepinephrine. However, these observations were true only for patients not receiving methyldopa. Patients receiving methyldopa had marked and significant reductions in their plasma norepinephrine concentrations that were disproportionately low considering their functional cardiac status. This suggests that methyldopa reduces adrenergic outflow from the central nervous system and peripherally in man and consequently reduces the circulating levels of catecholamines.

Correlation of plasma norepinephrine concentration, degree of heart failure and systolic time intervals: The observation that the elevated plasma norepinephrine concentration was indeed a reflection of the functional cardiac status of patients with heart failure was confirmed by the measurements of the systolic time intervals. Weissler et al.[23] have reported that congestive heart failure is characterized by a diminution of the left ventricular ejection time and a prolongation

of the preejection period but no change in the total electromechanical systolic interval (Q-S_2) when corrected for rate. These findings were confirmed in our study. In addition, these systolic intervals were shown to correlate very significantly with the plasma level of norepinephrine (Table IV). The most significant correlation with norepinephrine was that of the left ventricular ejection time, which reflects a progressive decrease in stroke volume in the presence of increasingly higher levels of plasma catecholamines in patients with congestive heart failure. The preejection period, which has been demonstrated to shorten in normal subjects after the intravenous administration of beta adrenergic receptor agonists,[27,28] was significantly prolonged (Fig. 3B) in patients with cardiac decompensation and correlated with high plasma levels of norepinephrine. This reflects a progressively slower velocity of isovolumic contraction in the patients with heart failure, in the presence of high plasma levels of norepinephrine.

In these patients, the opposite changes in the preejection period (PEP) and left ventricular ejection time (LVET) intervals as a function of the plasma norepinephrine level were clearly reflected in the PEP/LVET ratio, which increased as the plasma norepinephrine increased, demonstrating a highly significant correlation (Fig. 4). Because the PEP/LVET ratio has been shown by invasive studies to be well correlated with left ventricular ejection fraction and other measurements of left ventricular contractile performance,[29] the prolongation of the PEP/LVET ratio in the presence of increased plasma norepinephrine suggests an inverse relation between norepinephrine level and left ventricular ejection fraction. Ahmed et al.[30] demonstrated that either during exercise or after the intravenous administration of the beta receptor agonist (−) isoproterenol there is a significant decrease in the PEP/LVET ratio in normal subjects, due to a major decrease in the preejection period, with a smaller reduction in the left ventricular ejection time. Therefore, these patients with heart failure appear to respond in a manner opposite to that of normal subjects when the PEP/LVET is related to the level of catecholamine stimulation.

Our finding that patients with the most severe degree of left ventricular decompensation as shown by altered systolic time intervals demonstrated the highest levels of plasma norepinephrine suggests that, at best, the augmentation of sympathetic neural activity has failed to compensate adequately for a left ventricle exhibiting reduced ejection fraction and a marked decrease in stroke volume; at worst, it suggests that the high level of plasma norepinephrine actually contributes to the decrease in stroke volume and to the suppressed myocardial contractility by not exerting its expected biologic effect on the heart.

Beta receptor desensitization in patients with heart failure and elevated norepinephrine levels: The phenomenon of receptor desensitization has been described for the effects of polypeptide hormones such as insulin, vasopressin and luteinizing hormone, for neurotransmitters such as gamma amino butyric acid, and catecholamines.[31–35] For example, studies both clinical and experimental on insulin and its receptors have demonstrated that the concentration of insulin receptors is inversely related to the steady state concentration of the available insulin[36–39] and, from studies with isolated cell systems, it is clear that insulin can act directly to reduce the number of its own receptors.[40,41] In tissues as diverse as guinea pig tracheal muscle,[42] rat pineal gland[43] or frog erythrocyte,[44] it has been shown that beta adrenergic agonists are capable of producing beta receptor desensitization and that the degree of desensitization appears to be related to the potency of the agonist. The desensitization of the receptors was associated with a decrease in the total number of specific receptor binding sites as demonstrated by ^{3}H-l-alprenolol binding to beta receptors.

Because of reports such as these, it occurred to us that beta receptor desensitization might develop in patients with heart failure as a result of sustained elevated plasma norepinephrine levels. To examine this hypothesis, we tested the response to isoproterenol of lymphocytes from control subjects and patients with heart failure. The failure of lymphocytes from patients with advanced heart failure to generate normal amounts of cAMP may reflect a failure of beta receptor agonist isoproterenol to activate the membrane adenylate cyclase, and may be a demonstration of beta adrenergic receptor desensitization in these cells.

It is clear that an abundance of evidence exists to support the hypothesis that circulating hormones or pharmacologic agents both initiate the expected biologic response and act directly on cell receptors to cause a reduction in the number of available receptors and, thereby, a reduction of cell response. This evidence supports the proposal that the concentration of the specific receptors is inversely related to the maintained steady state concentration of the hormone or pharmacologic agent in the microenvironment surrounding the receptor.

Desensitization of cardiac beta receptors in chronic heart failure: We speculate that desensitization of cardiac beta receptors may be present in patients with chronic cardiac decompensation. The reasons for this speculation are summarized in the following evidence: (1) The heart rate and mean arterial pressure do not appear to respond appropriately to the large circulating norepinephrine concentration; (2) the preejection period is prolonged rather than shortened as would be expected if norepinephrine were exerting its inotropic effect; (3) the left ventricular ejection time is inappropriately shortened compared with its normal response to inotropic stimuli; (4) the PEP/LVET ratio, which normally decreases as a consequence of beta adrenergic receptor activation, shows a progressive increase with increasingly higher levels of plasma norepinephrine; and (5) peripheral blood lymphocytes from patients with the highest plasma levels of norepinephrine and the greatest degree of cardiac decompensation failed to generate a normal amount of cAMP after stimulation with the beta adrenergic receptor agonist. If desensitization exists in these patients, it is probably related to the maintained high levels of plasma nor-

epinephrine we have observed. The importance of this presumed desensitization is two-fold. First, it deprives the heart of one of its major inotropic processes in the presence of a diseased myocardium with altered contractility; second, it reverses the effectiveness of sympathetic activation when exercise-induced increases in the circulatory demand occur.

Clinical implications: That the phenomenon of desensitization might be operative in patients with severe congestive failure is supported by two recent reports encompassing both clinical and experimental research in heart failure. Waagstein et al.[45] reported that chronic beta adrenergic receptor blockade with the beta antagonists (−) alprenolol and (−) practolol for periods up to 1 year in patients with congestive cardiomyopathy refractory to conventional methods of therapy resulted in improvement in their clinical condition, with a decrease in exertional dyspnea and an increase in physical exercise tolerance. Noninvasive cardiologic measurements demonstrated an increase in the left ventricular ejection time in these patients with beta blockade, indicative of an increase in stroke volume. This could have resulted from a restoration of receptor sensitivity due to prolonged beta blockade. Newman[46] studied the inotropic response of the left ventricle to the intravenous administration of graded doses of norepinephrine and isoproterenol in dogs with congestive heart failure. Cardiac contractile responses to norepinephrine and isoproterenol were significantly depressed in dogs with heart failure when compared with control dogs. Both of these studies suggest that once decompensation occurs, norepinephrine appears not to produce the expected inotropic effect and may in fact increase the functional deficit. It is significant that Waagstein et al.[45] believed that blockade of beta adrenergic receptors of the myocardium was essential for favorable treatment in their patients with congestive cardiomyopathy, by demonstrating that cessation of treatment with the beta blocking agents rapidly resulted in decompensation.

In summary, our results clearly demonstrate that the plasma level of norepinephrine is directly related to the degree of left ventricular dysfunction both by clinical observation and by noninvasive cardiologic measurements in patients with cardiac failure. In addition, lymphocytes from patients with heart failure fail to generate normal amounts of cyclic 3′,5′-adenosine-monophosphate upon exposure to isoproterenol. We suggest, therefore, that beta adrenergic receptors are desensitized in these patients and that this contributes to the observed alterations in contractility.

Acknowledgments

We gratefully acknowledge the assistance of the Non-Invasive Cardiology Laboratory of Harper Hospital and Dr. A. M. Weissler for assistance in both performing and discussing the systolic time interval measurements. In addition, the technical assitance of Ms. C. Billups and Mr. R. Bordeau in the completion of this work is appreciated. The cooperation and assistance of Dr. David Schneider in performing the cyclic nucleotide assays has been indispensible.

Electrophysiologic Studies on Atrioventricular Nodal Wenckebach Cycles

MICHAEL B. SIMSON, MD*
JOSEPH F. SPEAR, PhD, FACC
E. NEIL MOORE, DVM, PhD, FACC

Philadelphia, Pennsylvania

Wenckebach cycles with a 4:3 ratio, produced by rapid atrial pacing, were studied in 27 anesthetized denervated dogs using programmed stimulation. A test stimulus (S′) could be inserted after any preselected beat of the Wenckebach cycle. An on-line computer measured the atrial (A) to His bundle (H) intervals. In all dogs a progressive increase in atrioventricular (A-V) nodal refractoriness was seen in the effective refractory period for each beat and a rightward shift of the A′-H′ relative to the A-A′ refractory curves. Atypical Wenckebach cycles could be produced by small changes in the basic cycle length. No evidence for reentry was found from the refractory curves of Wenckebach cycles and by interruption of stimulation after the third stimulus of a 4:3 Wenckebach cycle. Analysis of the A′-H′ relative to the H-A′ refractory curves did not confirm a positive feedback mechanism. In order to mimic a Wenckebach cycle, a blocked premature beat was inserted during stressed 1:1 conduction. The changes in the refractory curves for successive beats after the premature beat were rate-dependent and similar to those in Wenckebach cycles but smaller in magnitude. In Wenckebach cycles there is a progressive increase in refractoriness, caused by cumulative effect similar to that seen after a blocked beat during stressed 1:1 conduction, until block occurs and the cycle resets.

Although atrioventricular (A-V) nodal Wenckenbach block was described three quarters of a century ago[1] and is important to the understanding of A-V conduction disorders, it remains imperfectly defined and understood. A large incidence of atypical cycles is recognized,[2,3] and various phenomena have been evoked to explain the arrhythmia. These include decremental conduction,[4] summation,[5] inhomogeneous conduction,[6,7] electrotonus and temporal shifts in the recovery of A-V nodal cells,[8] dual conduction pathways,[3] reentry[9,10] and a positive feedback effect.[11,12]

To date, there have been few reported studies on Wenckebach cycles using a programmed stimulation technique despite the contribution of this technique to the understanding of various other arrhythmias.[13] The present investigation was undertaken using a programmed stimulation technique for the following purposes: (1) to define by refractory curves the functional properties of the A-V node for each beat during the Wenckebach cycle, (2) to study the effect of changes in basic cycle length on the refractory curves and the resultant Wenckebach cycles, (3) to assay for reentry during the cycle, (4) to evaluate the possibility of a positive feedback mechanism, (5) to define a fatigue or cumulative effect after a blocked beat during 1:1 conduction, and (6) to explore the role of a cumulative effect in the production and maintenance of Wenckebach cycles.

From the Cardiovascular Section, Hospital of the University of Pennsylvania; and Department of Animal Biology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania. This work was performed while Dr. Simson had a research fellowship (HL 05143-01) from the National Institutes of Health, Bethesda, Maryland and a research fellowship from the American Heart Association, Southeastern Pennsylvania Affiliate, Philadelphia, Pennsylvania. Manuscript received April 22, 1977; revised manuscript received July 6, 1977, accepted July 13, 1977.

Methods

Animal preparation: Experiments were performed in 27 adult mongrel dogs of either sex weighing 10 to 15 kg and anesthetized with sodium pentobarbital (30 mg/kg intravenously). The chest was opened using a right thoracotomy and the dog ventilated by a positive pressure respirator at a minute-volume determined from a body weight nomogram. Body temperature was maintained with a pediatric heating blanket. Normal saline solution was administered throughout the experiment (10 ml/kg per hour). In preliminary experiments the Wenckebach periodicity proved unstable unless the heart was denervated. Consequently, in all experiments the cervical vagi were cut and the stellate ganglia removed. Close bipolar plunge electrodes[14] were used to record simultaneously from the low right atrial septum, the His bundle and the low left ventricular septum at the site of earliest ventricular activation. The electrode amplifiers (Bloom Associates, Ltd., Narberth, Pennsylvania) had a 40 to 500 hertz bandpass and a noise level of less than 5 microvolts. A lead II electrocardiogram was continuously monitored. Plunge electrodes were applied to the right atrial appendage to pace the hearts; the stimulus was 4 msec long and two times the voltage threshold.

Stimulation instrumentation: The basic format of the experiments was to induce Wenckebach periodicity by rapid atrial pacing and then to insert a test stimulus after each beat of the Wenckebach cycle. To perform the experiment efficiently, we developed a stimulator that could insert a test beat after any preselected beat in the Wenckebach cycle.

The stimulator worked in the following manner: An amplified ventricular electrogram was detected by comparator which had a 120 msec lockout feature so that only one pulse per beat was generated. These pulses drove a missing pulse detector that allowed the blocked beats to be detected; an output was produced when the time between the input pulses exceeded a preselected interval. The output from the missing pulse detector reset a counter that was clocked by the stimulator driving the heart; thus, the stimuli after a blocked beat were counted. When a preselected count was reached, the driving stimulator was interrupted, an external digital stimulator (Bloom Associates) was enabled and it inserted a test stimulus after a preselected variable test interval. After the test stimulus, the basic driving stimulation was immediately resumed. The basic driving stimulator was a continuously variable analog unit with a precision of ±25 μsec and a resolution of 100 μsec; the test stimulus generator had a precision of ±50 μsec and a resolution of 1 msec.

The stimulation system could therefore synchronize onto the Wenckebach cycle, count the beats after a blocked beat and reliably insert a test beat after any preselected beat of the Wenckebach cycle. Using this instrument, we could repeatedly scan through the Wenckebach cycle with a given test interval, first inserting the test beat as the first beat of the cycle, then as the second beat, and so on.

Data acquisition and processing: In pilot experiments it was found that the time necessary to analyze the data using manual and analog techniques was prohibitive, and it was difficult to achieve adequate resolution. Consequently, we developed electronic instrumentation that detected, timed and statistically analyzed the electrophysiologic signals on line while the experiment was proceeding.

The instrumentation operated as follows: The signal from the low atrial septum (A), derived either from the His bundle electrogram or from a separate plunge electrode, was detected with a comparator circuit that was adjustable for level and slope. The output from the comparator passed through a gate that opened at an adjustable time after the stimulus (usually 20 msec) and closed after a variable interval, set to be shorter than the earliest detected His signal. The first signal from the atrial comparator that passed through the gate was interpreted as the atrial timing signal. The His bundle electrogram (H) was similarly processed except that the His gate opened after the atrial gate had closed and was kept open until 15 msec after the next stimulus in order to detect long A-H intervals. The atrial and His bundle timing signal controlled a Hewlett-Packard 5326A timer that continuously measured the A-H and the H-A intervals; the time resolution was set at either 10 or 100 μsec. If baseline drift or large local T waves interfered with detection of either the atrial or bundle of His signals, then 2 pole 30 hertz active filters were inserted before both the His bundle and the atrial comparators. The comparators were usually set to detect the largest and most rapidly moving component of the electrogram. Although this was not necessarily the earliest component in the electrogram, it was determined to have the most time stability. All electrograms and the status of the gates were continuously monitored on an eight channel storage oscilloscope (Tektronix 5103).

The data from the interval counter were stored in a temporary memory bank and joined there with coding information from the logic circuitry containing the following information: the status of the gates, whether or not a signal was detected when the gates were open, whether the stimulus was a basic driving or a test stimulus and the number of the beat in the Wenckebach cycle. The contents of the temporary memory were entered into a programmable calculator (Hewlett-Packard 9820A) that decoded the information, performed statistical analysis and printed the data in an easily readable format. The entire system functioned to detect the electrograms, measure their intervals and then present the data to the experimenters in real time.

The analog data and the signals from the electronic logic were recorded on magnetic tape using a Honeywell 5600C frequency modulation tape recorder. These data were later recorded on 35 mm film at a film speed of 200 mm/sec and projected onto a Hewlett-Packard 9864A digitizer board. To verify the electronic data analysis system, appropriate samples of the data were analyzed using the digitizer board and calculator. The resolution of this system was less than 0.5 msec.

Except for the commercially available equipment, the instrumentation used in this study was engineered by one of us (MBS) using standard linear and digital circuits.[15]

Experimental protocol: Before the experiments began, the measuring system was used to study the electrophysiologic stability of the animals and the stability of the electrographic configurations by evaluating the reproducibility of A-H conduction intervals during atrial pacing at a basic cycle length of 350 to 450 msec. Changes in the electrograms were the major source of variability in conduction intervals. Electrodes were readjusted until unambiguous and stable signals were obtained and a standard deviation of less than 1 percent was achieved for 20 consecutive A-H intervals. The mean standard deviation for all dogs was 0.6 percent. Stability of the electrograms during premature beats was studied by recording on the storage oscilloscope.

During studies on the Wenckebach periodicity, a test atrial response (A′) was evoked at different times both before and after the normally expected atrial response in order to scan conduction times and refractoriness of each beat in the cycle. Refractory curves were recorded by inserting the same test interval after each beat in the cycle. With each test interval and at each location within the Wenckebach cycle, six A′-H′ intervals were recorded. At least four control Wenckebach cycles were allowed between each test interval. Each beat of

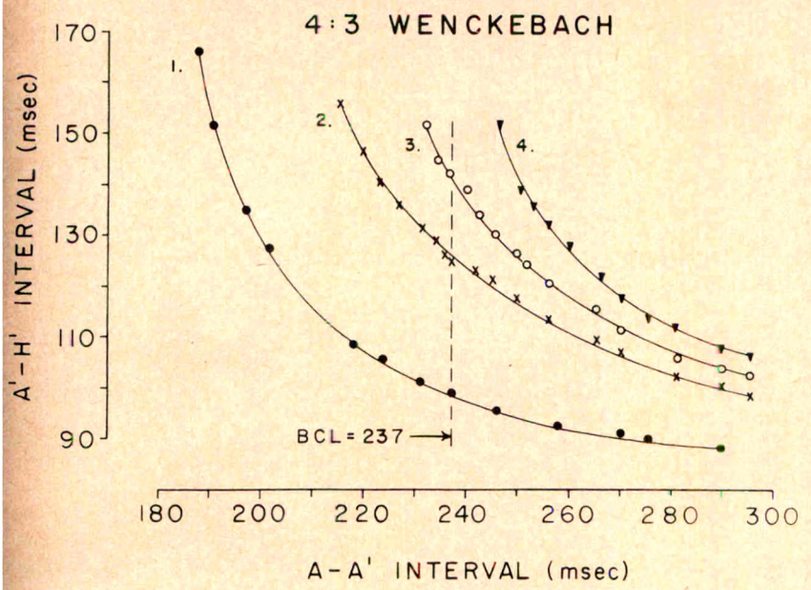

FIGURE 1. Refractory curves during 4:3 Wenckebach cycles. On the **vertical axis** is the A-V nodal conduction time for the test stimulus (A′-H′ interval). On the **horizontal axis** is the atrial test interval (A-A′), the time between the low atrial septal depolarization arising from the last basic cycle length stimulation to the atrial depolarization caused by the test stimulus. The basic cycle length (BCL) was 237.3 msec. Each point represents the mean of six observations. The control A-H conduction times were 100.9 ± 0.3 msec for the first beat, 126.4 ± 0.4 msec for the second beat and 143.7 ± 0.8 msec for the third beat. See text for details.

the Wenckebach cycle was tested with the same test interval before another test interval was used; approximately 2 minutes were required to record six intervals for all four beats of a 4:3 Wenckebach cycle. The test interval was then incremented to 5 to 20 msec and another cycle of testing initiated.

The effective refractory period, defined as the shortest atrial test interval that was reliably conducted, was determined to the nearest millisecond. The testing began at a test interval that was shorter than the effective refractory period after the first conducted beat of the Wenckebach cycle.

The conduction times of control 4:3 Wenckebach cycles were recorded frequently throughout testing. If the conduction times of the cycles had drifted from the control values, then a small readjustment of the basic cycle length was made. However, no adjustment of the basic cycle length was allowed while testing in the interval extending from the effective refractory period after the first conducted beat until 30 msec after the effective refractory period after the third beat. If at any time in testing during that interval the conduction times of the Wenckebach cycles had drifted from control values, the entire run was aborted and a new run begun. It was found that the basic cycle length could be readjusted when one was further than 30 msec beyond the effective refractory period of the third beat, since by that time the refractory curves were flat and relatively insensitive to small changes (less than 5 msec) in the basic cycle length. After each injection of pentobarbital anesthesia, the basic cycle length necessary to maintain 4:3 cycles lengthened transiently. However, after 10 to 15 minutes the same basic cycle length returned. No testing was done immediately after each injection of pentobarbital. Refractory curves were determined during Wenckebach cycles in all dogs in which this experiment was attempted.

Statistical methods: Statistical comparison of conduction times of different beats for the same test interval was made with use of Student's t test. Effective refractory periods were compared using the Fischer exact test comparing the number of test beats conducted in one location of the Wenckebach cycle with the number of test beats conducted for the same test interval at another location in the cycle. Listed results are means ± standard deviations.

Results

Rapid atrial pacing induced stable second degree A-V nodal block of a 4:3 Wenckebach periodicity in all 23 dogs in which it was attempted. Each dog produced classic[2,3,16,17] Wenckebach cycles; the A-H conduction time progressively increased for beats 1 through 3 and the largest increase in conduction time occurred between the first and second beats. The mean basic cycle length was 251.2 ± 32.4 msec (mean ± standard deviation). The A-H conduction time was 107.8 ± 20.1 msec for the first beat, 142.8 ± 23.7 msec for the second beat and 162.4 ± 29.0 msec for the third beat.

Stable 4:3 Wenckebach periodicity could easily be induced over a narrow range of basic cycle lengths; the range was usually 4 to 8 msec wide. Wenckebach cycles with a ratio higher than 4:3 were found to be unstable. In our denervated canine heart model 4:3 Wenckebach cycles were stable for several hours with only small adjustments (10 to 20 msec) in the basic cycle length. The conduction time for each beat of the cycle was quite precise. For each dog 10 to 20 consecutive cycles were analyzed, and the average standard deviation of the A-H conduction time, expressed as percent, was 0.7 percent for the first beat, 0.8 percent for the second beat and 1.3 percent for the third beat.

Refractory Curves for Wenckebach Cycles

Refractory curves were determined during Wenckebach periodicity using stimulator that could insert a test stimulus after any preselected beat of the Wenckebach cycle. The test beat was inserted multiple times in each location of the cycle; all four beats of the cycle were scanned with the same test interval before the next test interval was used.

Figure 1 records the results of such testing in a typical experiment. When the test stimulus was inserted at the first beat of the Wenckebach cycle, that is, just after the blocked beat of the preceding cycle, curve 1 was generated. Curves 2, 3 and 4 were produced when the test beat stimulus was in-

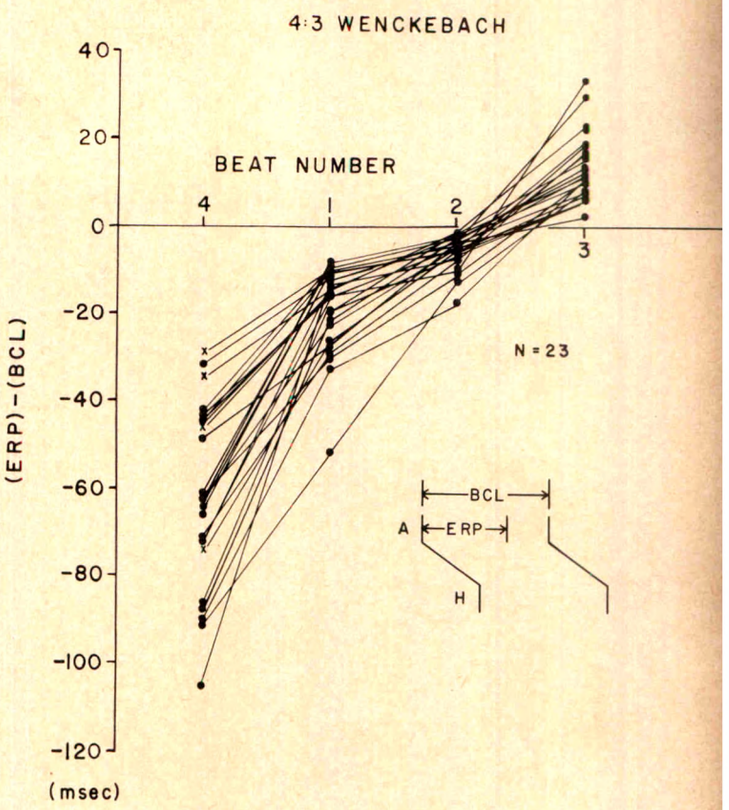

FIGURE 2. The relation between the effective refractory period (ERP) and the basic cycle length (BCL) for each beat of 4:3 Wenckebach cycles in 23 dogs. On the **horizontal axis** is the beat number. On the **vertical axis** is the difference between the effective refractory period after a given beat and the basic cycle length. The four points marked with a **cross** represent experiments in which the atrial functional refractory period was longer than the A-V nodal effect refractory period after the blocked beat. The effective refractory period was determined to the nearest millisecond. The effective refractory period after beat 4, the blocked beat, was 184 ± 23 msec, 66 ± 23 msec shorter than the basic cycle length; after the first beat it was 233 ± 30 msec, 19 ± 12 msec shorter than the basic cycle length; after the second beat it was 245 ± 31 msec, 6 ± 5 msec shorter than the basic cycle length; after the third beat it was 264 ± 34 msec, which exceeded the basic cycle length by 12 ± 7 msec. N = number of dogs.

serted as the second, third or fourth beat in the Wenckebach cycle. The A-V nodal effective refractory period is defined as the shortest atrial test interval that was reliably conducted. The effective refractory period after a given beat is denoted by the point on the curve for the next beat that has the minimal A-A′ interval. Earlier test beats were blocked. Figure 1 illustrates that as the Wenckebach cycle advances, there is a progressive increase in the refractoriness of the A-V node as marked by an increase in conduction time and an increase in the effective refractory period. The conduction time increases from beats 1 through 4 for any given test interval shown in ($P < 0.001$). The effective refractory period after the blocked beat, the fourth beat, is shorter than any subsequent effective refractory period; this period is marked by the point on curve 1 that has the minimal A-A′ interval (187 msec). The effective refractory period after the first beat (214 msec) is longer and the effective refractory period after the second beat is longer still (233 msec). The effective refractory period after the third beat (246 msec) exceeds the basic cycle length and consequently the fourth beat does normally not conduct. The fourth beat would conduct if the test interval were longer than the basic cycle length and effective refractory period after the third beat. Refractory curves during Wenckebach cycles were recorded in 23 dogs; they were all qualitatively similar to those in Figure 1.

Figure 2 illustrates the relation between the effective refractory period and the basic cycle length for each beat of 4:3 Wenckebach cycles in 23 dogs. In 4 of the 23 dogs, the atrial functional refractory period was longer than the effective refractory period of the A-V node after the blocked beat; in these cases (marked with an X in Fig. 2) the A-V nodal effective refractory period is only approximated. In all dogs there was a progressive increase in the effective refractory period as the Wenckebach cycle proceeded. Excluding the four experiments in which the effective refractory period after the fourth beat could not be reliably determined, the following mean results were obtained: The effective refractory period after beat 4, the blocked beat, was 184 msec. After the first beat, the effective refractory period was longer, 233 msec; after the second beat, it was further lengthened to 245 msec, which was only 6 msec shorter than the basic cycle length. After the third beat, the effective refractory period was 264 msec, which exceeded the basic cycle length by 12 msec. The effective refractory period after the third beat in all dogs was longer than the basic cycle length, hence the next beat, the fourth beat, was blocked.

The increase in effective refractory period as the Wenckebach cycle proceeded was highly variable. The largest increase in the effective refractory period occurred after the first conducted beat; among the 19 dogs in which the effective refractory period after the blocked beat could be determined, 18 showed the largest increase in the effective refractory period between beats 4 and 1. Although all dogs showed typical[2,3,16,17] Wenckebach progression in conduction times as the cycle proceeded, the effective refractory period did not increase with decreasing increments in 13 of the 23 dogs. In those dogs, the increase in the effective refractory period from beat 1 to beat 2 was smaller than the increase from beat 2 to beat 3. For each dog the increase in effective refractory period from beat 4 to beat 1, from 1 to 2, and then from 2 to 3 was significant ($P < 0.001$).

Effects of Changes in Basic Cycle Length

It is apparent from examining Figures 1 and 2 that during the Wenckebach cycle the A-V node is operating at four dis-

tinct states of refractoriness as defined by the four different refractory curves. The conduction times observed during the control cycles represent intersection of the basic cycle length with the refractory curves. It was found that small changes in the basic cycle length do not markedly alter the refractory curves during the Wenckebach cycle but could produce relatively large changes in the conduction times of the cycle. This was especially true for the last conducted beat, beat 3, because the basic cycle length intercepts refractory curve for that beat at a relatively steep portion of its curve.

Figure 3 illustrates the relation between small changes in basic cycle length and the resulting conduction times during a 4:3 Wenckebach cycle. The refractory curves were recorded at a basic cycle length of 275 msec. The control conduction times represent the intersections of the refractory curves with a vertical line representing the control basic cycle length of 275 msec. When the basic cycle length was shortened to 270 msec or lengthened to 277 msec, 4:3 Wenckebach cycles with different conduction times were recorded (illustrated by two sets of open circles). It is clear that the points recorded at the basic cycle lengths of 270 and 277 msec fall along the same refractory curves that were recorded at the control cycle length; the different basic cycle lengths intersect the same refractory curves at slightly different points. The conduction times for the 3 different basic cycle lengths are illustrated in Table I.

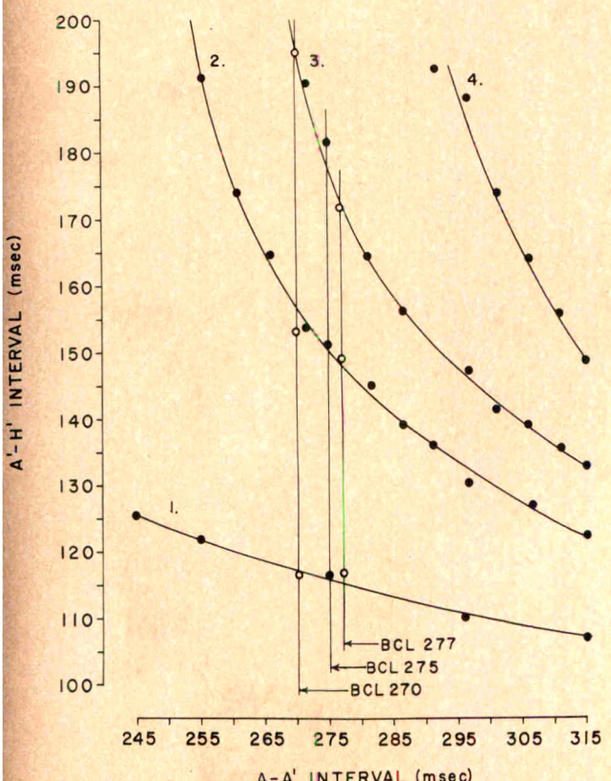

FIGURE 3. The A-V nodal conduction time (A′-H′) for a test beat versus the test interval (A-A′) for each beat of a 4:3 Wenckebach cycle at a basic cycle length (BCL) of 275 msec. The **open circles** are the control conduction times recorded when the basic cycle length was changed to 270 and 277 msec. Each point represents the mean of 6 to 10 observations.

TABLE I

A′-H′ Conduction Time for the 4:3 Wenckebach Cycles at Three Different Basic Cycle Lengths

Beat no.	Basic Cycle Length (msec) 277.0		275.0		270.1
1	115.9 ± 0.6		115.3 ± 1.2		115.5 ± 1.0
2	147.6 ± 1.5	*	150.2 ± 1.2	*	152.8 ± 2.3
3	170.9 ± 6.1	*	180.7 ± 8.3	*	194.6 ± 10.7

* $P < 0.01$.

The experiment is the same as that depicted in Figure 3. The values in msec are means ± standard deviation.

In the area of interest, the refractory curve for beat 3 has a steep slope (−3.4) and, consequently, the conduction times for the last conducted beat, the third beat, differ markedly (Table I). Expressed as percent change, an increase in the basic cycle length of 2.5 percent (270 to 277 msec) caused a decrease of 14 percent in the conduction time of the third beat (195 to 171 msec). At the longer cycle lengths of 275 and 277 msec, the Wenckebach cycle shows typical progression in conduction times; for example, at a cycle length of 275 msec, the increment in conduction from beat 1 to 2 (34.9 msec) is greater than from beat 2 to 3 (30.5 msec). At a cycle length of 270 msec, however, the Wenckebach cycle becomes atypical, and the increment in conduction time for beat 1 to 2 (37.3 msec) is less than the increment from beat 2 to 3 (41.8 msec).

During 4:3 Wenckebach periodicity, the A-V node functions at four distinct levels of refractoriness, as denoted by the refractory curves, and, at the time of the last conducted beat, the A-V node is very close to its effective refractory period and sensitive to the exact timing of atrial stimulation. Small changes in the basic cycle length can have large changes in the conduction times observed during Wenckebach cycles and can convert a cycle from one having a typical progression in conduction time to one that has an atypical progression. It is apparent from Figures 1 and 3 that 4:3 Wenckebach periodicity could be produced over a small range of basic cycle lengths. With further shortening of the basic cycle length, it would be expected that ultimately the third beat of the cycle would be blocked, when the basic cycle length became less than the effective refractory period after the second beat. Shortening of the cycle length would convert the 4:3 cycle into a 3:2 cycle.

To study the relation between cycle length and refractoriness of the A-V node during Wenckebach cycles of varying ratios, we drew refractory curves during 4:3, 3:2 and 2:1 cycles in three dogs (Fig. 4). At a basic cycle length of 261 msec, 4:3 Wenckebach periodicity was recorded (panel A). The refractory curves drawn during this rhythm were similar to those previously discussed. When the basic cycle lengths were shortened to 251 msec, a 3:2 Wenckebach cycle resulted (panel B); the third stimulus occurs during the effective refractory period after the second beat and the third beat does not conduct. If the third beat were delayed by 9 msec or longer, then it would conduct. With further shortening of the basic cycle length, 2:1 A-V nodal block was produced (panel C). It is apparent from the refractory curves drawn during this rhythm that the basic underlying phenomenon is the same as during 4:3 and 3:2 Wenckebach cycles. The basic cycle length of 230 msec is less than the effective refractory period after the first beat and the second beat fails to conduct. When the stimulus was delayed by 20 msec or longer, however, the second beat began to conduct.

The conversion from a 4:3 cycle to a 3:2 and then to a 2:1

cycle, which occurs because of shortening of the basic cycle length, is aided by a frequency-dependent increase in the refractoriness of the A-V node. In general, as the basic cycle length shortened, all the refractory curves shift rightward, denoting increasing refractoriness. For example, at a cycle length of 261 msec, the effective refractory period after the second beat is 254 msec (Fig. 4A). At a cycle length of 251 msec, after it increases to 260 msec (Fig. 4B). At the same time that the basic cycle length shortened, the refractory curve for the third beat moves rightward. Similarly, as the basic cycle length is shortened from 261 msec (4:3 cycle) to 230 msec (2:1 cycle), the effective refractory period after the blocked beat lengthens (174 to 205 msec), as does the effective refractory period after the first beat (245 to 250 msec).

Although the increase in refractoriness could be due to the change in conduction ratios of the Wenckebach cycles, data recorded during 1:1 conduction, to be discussed later, suggest that it is a rate-dependent effect. The increase in refractoriness resulting from a decrease in cycle length implies that, from the refractory curves recorded during 4:3 Wenckebach

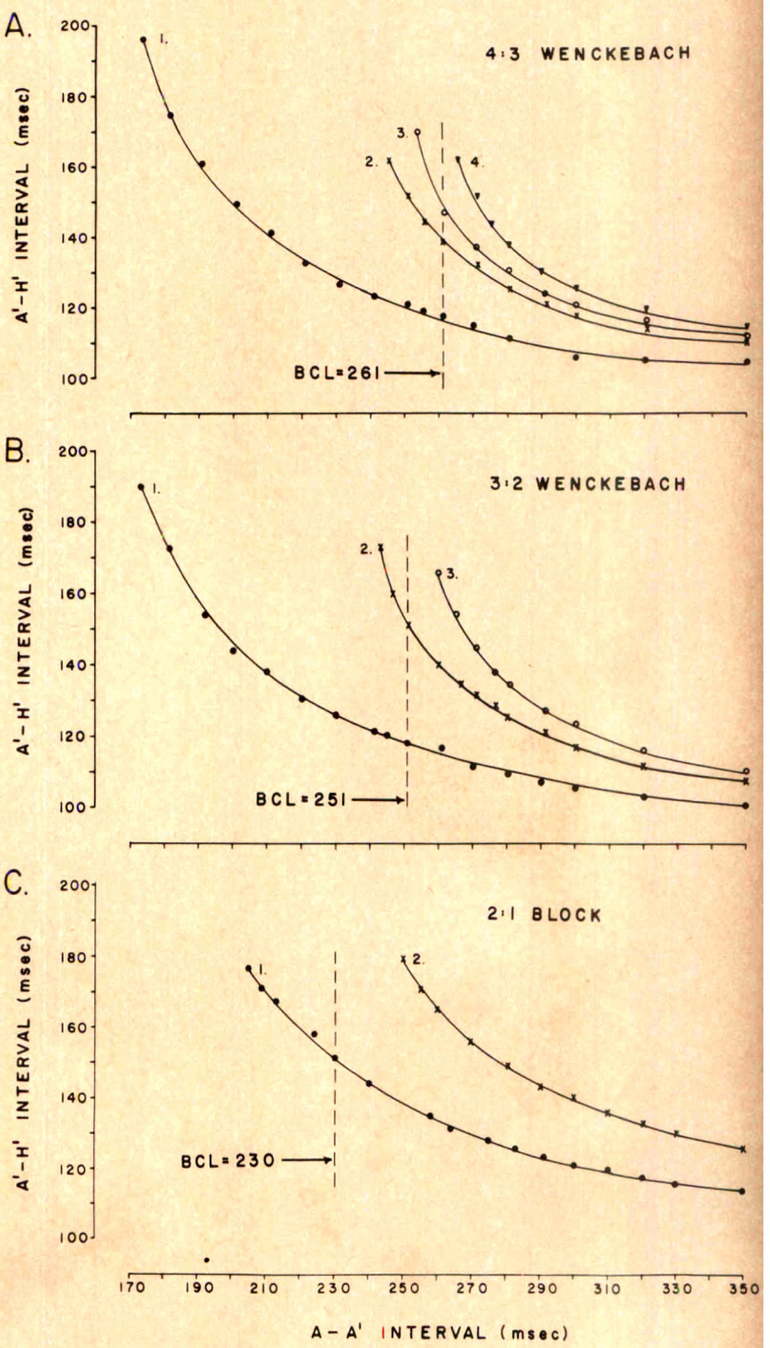

FIGURE 4. The conduction time (A′-H′) for a test beat versus the test interval (A-A′) for each beat of Wenckebach cycles recorded at three different basic cycle lengths (BCL) in the same dog (216 msec in A, 251 msec in B and 230 msec in C). Each point represents the mean of six observations.

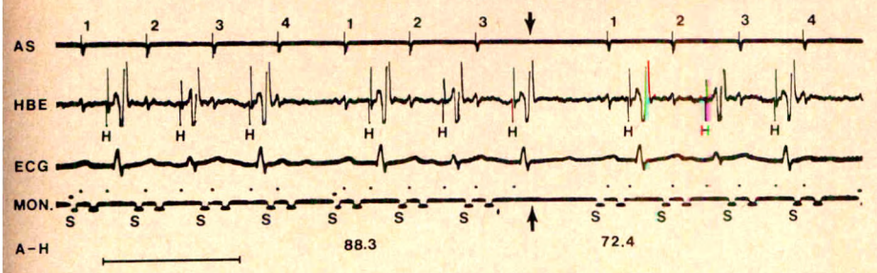

FIGURE 5. No reentry during 4:3 anterograde Wenckebach cycles. Tracings from above downward are a recording from the low atrial septum (AS), the His bundle electrogram (HBE) (His depolarizations are marked with an H), a lead II electrocardiogram (ECG) and a monitor signal (MON.) that depicts the activity of the atrial and His detection circuits; the transitions marked with an S occurred at the time of the stimulus. A control 4:3 Wenckebach cycle is shown. After the third beat of the second cycle, the stimulus was interrupted **(arrows).** No atrial echo was seen after the third beat. The basic cycle length was 234.3 msec. The A-H intervals for beats 1 to 3 were 88.3 ± 0.9 msec, 118.5 ± 1.5 msec and 128.0 ± 2.1 msec. The time calibration is 500 msec.

periodicity, one could not predict precisely the refractory curves during the shorter cycles. In other words, the refractory curves for a 4:3 Wenckebach rhythm were not superimposable with the refractory curves from the 3:2 and 2:1 rhythms.

Reentry During Wenckebach Cycles

It has been suggested that reentry occurs continuously during Wenckebach cycles and that the last beat of the cycles is blocked because of a collision and cancellation between a reentrant beat and the normally conducted beat.[9,10] Experimental results supporting this hypothesis have been obtained in Wenckebach cycles produced by retrograde stimulation of the A-V node in dogs and during anterograde and retrograde stimulation in the human and rabbit heart.[6,7,9,10,18–20]

In our experiments reentry did not occur during Wenckebach cycles. There are three lines of evidence supporting this conclusion: First, the refractory curves recorded during 4:3 anterograde Wenckebach cycles demonstrate that the blocked beat will conduct if the stimulus is delayed by a small interval, a mean of 12 msec for all 23 dogs (Fig. 2). If a reentrant beat were arising from the last conducted beat, the third beat, then a delay of the stimulus at the time of the fourth beat would allow the reentrant beat to proceed through the node even farther and eventually emerge in a retrograde direction. The effect of the emerging reentrant beat would be to leave the A-V node considerably more refractory than after a normally conducted beat. One would therefore expect that the effective refractory period after the third beat would be considerably prolonged. The fact that the fourth beat would conduct if the stimulus were delayed a mean of 12 msec implies that the A-V node was not engaged by a reentrant beat conducting in a retrograde fashion.

In 16 dogs further experiments were performed to test directly for reentry during 4:3 Wenckebach cycles. In these experiments, stimulation was interrupted after the stimulus producing a third beat to assay for a reentrant beat; if reentry were occurring during Wenckebach cycles, one would expect an atrial echo after the third beat.[9,10] Figure 5 illustrates a typical experiment. Stable 4:3 Wenckebach cycles were produced by rapid atrial pacing at a basic cycle length of 234.3 msec. After four control cycles, atrial stimulation was interrupted after the stimulus producing the third beat (arrows). As can be seen, there is no evidence of an atrial or ventricular echo occurring after the third beat of the cycle. Stimulation was interrupted for a period of time equal to two times the basic cycle length. Assuming that retrograde conduction began as late as the last His potential of the cycle, 340 msec was allowed for the reentrant beat to emerge, a period 2.7 times longer than the longest anterograde conduction time in the cycle. The first atrial response after the pause in stimulation was paced, and the latency was unchanged. This experiment was performed 588 times in 16 dogs. No examples of atrial or ventricular echoes were seen during any of these trials.

Another line of evidence against reentry during anterograde 4:3 Wenckebach cycles is that, when the fourth stimulus was not delivered, the first beat of the next cycle always had a shorter conduction time. In Figure 5, for example, the control conduction time for the first beat is 88.3 msec. After the cycle in which the stimulation was interrupted, the conduction time for the first beat of the next cycle was shorter, 72.4 msec ($P < 0.001$), and similar to the conduction time (69.5 msec) recorded in the same dog during 1:1 conduction at a cycle length of 450 msec. This phenomenon was seen in all 16 dogs in which the experiment was performed. The conduction time was shortened by a mean of 15.3 ± 7.1 msec. The decrease of the conduction time implies that during 4:3 Wenckebach cycles concealed conduction occurs;[21–25] the fourth stimulus penetrates into the A-V node, is blocked there and prolongs the refractoriness of the A-V node. When the fourth stimulus is not delivered, then the A-V node is less refractory and can conduct more rapidly. If there were reentry after the third beat of the cycle, and if the reentrant beat were blocked in its retrograde passage through the node, one would expect that it would leave the node refractory to a degree similar or greater than that after the blocked fourth beat in a normal cycle.

Wenckebach Phenomenon as a Manifestation of Positive Feedback

Levy et al.[11,12] hypothesized that the Wenckebach phenomenon can be described in terms of a positive feedback mechanism. In this theory, the conduction time of a test beat (the P′-R′ interval in their experiments) is expressed as a function of the preceding R-P′ interval, that is, P′-R′ = f(R-P′). Because the P-P′ interval by definition equals P-R + R-P′, one could predict subsequent P′-R′ intervals on the basis of knowing one P-R interval if one knew the P-P′ intervals and if the function P′-R′ = f(R-P′) were stable. Depending on the exact shape of the curve that defines the function and depending on the P-P′ intervals, a series of P′-R′ conduction times could show a variety of behavior such as convergence to a final value, or a gradual increase and eventual block, as during Wenckebach periodicity. Levy and coworkers[11,12,26] have provided and analyzed examples of such behavior. On the basis of conduction studies in the rat heart, Van Capelle et al.[27] suggested a mechanism for Wenckebach cycles similar to positive feedback.

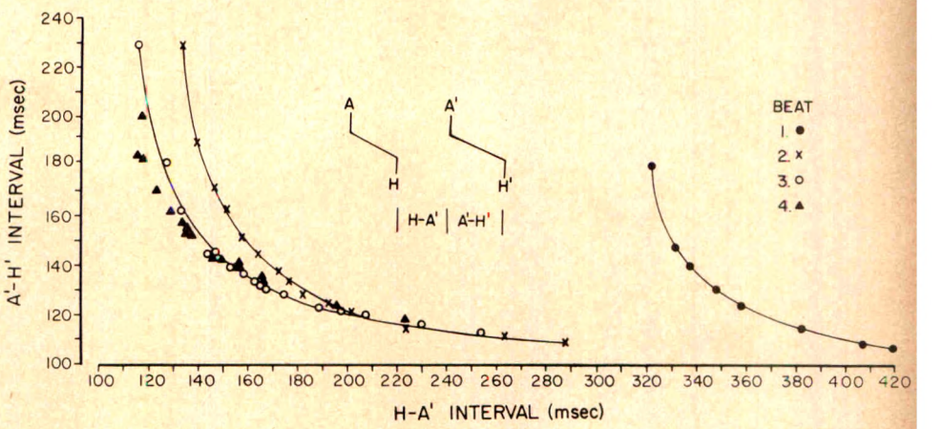

FIGURE 6. The conduction time for a test beat (A′-H′) versus the interval from the preceding His bundle signal to the low atrial septal electrogram for the test beat (H-A′). All four beats of a 4:3 Wenckebach cycle were tested. The symbol identification for the four beats is shown. The basic cycle length was 275.0 msec. The refractory curves in this figure were recorded simultaneously with the refractory curves shown in Figure 3 in the same experiment. Each point represents the mean of six observations.

For the positive feedback theory to be useful as a description of A-V nodal function, one must be able to define a function P′-R′ = f(R-P′) that is stable or at least varies predictably over time and with different perturbations. If the function varied unpredictably after a perturbation such as a blocked beat, then one could not use it to predict subsequent P-R intervals. The mathematical model would have limited value because one could not use it to define conduction time under varying circumstances. In our experiments on Wenckebach periodicity, the A-V node caused the varying A-V conduction times; in other words, the atrial and infranodal conduction times did not vary significantly (less than 0.5 msec) during the Wenckebach cycles, as previous workers have noted.[18,28,29] One could therefore convert the equation P′-R′ = f(R-P′) into the equivalent form A′-H′ = f(H-A′) by subtracting the constant atrial and infranodal conduction times.

We tested for a positive feedback mechanism during Wenckebach cycles in 23 dogs by assaying the stability of the function A′-H′ = f(H-A′) for each of the four beats during a 4:3 cycle. The function was defined by plotting the refractory curves expressing the A′-H′ interval as a function of the H-A′ interval for each of the four beats during testing with programmed stimulation. Figure 6 records a typical example. As can be seen, the relation between the A′-H′ and H-A′ intervals, is not constant throughout the Wenckebach cycle. The curve for the first beat is shifted rightward from the curves of subsequent beats because, to measure the H-A′ interval for the first beat, one must go back to the His potential of the last conducted beat, the third beat. The curves for the second through fourth beats, however, do not lie along the same curve; instead, there is a family of at least two and perhaps three separate curves that define the function A′-H′ = f(H-A′) during those beats. By comparing the H-A′ interval at the same A′-H′ interval for different beats, at least three statistically distinct curves were found in all 23 dogs. In Figure 6 the curves for beats 1, 2 and 3 were distinct from each other ($P < 0.001$) over the A′-H′ interval of 130 to 230 msec. Moreover, expressing the A′-H′ conduction time as a function of the H-A′ interval appears no more precise than expressing it as a function of the A-A′ interval. Figures 3 and 6 were recorded simultaneously from the same dog. In both figures, the refractory curves for the second and third beats are separated horizontally by approximately the same interval, 15 msec.

The results of these experiments demonstrate that during Wenckebach periodicity the function A′-H′ = f(H-A′) is not stable. Consequently, one cannot use a positive feedback mechanism that assumes that this function is stable in order to predict from the conduction time of one beat the conduction times of subsequent beats. We explored whether the function could be made more stable by including a second independent variable, such as the time from the blocked beat, the position of a beat within the cycle or the A-A′ interval. We were unable to find a function of two independent variables that was satisfactorily stable. Specifically, in four dogs the function A′-H′ = f(H-A′, A-A′) was studied when the A-A′ interval was held constant by plotting the A′-H′ versus H-A′ intervals for the beats after a test stimulus; in all four dogs the resulting curves were statistically distinct ($P < 0.01$). We conclude from these experiments that no positive feedback mechanism is operative during Wenckebach cycles that depends on a function describing the A′-H′ versus the H-A′ interval. It appears unlikely, also, that there is a feedback mechanism that depends on a function of two independent variables.

Studies in the isolated rat heart[27] showed that the effective refractory period after a beat occurred at a constant time interval after the ventricular depolarization of that beat and was independent of the previous history of the A-V conduction system. In Figure 6, the effective refractory period after various beats of the Wenckebach cycle does not occur at a constant H-A′ interval. It appears, therefore, that in the canine heart during Wenckebach cycles, one cannot adequately describe refractoriness as a function of the H-A′ interval alone.

Cumulative Effect

During 1:1 conduction when the frequency of atrial stimulation is abruptly changed to a new steady level, the A-H conduction time does not immediately jump to a new final value. Instead, a cumulative effect is seen; that is, a final value is approached through a series of intermediate steps. This effect has been seen in the canine and rabbit A-V nodes.[30,31] Heethaar et al.[32,33] described a similar phenomenon in the rat heart and found that one could describe the conduction time of the intermediate beats by means of an exponential equation.

During the Wenckebach phenomenon, the input frequency to the A-V node, the A-A′ interval, is constant and a cumulative effect could not occur on the basis of a change in input frequency. In a series of experiments, we studied whether one could find a cumulative effect after a blocked beat. Our reasoning was as follows: If, after a blocked beat, there was a slow increase in refractoriness of the A-V node during the subsequent series of beats, and if this increase in refractoriness were large enough to block another beat, then a self-sustaining cycle similar to a Wenckebach cycle would be established.

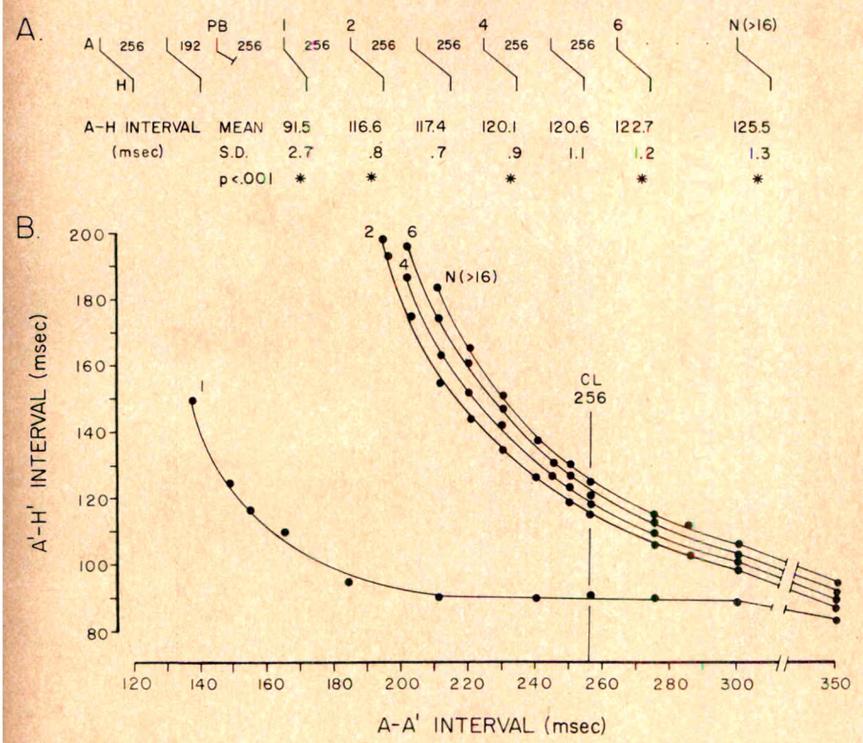

FIGURE 7. A, the pattern of stimulation used to study a cumulative effect during 1:1 conduction. At a basic cycle length of 256 msec a blocked premature beat (PB) was inserted at an A-A′ interval of 192 msec. Basic driving stimulation was immediately resumed. The A-H conduction times for the subsequent beats are listed. The nth beat (N) was more than 16 beats after the blocked premature beat. Each measurement represents the mean of 10 observations. p = probability; S.D. = standard deviation. **B,** refractory curves recorded when the test beat was inserted in various locations after the blocked premature beat. The conduction time for the test beat (A′-H′) is plotted against the test interval (A-A′). The basic cycle length (CL) is 256 msec Each point represents the mean of six observations.

We investigated this hypothesis in two series of experiments: First, during stressed 1:1 conduction, we explored whether one could find a cumulative effect on refractoriness and conduction time after a blocked beat. Second, we assayed the effect of a change in basic cycle length on the degree of cumulative effect to detect if, as the limit of 1:1 conduction is approached, the cumulative effect is large enough to spontaneously block another beat.

In the first set of experiments (*Fig. 7*) the heart was paced at a rate near the maximum rate permitting 1:1 conduction. No spontaneously blocked beats were observed during a 10 minute control period. Intermittently, after more than 16 basic driving beats, a premature beat was inserted at a time that was 10 to 20 msec less than the effective refractory period after the control beats. The premature beat was reliably blocked. Immediately after the premature beat, pacing resumed at the basic cycle length. Figure 7A diagrammatically represents the stimulation pattern in a typical experiment. The basic cycle length was 256 msec. The premature beat was inserted with a test interval of 192 msec. The conduction time for the nth or control beat, which occurred more than 16 cycles after the blocked premature beat, was determined. The conduction time for the first beat after the blocked premature beat did not immediately return to control; instead there was a gradual progressive increase in conduction times from the second beat (116.6 msec) to the nth beat (125.5 msec). Beats 3 to 6 after the premature beat had intermediate levels of conduction time. These results were significant (P <0.001). After a blocked premature beat during stressed 1:1 conduction there is a gradual progressive increase in conduction time.

We then explored whether the increase in conduction time was reflected in refractory curves (*Fig. 7B*). Refractory curves (A′-H′ versus A-A′ intervals) were drawn in a manner analogous to that in the Wenckebach studies. Figure 7B shows the refractory curves for beats 1, 2, 4 and 6 and for the nth beat from the same experiment as in Figure 7A. The conduction times observed during the control stimulation period are seen to be the results of the intersection of the basic cycle length with the refractory curves. It is also apparent that there is a progressive increase in refractoriness from the first to the nth beat as marked by an increase in A′-H′ conduction time for all the illustrated beats (P <0.005 for the A-A′ intervals 140 to 300 msec). The effective refractory period is shortest after the blocked beat and increases after the first beat to the nth beat (P <0.001). The largest increase in refractoriness occurs between the first and second beats; after the second beat there is a slow increase in refractoriness to the nth beat.

These experiments demonstrate that after a blocked premature beat the refractoriness of the A-V node shortens and does not immediately return to control value of refractoriness; instead there is a cumulative effect of a gradual increase in refractoriness lasting more than six beats. This experiment was performed in eight dogs with similar results. In seven of the eight dogs, the refractory curves for the second and nth beats were statistically distinct (P <0.01); in all eight dogs the refractory curves for the first beat were distinct from the second and nth beats (P <0.001). The refractory curves recorded in these experiments differed from those measured during the Wenckebach rhythm in two important aspects: First, the degree of increase of refractoriness from the second to the nth beat was less than that observed during Wenckebach periodicity. Second, although there was an increase in the duration of refractoriness from the first to the nth beat, it was not sufficient to cause the nth beat to block. The experiments were performed at 1:1 conduction and the nth beat continued to conduct; that is, the basic cycle length was longer than the effective refractory period after the n-1 beat (Fig. 7B). During Wenckebach phenomenon the effective refractory period after the last conducted beat exceeds the basic cycle length and the next beat is blocked.

A second set of experiments (*Fig. 8*) *was designed to explore the following two points:* (1) The effect of changes in

basic cycle length on the extent of the cumulative effect after a blocked beat, as marked by changes in the effective refractory periods for the subsequent beats. (2) The relation between the effective refractory period of the nth beat and the basic cycle length at different basic cycle lengths. These experiments were performed in a manner similar to those just described. The effective refractory periods were determined for the beats during Wenckebach cycles and for the series of beats after a blocked premature beat during stressed 1:1 conduction at different cycle lengths. The basic cycle lengths used were (1) the minimal basic cycle length that reliably produced 1:1 conduction, (2) a basic cycle length 15 msec longer, and (3) a basic cycle length that produced 4:3 Wenckebach periodicity. This experiment was performed in eight other dogs (Fig. 8). The mean results for testing only in the first, second and nth positions are shown diagramatically; the effective refractory periods for the intermediate beats had intermediate values.

During 1:1 conduction at the longer basic cycle length, 281.7 msec, the effective refractory period for the nth beat was a mean of 64.2 msec shorter than the basic cycle length (Fig. 8A). When the basic cycle length was shortened by 15.5 msec (Fig. 8B), the effective refractory period for the nth beat was found to be 33.8 msec shorter than the basic cycle length of 266.2 msec ($P < 0.001$). The effective refractory period for the nth beat rapidly approaches the basic cycle length because of both a decrease in basic cycle length and an increase in the effective refractory period; shortening the basic cycle length caused the effective refractory period for the nth beat to lengthen by 14.9 msec (217.5 to 232.4 msec). Because the nth beat occurs more than 16 beats after the blocked beat, the increase in refractoriness represents the effect of the change in basic cycle length on the general level of refractoriness of the A-V node.

When the basic cycle length was shortened further to 252.0 msec, reliable 4:3 Wenckebach periodicity ensued (Fig. 8C). Although there is no nth beat in a Wenckebach cycle, the effective refractory period after the last conducted beat of the cycle serves as an estimate of the minimal control level of refractoriness because refractoriness is increasing throughout the cycle. The effective refractory period after the third beat is 268.4 msec, longer than any effective refractory period recorded during 1:1 conduction, and represents a continuation of the rate-dependent increase in refractoriness. In the three experimental situations, as the basic cycle length decreases from 281.7 to 266.2 msec, then to 252.0 msec, the effective refractory period after the blocked beat lengthens (143.2 msec, 153.5 msec and 170.1 msec, respectively), as does the effective refractory period after the first beat (215.5 msec, 221.0 msec and 234.0 msec). The increase represents a general frequency-dependent change in refractoriness. A similar phenomenon was seen in Wenckebach cycles of various ratios discussed earlier (Fig. 4).

During the Wenckebach cycle, the basic cycle length is 16.4 msec less than the effective refractory period after the last conducted beat; consequently, the next beat, the fourth beat, is blocked. By design, the premature beat in the experiments during 1:1 conduction was inserted at a test interval that was less than the control effective refractory period by a similar degree (19 msec and 14 msec at cycle lengths of 281.7 and 266.2 msec, respectively). Hence the blocked premature beat during 1:1 conduction mimics closely the effects of the spontaneously blocked beat during the Wenckebach cycle.

The experiments at 1:1 conduction show that as the frequency of stimulation increases the cumulative effect also increases. At the longer basic cycle length, 281.7 msec, the cumulative effect was small. A change in the effective refractory period after the first beat to the effective refractory period after the nth beat was 2.0 msec (Fig. 8A). When the basic cycle length was shortened by 15.5 msec, the extent of the cumulative effect increased to 11.3 msec (Fig. 8B). An increase in the cumulative effect as the basic cycle length shortened was seen in all eight dogs ($P < 0.005$). When the basic cycle length was decreased further to 252.0 msec, producing 4:3 cycles, the difference between the effective refractory period after the first beat to that after the third beat was 34.4 msec. For each dog the difference was larger than the cumulative effects seen during 1:1 conduction ($P < 0.005$).

These experiments demonstrate that a cumulative effect is observable after a blocked premature beat during a stressed 1:1 conduction, that it increases as the frequency of stimulation increases and that a similar but larger phenomenon is observed during Wenckebach cycles. As the limit of 1:1 conduction is approached, it seems logical to extrapolate that the effective refractory period would at some time exceed the basic cycle length and a beat would spontaneously become blocked. The blocked beat would then establish a cumulative effect; that is, the refractoriness would immediately shorten and then return to its control level only after a series of conducted beats. If the basic cycle length were short enough, eventually the effective refractory period of the node would exceed the cycle length and another beat would become blocked. This sequence would establish a Wenckebach cycle.

The Wenckebach cycle appears to represent the interplay of three factors: (1) a rate-dependent increase in refractori-

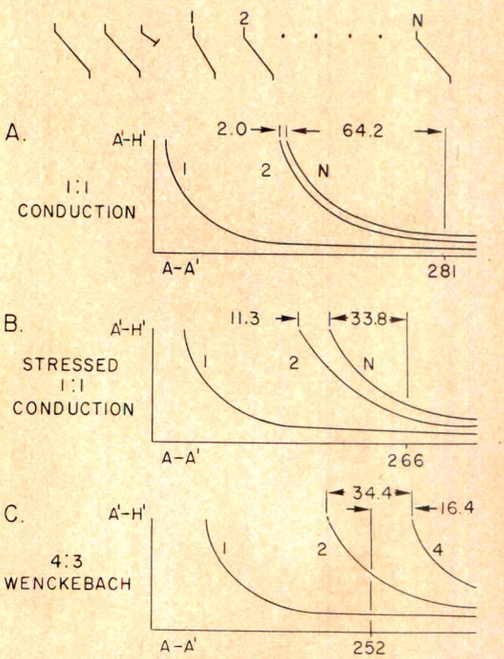

FIGURE 8. A and **B,** cumulative effect after a blocked premature beat as measured by a change in the effective refractory periods after the first and n-1 beats during testing at a basic cycle length of 281.7 msec **(A)** and 266.2 msec **(B).** The experimental protocol was similar to that depicted in Figure 7. The effective refractory period after the first beat is marked by the point on the curve for the second beat, which has the mimimal A-A′ test interval. The measurements in milliseconds represent the mean results of experiments in eight dogs. **C,** relation between the effective refractory periods after the first and third beats of a 4:3 Wenckebach cycle at a basic cycle length of 252.0 msec in the same eight dogs.

ness, (2) a shortening of refractoriness after a blocked beat, and (3) a cumulative effect after a blocked beat allowing a gradual increase in refractoriness. All three factors are seen during stressed 1:1 conduction. As the rate of stimulation increases during 1:1 conduction, both the control level of refractoriness and the cumulative effect increase in a manner that, if continued, would allow Wenckebach cycles to occur spontaneously. The effects of a blocked beat on subsequent refractoriness of the A-V node are essential to the mechanism of Wenckebach cycles.

Discussion

The refractory curves recorded during Wenckebach periodicity show that there is a progressive increase in refractoriness as the cycle proceeds and that during 4:3 Wenckebach cycles the A-V node repetitively advances through four distinct steps of increasing refractoriness. The blocked beat occurs because eventually a beat falls within the effective refractory period of the node. Refractory curves for all beats were smooth and without discontinuities, suggesting that dual pathways[34–36] through the A-V node were not involved in the production of Wenckebach cycles. The refractory curves had a continuously negative slope; therefore, any increase in refractoriness was qualitatively mirrored by an increase in conduction time.

Atypical Wenckebach Cycles

As classically defined,[16,17] typical Wenckebach cycles are marked by a progressive increase in A-V nodal conduction time, and the increment in conduction time continually decreases as the cycle proceeds. As a consequence of the progressive decrease in the increments in conduction time, the interval between ventricular depolarizations (R-R interval) decreases as the cycle advances.[17] Many observers[2,3,17,18] have noted that atypical Wenckebach cycles are frequently seen. This study offers several explanations for atypical cycles.

Small changes in the basic cycle length: The conduction times observed during Wenckebach cycles represent the intersection of the basic cycle length with the refractory curves. Small changes in the basic cycle length did not vary the refractory curves (Fig. 3) but had a large effect on the conduction time of the last conducted beat, the third beat, because the basic cycle length intersected the refractory curve for this beat at a steep portion of the curve. Consequently, small changes in the basic cycle length were magnified and caused much larger changes in the conduction time of the third beat. The most common feature of atypical Wenckebach cycles is that the conduction time of the last conducted beat is longer than expected.[2,17] The variability in conduction time of the last conducted beat reflects the fact that at the time of that beat the A-V node is very refractory and sensitive to the precise timing of the atrial input. Small, almost inapparent shifts in the basic cycle length can convert a typical cycle into an atypical one (Fig. 3).

Variable increase in refractoriness occurring during the Wenckebach cycle: This is a second reason for atypical cycles. Although conduction times of control Wenckebach cycles were typical in all dogs in our study, the increase in refractoriness as the cycle proceeded, as measured by the effective refractory periods, was frequently atypical. In 56 percent of the dogs (13 of 23) the effective refractory period did not increase with decreasing increments as the cycle advanced (Fig. 2). Moreover, the relation between the effective refractory period and conduction time is highly nonlinear, as can be seen by the shape of the refractory curves. The refractory curves, also, were not merely shifted rightward as the cycle proceeded, but changed shape; the curves for various beats were not superimposable. Because the observed conduction times in a Wenckebach cycle represent the intersection between the basic cycle length and the refractory curves, and because the refractory curves may vary in shape and position as the cycle proceeds, the increments of conduction time could also be highly variable. These studies demonstrate that a progressive decrease in the increments of conduction time is not at all a central feature of the Wenckebach arrhythmia. Because the increments of conduction time need not progressively decrease, the intervals between ventricular depolarizations need not also progressively decrease.

Fluctuations in the level of autonomic nervous system tone: This is another reason for the large incidence of atypical Wenckebach cycles. In our studies, the effects of the autonomic nervous system on the A-V node were minimized by interrupting the stellate ganglia and the vagi. Under these circumstances, it was found that the A-V node is quite precise. The mean standard deviation of the A-H conduction time for all dogs was 0.6 percent during 1:1 conduction. During Wenckebach cycles, the average standard deviation ranged from 0.7 percent for the first beat to 1.3 percent for the third beat. The precision of the denervated canine A-V node in our study exceeded the precision of commonly used electrophysiologic recording systems; speed variations of 15 percent have been reported for photographic paper recorders, for example.[37]

Changes in the tone of the autonomic nervous system can have marked effect on the sinus node rate and on the conduction time and refractoriness of the A-V node.[30,38] The effect of a change in autonomic tone on the Wenckebach rhythm could be complex and unpredictable for several reasons. First, altering the autonomic tone would produce changes in sinus rate and A-V nodal refractoriness that would produce opposing effects on Wenckebach cycles. An increase in vagal tone, for example, slows the sinus rate and thereby promotes Wenckebach cycles of longer conduction ratios, just as lengthening the basic cycle length does (Fig. 4). At the same time, a vagally induced increase in A-V nodal refractoriness would tend to produce Wenckebach cycles of a shorter conduction ratio because the refractory curves would shift rightward relative to the basic cycle length. The net effect of an increase in vagal tone would thereby be complex. Second, alterations in pulse pressure and cardiac output induced by the changing ventricular rate and the varying relation between atrial and ventricular depolarization during the Wenckebach cycle would alter autonomic tone.[39] Latency between the

change in autonomic tone and its effect on sinus rate or A-V nodal conduction time appears to be 200 to 450 msec.[28,40] As a consequence, the level of autonomic tone during a Wenckebach cycle could be continually varying in response to cardiac output changes induced by the cycle. Moreover, the autonomic nervous system receives inputs from diverse physiologic processes, such as respiration, which would independently influence the Wenckebach cycles.[39] Alteration in the tone of the autonomic nervous system is undoubtedly a frequent cause of atypical Wenckebach cycles.

Cumulative Effects in Wenckebach Cycles

A major purpose of our work was to document a cumulative effect after a blocked premature beat and to explore the relation between the cumulative effect and Wenckebach cycles. When the frequency of input stimulation to the A-V node is abruptly changed from one steady value to another, the conduction time and refractory period do not immediately follow the step in input frequency. Instead the conduction time and refractory periods for the beats after the frequency step show a gradual change to a new stable value. The change in conduction time and refractory period is usually the largest for the first beat after the step, and subsequent changes are smaller. This phenomenon, termed a cumulative or fatigue effect, has been observed in the conduction time and refractory period of the A-V node and in the refractory period of the atrium, His bundle and ventricular muscle.[31,32,41,42]

Cumulative effect after a blocked premature beat: Cumulative effects have usually been studied by changing the input frequency from one steady value to another. One purpose of our study was to document a cumulative effect after a brief transient perturbation, a blocked premature beat. A cumulative effect was seen for the effective refractory periods and conduction times of beats after a blocked premature beat during stressed 1:1 conduction (Fig. 8B). This effect was strongly dependent on frequency of stimulation and was apparent only during rapid rates of atrial stimulation. At slightly slower rates of stimulation, a cumulative effect was barely noticeable (Fig. 8A). Heethaar et al.[33] measured a similar cumulative effect after a blocked beat in the rat heart.

Cumulative effect on refractoriness: The cumulative effect observed after a blocked premature beat during stressed 1:1 conduction is intimately related to the production and maintenance of Wenckebach cycles. If the cumulative effect on refractoriness were large enough so that the A-V node would block another beat, then a self-sustaining cycle would be established. After a blocked beat, refractoriness shortens, and then only gradually increases because of a cumulative effect, allowing the beats after the blocked beat to conduct. Eventually refractoriness increases sufficiently to block another beat, which in turn establishes another cycle.

The logic of invoking a cumulative effect after a blocked beat in the production of Wenckebach cycles rests on the following observations: (1) Cumulative effects were seen at stressed 1:1 conduction that produced changes in the conduction time and refractoriness qualitatively similar to those observed during Wenckebach cycles. (2) Cumulative effects increased as the limit of 1:1 conduction was approached. (3) Because of a rate-dependent increase in the refractoriness of the A-V node, the effective refractory period rapidly converged on the basic cycle length as the limit of 1:1 conduction was approached. It seems logical to assume that with further shortening of the basic cycle length, the effective refractory period would exceed the basic cycle length, a beat would therefore block, and a cumulative effect would ensue, ending in another blocked beat.

The cumulative effect is most closely involved in the maintenance of Wenckebach cycles with conduction ratios greater than 2:1. If the cumulative effect were nonexistent, then the A-V node would not be able to sustain Wenckebach cycles with conduction ratios greater than 2:1. For example, if the A-V node had at all times a response to a blocked beat similar to that demonstrated in Fig. 8A, i.e., little or no further increase in refractoriness after the first conducted beat following the blocked beat, then the A-V node would be able to sustain only 2:1 cycles. After the first beat of the cycle, the node would immediately return to its control level of refractoriness, which would have to be in excess of the basic cycle length if beats were to block spontaneously. Hence, every other beat would block, and only 2:1 cycles could be maintained. The refractory curves in this situation would be expected to be similar to the 2:1 cycles recorded in Figure 4.

Electrophysiologic Mechanisms

Although the electrophysiology of the A-V node is not fully understood, two mechanisms are likely to be important in the production of a cumulative effect: (1) the effect of electrotonic interactions on the refractoriness of the cells of the A-V node, and (2) intrinsic, frequency-dependent changes in the duration of refractoriness of A-V nodal cells.

Electrotonic interactions and refractoriness of A-V nodal cells: The A-V node functions as a syncytium with electric interconnections between cells that allow them to pass current from one to another, thereby interacting with each other.[4,43,44] These interactions, termed electrotonic interactions, allow a cell that depolarizes, for example, to supply depolarizing current to neighboring cells, thereby depolarizing them to a variable degree. If the neighboring cells do not fully depolarize, they in turn will supply repolarizing current back to the original cell, thereby tending to repolarize it. Electrotonic interactions are thought to be responsible for shortening the action potential duration of cells at the edge of an arrested wave front of depolarization and prolonging the action potential duration of cells at the edge of a slowly conducting wave front of depolarization.[43]

Mendez and Moe[43] demonstrated that there is a correlation between action potential duration and the duration of refractoriness. After an abbreviated action potential, arising from a blocked beat, the duration of

refractoriness is shorter than after a normally conducted beat with a longer action potential duration. Conversely, there is a longer duration of refractoriness when the action potential duration is prolonged by slow conduction.

A cumulative effect could be explained in terms of electrotonic interactions and action potential duration in the following manner[8]: The blocked beat enters the A-V node and blocks at a variable distance within the node. The action potential duration of the cells that conducted the beat is shortened because of electrotonic interactions. The refractoriness of the node therefore is relatively less than normal because the action potential duration of the cells that conducted the beat is shortened and because the more distal portions of the A-V node are not fully depolarized. Consequently, the first beat after the blocked beat conducts in the node reasonably rapidly. The action potential duration of the first beat is longer than that after the blocked beat because there are no electrotonic interactions tending to shorten it. Because the action potential duration is longer, the second beat finds the cells of the A-V node more refractory. Therefore the second beat conducts even more slowly, and the action potential duration of the second beat is even longer. Consequently, the third and successive beats find the A-V node even more refractory. Because cells conducting slowly have a longer action potential duration as a results of electrotonic interactions and because action potential duration influences the duration of refractoriness, successive beats would conduct progressively more slowly and would, in turn, promote progressively more refractoriness. Depending on the degree to which action potential duration and the duration of refractoriness interact, the A-V node would either become sufficiently refractory to block another beat, as in Wenckebach cycles, or stabilized to a final value of increased refractoriness, as in the cumulative effect seen after a blocked beat during 1:1 conduction. In support of the theory of electrotonic interactions, microelectrode studies of cells during Wenckebach conduction[4,5,7] have shown shortening of action potential duration for the blocked beat and then a progressive increase in action potential duration for the subsequent beats.

Intrinsic, frequency-dependent changes in duration of refractoriness of A-V nodal cells: A second explanation for the cumulative effect may lie in the delayed recovery of electrical excitability of A-V nodal cells. With direct intracell stimulation of A-V nodal cells, Meredith et al.[31] found that the recovery of excitability lags behind full electrical repolarization by as much as several hundred milliseconds. A lag in recovery is not seen in other cardiac cells under normal circumstances, and these data provide one line of evidence that the physicochemical basis for the action potential in the A-V nodal cells differs from that in other cardiac cells and may involve a slow channel calcium-dependent mechanism.[45,46]

As the frequency of stimulation increases, the lag in recovery of electrical excitability prolongs and the threshold for electrical excitability increases.[31] The time courses for the increase in the delay of recovery of electrical excitability and for the increase in diastolic threshold after a frequency step or after a blocked premature beat are unknown. By analogy to the increased conduction time and the increased effective refractory period of the A-V node with increasing frequency of stimulation, one might conclude that the lag in recovery and the diastolic threshold of individual cells may show cumulative effects. In other words, cells distal to a blocked beat may decrease their delay in recovery of excitability and diastolic threshold, and with subsequent beats only gradually increase these variables. Hence, the cumulative effect after a blocked beat for the conduction time and the effective refractory period of the entire A-V node may mimic and be due to changes in excitability occurring at the cell level.

Positive Feedback

The mechanisms discussed so far involve the concept of positive feedback, that is, a means by which a change in a given function (the slowing of conduction) engenders a process (increased refractoriness) that in turn causes a further change in the same direction of the original function (further slowing of conduction). The concept of positive feedback has been extensively applied to Wenckebach cycles by Levy et al.[11,12] One could consider the cumulative effect for the conduction time and effective refractory period after a blocked beat to be a manifestation of a self-limited form of positive feedback.

In our studies, the conduction time through the A-V node, the A-H interval, could not be expressed in terms of a positive feedback process with the diastolic interval, the H-A′ interval, as the sole independent variable. The function $A'\text{-}H' = f(H\text{-}A')$ was not stable throughout the Wenckebach cycles, and consequently one could not use it to predict subsequent conduction times. This finding does not invalidate the concept of positive feedback; rather it indicates that it should not be applied literally. There appear to be multiple determinants of conduction time through the A-V node, and this is not surprising in view of the complexity of A-V nodal conduction involving many elements that may combine in a highly nonlinear fashion: the complex geometry,[37] inhomogeneous conduction pathways,[6,7] summation,[5,44] the variable length of conduction pathways,[7,25] a poorly defined physicochemical basis for electrical activity within the cells,[45,46] electrotonic influences on repolarization and delayed recovery of excitability,[8,31,43] and so on.

Reentry During Wenckebach Cycles

In these studies we found no evidence for overt or concealed reentry during anterograde Wenckebach cycles. Unambiguous evidence for concealed and manifest reentry has been documented during retrograde Wenckebach cycles in the canine heart, and during anterograde and retrograde cycles in the rabbit and in the human A-V node.[6,9,10,18,19] It has been suggested by Damato and co-workers[9,10] that concealed reentry occurs continuously throughout Wenckebach cycles; they

interpreted notches seen on the action potential of A-V nodal cells during Wenckebach cycles as evidence of reentry. However, others[4,7,19,24,43] have thought that notches during the action potential of A-V nodal cells were due to electrotonic influences during slow conduction.

It appears most likely that Wenckebach cycles and reentry are associated conditions, not necessarily causally related. The critical prerequisites for reentry appear to be (1) multiple pathways through the A-V node, (2) at least one pathway must be sufficiently refractory so that an impulse blocks in that pathway and reenters it at a later time in the opposite direction.[9,10,34,48,49] As the A-V node becomes increasingly refractory during a Wenckebach cycle, these conditions could be met and reentry could occur. The reentrant beat could then terminate the Wenckebach cycle by collision with the next impulse. However, the underlying mechanism for the reentrant beat is the increasing refractoriness as the Wenckebach cycles proceed; the reentrant beat is the effect and not the cause.

Myocardial Hemorrhage After Coronary Reperfusion in Pigs

ROBERT J. CAPONE, MD, FACC*
ALBERT S. MOST, MD, FACC

Providence, Rhode Island

The effects of 1 hour of occlusion of the left anterior descending coronary artery and subsequent reperfusion were studied for 3 hours in anesthetized closed chest pigs using an intracoronary balloon occluding technique. In 12 pigs subjected to reperfusion, S-T segment elevation decreased to control levels within 30 minutes and was significantly less than in 10 control pigs without reperfusion ($P < 0.05$). R wave amplitude was unaffected by the reperfusion. The more rapid fall of S-T segments in the reperfused group was accompanied by major hemorrhage in all reperfused hearts; hemorrhage occurred in only one control heart. The extent of hemorrhage was quantified and was significantly greater in the reperfused than in the control group ($P < 0.01$). Hemorrhage after reperfusion was unaffected by mannitol-induced increase in serum osmolality but was greatly decreased by limitation of the occlusion period to 15 minutes. Myocardial wall motion was quantified angiographically. Shortening fraction of the area of the left ventricle most severely affected by occlusion decreased to similar levels in both groups. After reperfusion it remained similar in both groups at three hours. Adjacent left ventricular areas were likewise unaffected by reperfusion.

This study thus documents the occurrence of postreperfusion myocardial hemorrhage in an animal with a coronary circulation similar to man's. Hemorrhage is directly related to the duration of occlusion but appears to be unaffected by mannitol given before reperfusion. Caution is advised both during bypass surgery, in which occlusion and reperfusion occur, and in efforts to restore coronary blood flow during acute myocardial infarction.

Coronary bypass surgery performed during acute myocardial infarction is a logical therapeutic maneuver undertaken to salvage ischemic myocardium and preserve myocardial function. Reports of bypass surgery in patients with acute infarction or ischemia have shown that the procedure is technically feasible and can be undertaken at an acceptable operative risk.[1–6] Despite the expected difficulty in defining an adequate control group for these observations, clinical improvement,[1–6] reversal of electrocardiographic evidence of ischemia[2] and serial improvement of segmental dysfunction[6] in those patients surviving surgery have suggested an improvement in ischemic myocardium. However, a recent report[7] of hemorrhagic necrosis in the myocardium served by patent bypass grafts indicates that the results of reperfusion during the course of myocardial infarction in man are not fully known.

Experimental studies in animals, performed to define the conditions under which potential benefits can be realized, have had widely divergent results. Segmental wall motion has been shown to be improved[6,8,9] or worsened[10–13] and infarct size decreased[8,14–17] or increased.[18] Intramyocardial hemorrhage, sometimes of massive proportions, has been reported and has been correlated with the duration of the preceding cor-

onary occlusion.[10,15,17,18] Although such hemorrhage has been thought to be related to direct disruption of vascular integrity,[19] Diaz et al.[20] reported a greatly reduced incidence of postreperfusion hemorrhage in the anesthetized or propranolol-treated dog, suggesting that reduced sympathetic tone under these circumstances may be responsible for this observation.

The applicability of experimental studies to man may be directly dependent on the animal model used. Our study of the effects of coronary reperfusion on intramyocardial hemorrhage, segmental wall motion and the precordial electrocardiographic map was therefore carried out in the pig, which has a heart similar to man's.[21–24]

Methods

Thirty-eight farm-bred pigs were anesthetized with chlorolose, 60 mg/kg body weight, and sodium pentobarbital, 35 mg/kg intravenously and placed supine. A precordial electrocardiographic map of 18 electrodes was recorded as previously described.[25] Three leads from the map were recorded simultaneously at double standard (1.0 mv = 20 mm) and at a paper speed of 25 mm/sec on an eight channel recording system. S-T segment elevation was measured 0.1 second beyond the beginning of the QRS complex; mean S-T elevation and mean R wave amplitude were calculated.

Femoral arterial pressure was monitored with a Statham P23Db pressure transducer. A no. 7F Eppendorf catheter, introduced through the other femoral artery, was passed retrograde into the left ventricle. Cardiac output determination was carried out using either the thermodilution technique with a thermistor catheter in the pulmonary artery or the indocyanine green technique with dye injection into the pulmonary artery and femoral arterial sampling. Arterial blood gases were monitored to assess the adequacy of ventilation; animals were rejected for study if the initial arterial partial pressure of oxygen (PO_2) was less than 80 mm Hg; if evidence of hypoxia developed during the study, supplemental oxygen was given to maintain PO_2 between 80 and 100 mm Hg.

Left ventriculograms were recorded in a 30° right anterior oblique projection. Fifteen to 20 cc of sodium and meglumine diatrizoates (Hypaque-M 75 percent®, Winthrop Laboratories) was power-injected over 2 seconds while 35 mm cine film was exposed at 60 frames/sec using a 6 inch image intensification system.

Occlusion technique: Details of the technique for coronary occlusion have previously been described.[25] In brief, a no. 8F thin-walled catheter was guided fluoroscopically into the left anterior descending coronary artery and 1 cc of sodium and meglumine diatrizoates was injected to permit visualization of its length and course. A no. 3F embolectomy catheter (Edwards Laboratories) was passed through the larger catheter into the left anterior descending coronary artery and the outer catheter was then withdrawn into the aorta. The tip of the catheter was positioned in a similar location in all animals: two thirds of the distance between the origin of the left anterior descending coronary artery and the inferior border of the heart. This position was always beyond the largest septal perforating vessel.

Protocol: Animals were randomly assigned to the reperfusion group (no. = 12) or to the nonreperfused control group (no. = 10). Control measurements were made of the precordial map, arterial blood gases, cardiac output, heart rate and arterial blood pressure. A left ventriculogram was next performed, completing the control condition. Hemodynamic and blood gas measurements were repeated at 60, 90, 120 and 180 minutes. Ventriculography was repeated at 60, 90 and 180 minutes. S-T segments were measured at 5, 10, 15, 30, 45 and 60 minutes, similarly during the second hour, and at 150 and 180 minutes. Precordial R wave amplitude was measured in the control period and at 60, 75 and 180 minutes.

Reperfusion was carried out in the reperfusion group immediately after the 60 minute measurements by abruptly deflating the coronary occlusion balloon and withdrawing the catheter into the aorta.

Pathologic analysis: The left ventricle was sectioned into seven slices by cuts placed perpendicular to an imaginary line extending between the left ventricular apex and aortic valve. Each slice was divided into five portions (septum and anterior and posterior right and left ventricles); the free ventricular portions were further divided into epicardial and endocardial portions and the septum into right and left ventricular portions. Each of these portions was examined for hemorrhage and scored as follows: 1 point for scattered involvement of less than 25 percent, 2 points for continuous involvement of less than 25 percent, 3 points for scattered involvement constituting 25 to 50 percent of the portion, 4 points for continuous involvement of 25 to 50 percent, and 5 points for continuous involvement of more than 50 percent. The score for each animal was obtained by summing all points.

Ventriculographic analysis: Left ventricular wall motion was analyzed by comparing the end-systolic and end-diastolic ventricular outlines during contrast opacification of the chamber. Analysis was carried out in a manner that corrected for rotation of the ventricle as follows: (1) A longitudinal reference line was drawn on the end-diastolic frame from the ventricular apex to the junction of the aortic and mitral valves. This junction is fibrous, noncontractile and easily identifiable, and it therefore served as a reliable reference point. (2) A similar reference line was drawn on the end-systolic frame. (3) Each longitudinal axis was divided into four equal segments by three hemiaxes drawn perpendicular to it; these hemiaxes were extended to the outline of the opacified ventricular chamber as previously drawn, thereby dividing the chamber into eight sectors.

The change in planimetered sector area was used to describe wall motion. Shortening fraction (SF) (percent) for each segment was calculated according to the formula:

$$SF = (A_{ed} - A_{es})/A_{ed} \times 100$$

where A_{ed} = end-diastolic sector area and A_{es} = end-systolic sector area.

This report describes the changes occurring in three sectors of each ventriculogram: the sector showing major depression secondary to the coronary occlusion and those two sectors adjacent to the major sector. The former was defined as that sector showing the most marked depression of the S-T segment at 1 hour when compared with the preocclusion state. The adjacent sectors were located, one superior to and one inferior to the major sector. If the latter was at the apex, the two adjacent sectors were located above and lateral to it.

Early release group: Seven animals underwent a similar coronary occlusion with reperfusion at 15 minutes. These animals were observed over the next 2 hours. They were then killed and their hearts studied pathologically to determine the effect of this brief occlusion on the incidence and extent of myocardial hemorrhage.

Mannitol group: Mannitol (62.5 g) was given to nine additional animals to examine its effect on the incidence or extent of myocardial hemorrhage. It was administered by constant infusion 30 to 45 minutes after occlusion, resulting in a significant rise of serum osmolarity, 30 ± 9 (standard error of

the mean) mOsm from baseline ($P < 0.05$). Reperfusion was then carried out at 1 hour and continued for a 2 hour period as in the control and reperfusion groups.

Statistical analysis: Data were analyzed using Student's *t* test for group data and for paired data where changes in each animal were examined. $P < 0.05$ was considered the lower level of significance.

Results

Hemodynamics (Table I): Heart rate was similar for both the control and reperfusion groups before occlusion. After occlusion, heart rate increased in the control group, resulting in a significant difference from values in the reperfusion group at 60 and 90 minutes after occlusion. Heart rates of both groups were similar for the remainder of the study, remaining slightly higher in the control group. Arterial pressure was similar in both groups except at 180 minutes, when mean arterial pressure was lower in the control group, thus coinciding with a tendency toward a higher heart rate in this group. Cardiac output was similar in both groups during the control period and remained so throughout the study. These measurements were examined within each group to detect serial changes occurring after 60 minutes. Comparison of the values at 90, 120 and 180 minutes with that at 60 minutes showed no changes in heart rate or cardiac output. There was a significant decrease in arterial pressure in both groups terminally.

Prevalence of hemorrhage (Fig. 1): Scores indicative of the severity and extent of hemorrhage ranged from 0 (no hemorrhage) to 72 for all 22 animals in the study. Of the 10 control animals, 6 were without hemorrhage, and only 1 had hemorrhage of major proportions (score 41); one had a small area of confluent septal hemorrhage and one a few spotty areas of septal hemorrhage. In the latter two hearts, the hemorrhage was confined to only one section. One heart in the control group was not available for examination. The mean score for the control group was 4 ± 4 (mean ± standard error of the mean). In contrast, 10 hearts from the 12 animals subjected to reperfusion alone were available for examination, and all showed extensive hemorrhage in the septal and anterior left ventricular walls, with occasional extensions seen into the posterior left ventricle and anterior right ventricle. Scores ranged from 9 to 72, with a mean of 25 ± 6. There was a highly significant difference between the scores of the reperfusion and control groups ($P < 0.01$).

Reperfusion in the nine animals with increased osmolarity due to prior mannitol infusion did not result in a lesser incidence of hemorrhage than in the animals

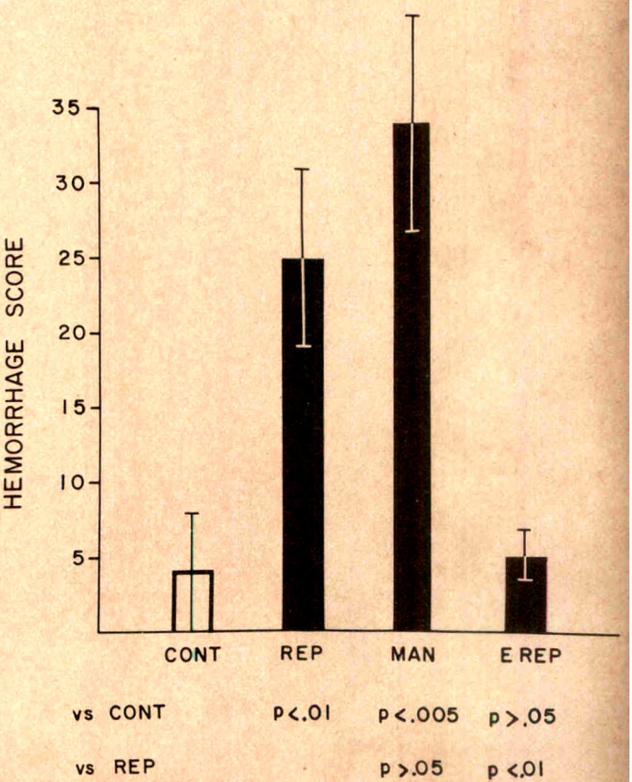

FIGURE 1. Hemorrhage score for control (CONT), reperfusion (REP), and mannitol (MAN) groups as well as for the group with early reperfusion (E REP). Statistical comparisons made with control (vs CONT) and with reperfusion (vs REP) groups are indicated below the bars. See text for the details of score calculation.

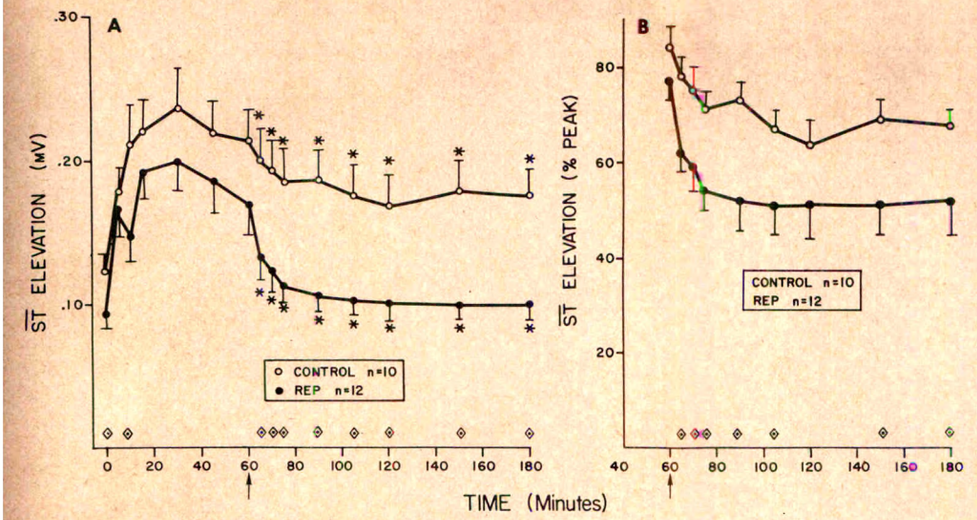

FIGURE 2. Mean S-T segment elevation (ST) ± standard error of the mean in the control and reperfusion (REP) groups. Values are in millivolts (mV) for the entire study **(A),** and in percent of peak S-T elevation for the period 60 to 180 minutes **(B).** Release of coronary occlusion at 60 minutes in the reperfusion group is indicated by the **vertical arrow.** In **A,** significant change from the 60 minute value ($P < 0.05$) within each group is indicated by an **asterisk** (*); significant difference between the two groups is indicated by a **diamond** (◊). In **B,** statistical analysis is carried out only between the two groups.

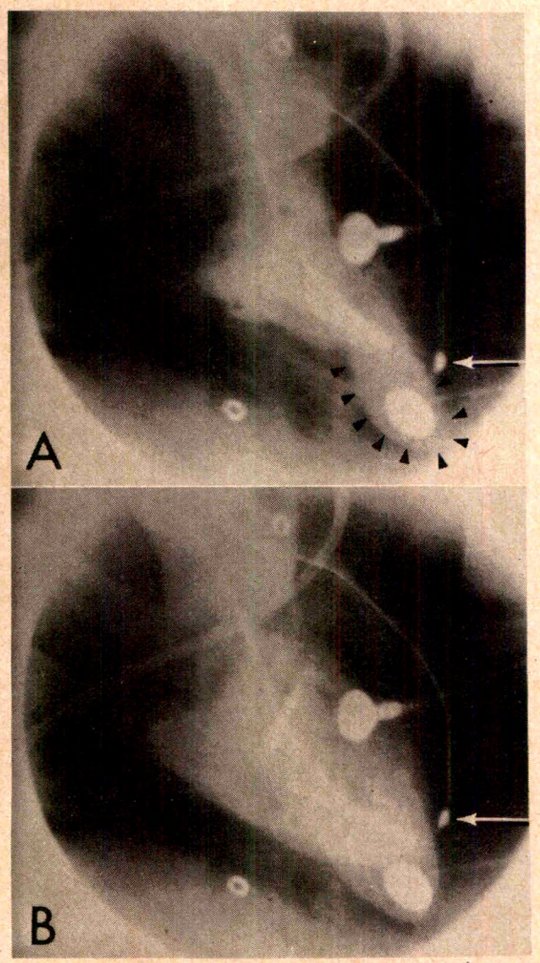

FIGURE 3. End-systolic **(A)** and end-diastolic **(B)** frames from the ventriculogram of one animal 60 minutes after occlusion, immediately preceding reperfusion. The **black arrows** identify an apical akinetic area that developed after the occlusion. Note the balloon occluder and catheter, opacified by contents of mercury **(white arrow).**

in the reperfusion alone; all eight hearts available for examination had extensive areas of hemorrhage with scores ranging from 8 to 59 with a mean 34 ± 7 ($P > 0.05$ mannitol versus reperfusion groups).

In the early reperfusion group (seven animals), four showed no hemorrhage and three small amounts of hemorrhage, with scores of 17, 9 and 6, respectively. The mean score of 5 ± 2 was significantly different from that of the reperfusion group ($P < 0.01$) and similar to that of the control group ($P > 0.05$).

Precordial mapping (Fig. 2, Table II): S-T segment changes were characterized by a rapid elevation from control level after occlusion, reaching a peak 30 minutes after occlusion. During the second and third hours, both groups demonstrated significant ($P < 0.001$) but unequal rates of decline from the 1 hour value. In the reperfusion group, mean S-T elevation returned to the preocclusion level within 30 minutes after reperfusion ($P > 0.05$); in the control group it continued elevated for the duration of the study and remained significantly above the level in the reperfusion group.

These differences can be further analyzed by consideration of mean S-T elevation as a percent of peak S-T elevation thereby discounting the small differences in peak values (Fig. 2B). After reperfusion, the mean S-T elevation of the reperfusion group decreased 16 percent from the peak level within 5 minutes and 24 percent from the peak level within 15 minutes. Although similar to values in the control group just before reperfusion, the mean S-T elevation as a percent of peak elevation remained significantly less than values in the control group except for one measurement made after reperfusion.

R wave amplitude (Table II) was similar in both the control and reperfusion groups during the control period and decreased significantly in both groups after occlusion. It remained depressed for the remainder of the study and was statistically similar in both groups.

TABLE II

R Wave Amplitude (mv) (mean ± standard error of the mean)

Period	Control Group	P*	Reperfusion Group	P*	P†
Control	0.71 ± 0.22	. . .	0.65 ± 0.16	. . .	>0.05

* Versus control period.
† Control versus reperfusion group. *P* = probability.

Left ventricular wall motion: An end-systolic and end-diastolic frame from the left ventriculogram of one animal is shown in Figure 3. Taken at 60 minutes, immediately before reperfusion, it shows an akinetic apex with good motion of the adjacent areas.

Group analysis of wall motion (Fig. 4) showed that the most depressed segment in each group was similarly depressed at 60 minutes (before reperfusion), with a shortening fraction of 5 ± 6 percent for the control and 11 ± 6 percent for the reperfusion group ($P > 0.05$). When compared at 90 minutes, shortening fraction was significantly lower in the control than reperfusion group (−4 ± 7 percent versus 15 ± 5 percent, $P < 0.025$), in part related to worsening of the control group wall motion. At 180 minutes both groups were once again comparable (9 ± 8 percent versus 11 ± 6 percent, $P > 0.05$). There were no significant changes *within* either group when shortening fraction at 60 minutes was compared with measurements at 90 or 180 minutes ($P > 0.05$).

In the adjacent sectors, there existed no differences between the control and reperfusion groups at any time during the study (Fig. 5). There were no changes *within* either group when shortening fraction at 60 minutes was compared with measurements at 90 or 180 minutes.

Discussion

Previous experimental observations: The occurrence of postreperfusion myocardial hemorrhage in the setting of experimental acute myocardial infarction is well known. Bresnahan et al.[18] found that 7 of 16 dogs undergoing reperfusion 5 hours after infarction demonstrated extension of their infarct after reperfusion; this extension was associated with myocardial hemorrhage in all 7 animals. Lang et al.,[10] studying closed chest dogs undergoing reperfusion after 3 hours of occlusion, found intramyocardial vascular congestion and hemorrhage in all of six animals with pathologic evidence of myocardial infarction. Mathur et al.[15] noted hemorrhagic infarction in "most of the reperfused groups" although infarct size was reduced when reperfusion was carried out at 2 rather than at 5 hours. Similar results have been reported in rats undergoing reperfusion at 6 hours rather than at 1 hour.[17] However,

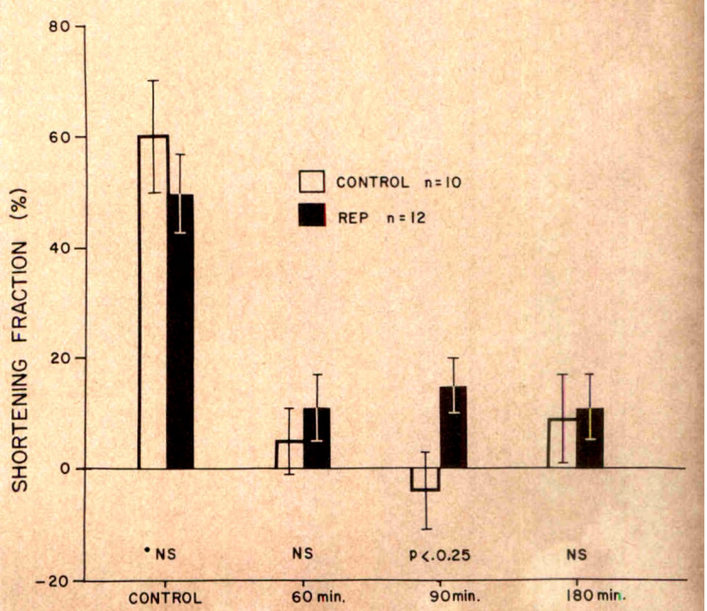

FIGURE 4. Shortening fraction of the most depressed left ventricular segment (mean ± standard error of the mean). Significance of changes between control and reperfusion (REP) groups is indicated below each bar. Comparison of the 90 and 180 minute values with the 60 minute value within each group showed no significant differences ($P > 0.05$). NS = not significant; p = probability.

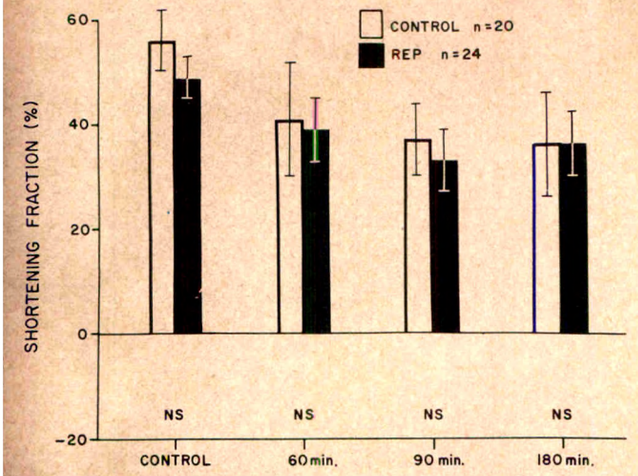

FIGURE 5. Shortening fraction of the adjacent ventricular segments (mean ± standard error of the mean). Significance between the control and reperfusion (REP) groups is indicated below each bar group. Comparison of the 90 and 180 minute values with the 60 minute value within each group showed no significant difference ($P > 0.05$).

others have failed to comment upon the presence of hemorrhage after reperfusion.[8,9,14,16] In fact, Maroko and co-workers[8] reported that the hearts of dogs reperfused after 3 hours of occlusion demonstrate preservation of structural integrity histologically and reduction of infarct size at 24 hours as well as marked reduction in the necrotic area 7 days after reperfusion.[16] This lack of agreement among investigators concerning postreperfusion hemorrhage may be related to differences in species of animals used or to differences in experimental design; it suggests that the effects of reperfusion on myocardial hemorrhage are far from understood.

Intramyocardial hemorrhage after reperfusion in the pig: In this study of reperfusion we used the pig as the experimental model because its heart is similar to man's in weight, coronary circulation and collateralization.[21–23] The pig also shows less interanimal variation in coronary anatomy and distribution than the dog[24] and predictably has a myocardial infarction after coronary occlusion. Closed chest conditions were used to avoid alteration of cardiac function associated with open chest preparations. Myocardial reperfusion in the pig 1 hour after occlusion of the distal third of the left anterior descending coronary artery consistently resulted in massive intramyocardial hemorrhage. This was in contrast to little or no hemorrhage found in the control group animals. The hemorrhagic phenomenon appeared to be time-dependent because it did not occur to a significant degree in seven animals undergoing reperfusion after only 15 minutes of coronary occlusion. The absence of hemorrhage in the latter group also indicates that the hemorrhage was not a consequence of the occlusion technique itself. It therefore appears that in the pig the critical period with respect to intramyocardial hemorrhage lies between occlusion times of 15 and 60 minutes.

Mechanisms of intramyocardial hemorrhage: The mechanism for such hemorrhage may relate to disruption of capillary integrity during myocardial ischemia[19] followed by leakage of red cells during the reflow period. Diaz et al.[20] reported an association between autonomic tone and postreperfusion myocardial hemorrhage. They found extensive hemorrhage in 15 of 17 dogs undergoing reperfusion in the awake state but in only 3 of 16 anesthetized dogs undergoing reperfusion. Decreased autonomic tone due to general anesthesia was postulated as the basis for the decreased incidence of hemorrhage because a similar reduction of hemorrhage was also seen in conscious dogs pretreated with propranolol before reperfusion. In contrast, we found that general anesthesia offered no protection against postreperfusion hemorrhage. Moreover, a recent report, has suggested that these findings may be applicable to human beings undergoing coronary bypass surgery during other than acute conditions. Bulkley et al.[7] studying the hearts of patients who died within 30 days of coronary bypass surgery described necrosis, primarily of the hemorrhagic contraction band type, in the majority of myocardial areas subserved by patent bypass grafts. However, hemorrhage was infrequent in those areas subserved by an occluded graft. Thus the transient ischemia that occurs during surgery may predispose to myocardial hemorrhage in the same manner as during reperfusion after an acute occlusion.

Effect of mannitol: No reduction in hemorrhage occurred when mannitol was given before reperfusion despite reports that this agent reduces myocardial cell swelling and coronary vascular resistance due to myocardial ischemia[26] and increases collateral blood flow into ischemic myocardium.[27–29] Our observations are consistent with the lack of improvement of mitochondrial function after reperfusion in mannitol-treated pigs.[30] It further suggests that mannitol is less effective in increasing collateral flow before reperfusion in the pig than in the dog, possibly because of near complete ischemia in the porcine infarct area restricting the access of therapeutic agents to the reperfused zone.[31]

Effect of reperfusion on hemodynamics: In general, hemodynamics were not affected by the reperfusion process. Heart rate in the control group was unaccountably higher than in the reperfusion group despite the similarity in the animals and in the experimental procedure during the first hour of the study and the randomization of animals into the two study groups. This difference in heart rate is compatible with a smaller area of ischemia in the reperfusion group, which also tended to have less S-T elevation during the first hour than the control group. Nevertheless, such differences are probably slight because the degree of wall motion abnormality at 60 minutes was comparable in both groups.

Effect of reperfusion on ventricular wall motion examined angiographically: We observed no improvement in function of either the most depressed left ventricular segment or adjacent segments during re-

perfusion. Some investigators have agreed and others disagreed with this finding. Maroko et al.[8] found reversal of paradoxical ventricular motion 1 hour after reperfusion in the dog, whereas Banka et al.,[10] using a similar protocol, observed marked deterioration in left ventricular wall motion at this time. In the very acute infarct-reperfusion setting, Smith et al.,[13] using ultrasonic myocardial sensors, found immediate recovery of function in the dog after reperfusion followed by rapid deterioration of wall motion. In a more prolonged study of dogs, Theroux et al.[32,33] found initial deterioration (at 2 hours) of wall motion but at 3 weeks noted greater recovery of function in animals undergoing reperfusion. Similarly, McNamara et al.,[9] using a ventriculographic technique, found improvement in left ventricular wall motion in seven of nine monkeys 7 days after reperfusion; however, a nonreperfused control group of three monkeys also showed improved wall motion at 1 week.

Recovery of function has been linked to the duration of coronary occlusion preceding the reperfusion. Hendricks et al.,[12] using a brief 5 minute occlusion, found continued depression of wall motion 3 hours after reperfusion, whereas recovery was delayed more than 6 hours after reperfusion if coronary occlusion was increased to 15 minutes in duration. In canine myocardial pedicle grafts recovery of function did not occur if coronary occlusion was extended beyond 30 minutes.[34] Recovery of ventricular wall motion after reperfusion in dogs failed to occur after occlusion times of more than 45 minutes when studied using Walton-Brodie strain gauge measurements[10] or after 2 hours using a ventriculographic analysis of wall motion.[6] Although investigators disagree on the wall motion abnormality after reperfusion, most conclude that failure of improvement or actual deterioration of wall motion occurs acutely and is directly related to the duration of the preceding occlusion. There appears to be some evidence for long-term improvement of left ventricular function if one considers those animals that survive beyond the acute period.[9,16,33]

Precordial electrocardiographic mapping: The failure of wall motion to improve in our study is in marked contrast to the significant reduction in S-T segment elevation after reperfusion. Similar observations regarding S-T segment changes in open chest dogs,[8] rats[17] and primates[14] have previously been used as indirect evidence of reduction of infarct size. However, R wave voltage, previously noted to correlate well with the degree of histologic necrosis,[14,35] did not improve in the reperfusion group relative to the control group. This observation raises the possibility that the more rapid fall of S-T segment elevation may be attributed to hemorrhage and accelerated cell necrosis rather than to myocardial salvage. This does not exclude the possibility that the more rapid S-T normalization may correlate with a return of mechanical function at a much later time after reperfusion. However, since S-T elevation has been used as an index of the extent of myocardial injury,[8,36–42] our results suggest caution in the use of accelerated normalization of the S-T elevation as an indicator of reduction of infarct size.

In conclusion, our study has not shown reperfusion in the pig to be of benefit in the presence of acute myocardial infarction with occlusion times of 1 hour. Extensive intramyocardial hemorrhage and failure to witness improvement of ventricular wall motion after reperfusion was coupled with a significant decrease of S-T segment elevation. Neither mannitol nor general anesthesia reduced the severity of hemorrhage. Because hemorrhagic necrosis has also been noted in man in routine revascularization procedures in which patent grafts are found,[7] additional measures may be necessary to reduce temporary occlusion time or otherwise improve vascular integrity during revascularization surgery.

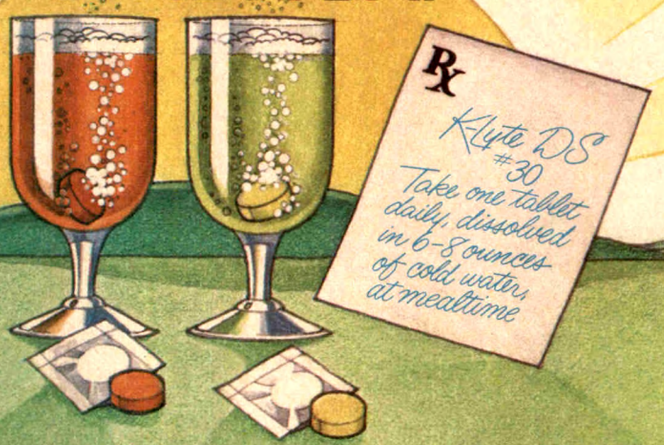
In Liquid Potassium Therapy

A GREAT NEW WAY TO START THE DAY

ONE TABLET ONCE-A-DAY



Announcing

K-LYTE® DS DOUBLE STRENGTH EFFERVESCENT TABLETS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate.

And in good-tasting orange and lime flavors

- Easy dosage to remember in preferred liquid form—50 mEq potassium/tablet.
- Eliminates multidose confusion when taken concurrently with other drugs.
- A record of safety...no reports of GI ulceration in over a decade of use of original K-LYTE.®*
- Cost is less than a diet of potassium-rich foods.

*See Prescribing Considerations

Prescribing Considerations

Indications: K-LYTE DS, is an oral potassium supplement for therapy or prophylaxis of potassium deficiency. It is particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 tablet completely dissolved, 1 to 2 times daily, depending upon the requirements of the patient: 1 tablet (50 mEq. potassium) in 6 to 8 ounces of cold or ice water. The normal adult daily requirement is approximately 50 mEq. of elemental potassium.

NOTE: It is suggested that K-LYTE DS be taken with meals and sipped slowly over a 5-10 minute period.

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 individually foil-wrapped tablets. **Also available,** K-LYTE (25 mEq. potassium) effervescent tablets (orange or lime flavors) in cartons of 30 and 250.

The art of the heart...

"Greek Heart". 19th century Greek ex-voto heart from Mykonos.

Persantine is a non-nitrate coronary vasodilator, with no known contraindications, for the long-term therapy of chronic angina pectoris.* The key to Persantine efficacy: *give enough...long enough.*

(dipyridamole)

Persantine®

Persantine®.
(dipyridamole)

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg

For complete details, please see the full prescribing information.

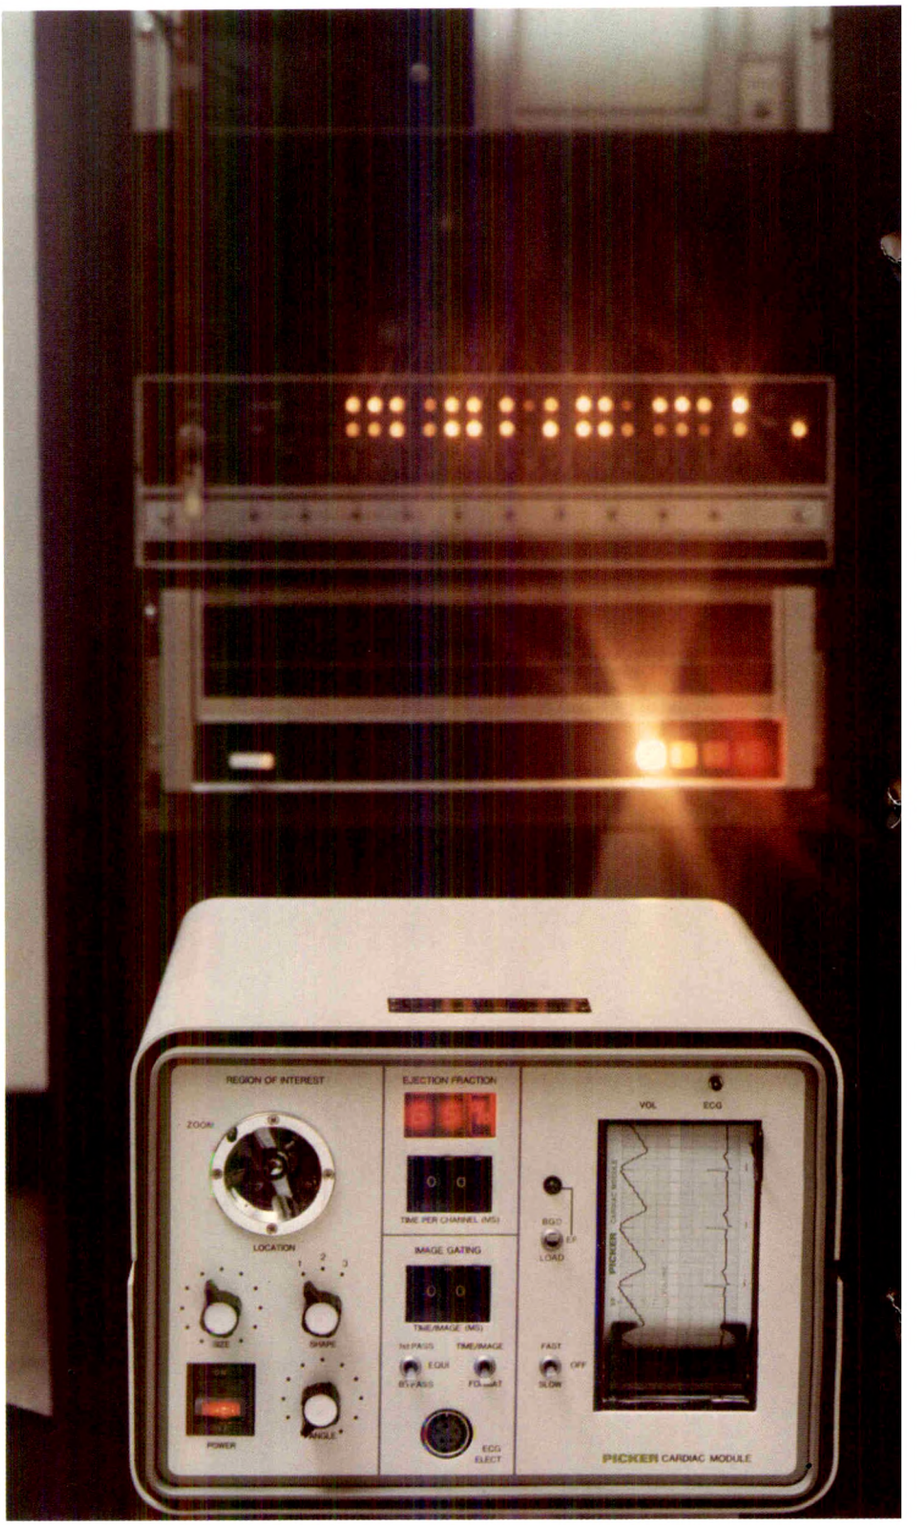
Now you can compute without an expensive

Real time diagnostics at a realistic price. Computing cardiac ejection fraction is a vital job. But, it's also an expensive and complicated one. Most hospitals cannot afford the luxury of a nuclear medicine system and the computer-trained personnel required to accomplish this time-consuming technical task. But, they can afford the efficiency of a Picker Nuclear Cardiology Module, which can quickly determine ejection fraction at a fraction of the cost of a computer.

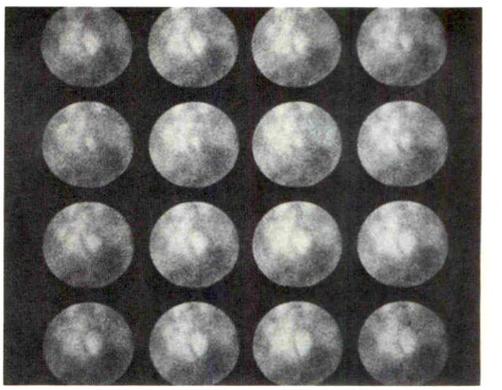
Complex cardiac assignments, simply performed. Picker's new Cardiac Module, the first of its kind in the marketplace, is an easy, uncomplicated way to produce meaningful left ventricular function data. Now, without the services of a computer-trained technologist, you can obtain instant on-line, 30-second sequential ejection fraction, indicated on an LED display, with corroborative hard copy strip chart recordings. The Picker Cardiac Module, used with our Dyna® Camera, will

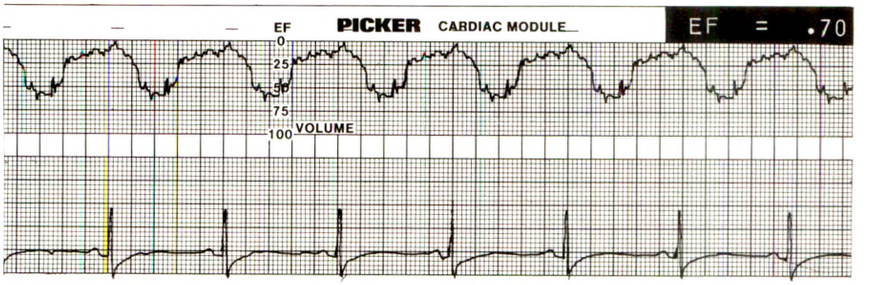


Cardiac ejection fraction nuclear computer.

produce the ejection fraction value six times faster than the first pass probe method at a third the cost.

In less than one minute after patient input has been completed, the Picker Cardiac Module will interrogate its own memory and calculate and display the on-line ejection fraction. It will print the left ventricular gated time ejection cycle images on 8 x 10" (20 x 25 cm) film, showing 12, 24, or 48-time integrated frames and print the left ventricle integrated time activity curve and its associated ECG on a strip chart at the same time. Not only will it perform these tasks in less than a minute, but it will take up a fraction of the space required for a nuclear medicine computer, without the complexities that call for elaborate training.

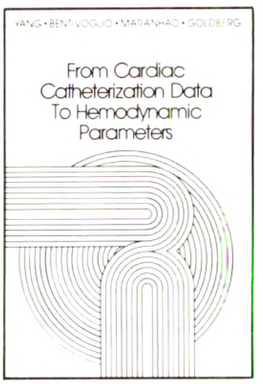




Opening a new world for nuclear medicine. Our new Cardiac Module means the radiologist can now provide prophylactic nuclear medicine. He can screen patients prior to surgery with real-time results in 30 seconds, at a reasonable cost to hospital and patient. He can help forestall problems arising from insufficient pre-operative input and provide significant postoperative patient management. He can begin to minimize the need for cardiac catheterization. The Picker Cardiac Module: another indication of Picker's leadership in supplying state-of-art equipment for Nuclear Cardiology. For additional information, contact your Picker representative, write Picker Corporation, 12 Clintonville Road, Northford, CT 06472 (203/484-2711), or Picker International, 595 Miner Road, Cleveland, OH 44143.

PICKER®
ONE OF THE C.I.T. COMPANIES

THREE SIGNIFICANT STEPS FORWARD... IN THE FIGHT AGAINST CARDIOVASCULAR DISEASE

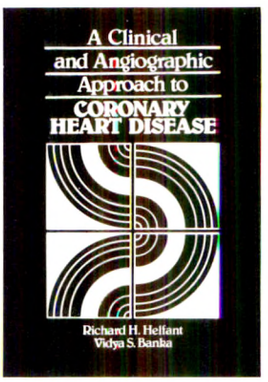


FROM CARDIAC CATHETERIZATION DATA TO HEMODYNAMIC PARAMETERS. Second Edition

By **Sing San Yang, MD,** Associate Cardiologist, Deborah Heart and Lung Center; **Lamberto G. Bentivoglio, MD,** Associate Clinical Professor of Medicine, Medical College of Pennsylvania; **Vladir Maranhão, MD,** Director, Cardiac Catheterization Laboratories, Deborah Heart and Lung Center and **Harry Goldberg, MD,** Director, Cardiology Department, Deborah Heart and Lung Center, Browns Mills, N.J.

Reflecting both advances in knowledge and refinements in techniques, this revised and expanded edition provides a practical way to convert data from the cardiac catheterization laboratory into relevant hemodynamic parameters for the assessment of cardiac function. From the simplest readings to the most complex calculations, instructions are so complete that no other reference is needed for their practical application. The book is equally useful for physicians performing catheterization and those who must interpret the data.

440 pp, (1978) $25.00 (CIP)

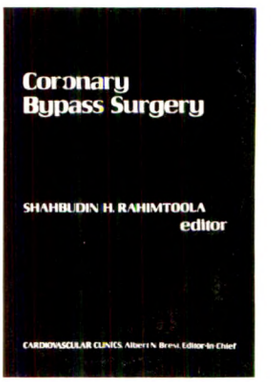


A CLINICAL AND ANGIOGRAPHIC APPROACH TO CORONARY HEART DISEASE.

By **Richard H. Helfant, MD,** Chief, Division of Cardiology and Associate Professor, Presbyterian-University of Pennsylvania Medical Center; and **Vidya S. Banka, MD,** Director, Cardiac Catheterization Laboratory and Assistant Professor of Medicine, Presbyterian-University of Pennsylvania Medical Center

"This text is an excellent correlative study which interrelates the findings on coronary visualization with the clinical expressions of coronary heart disease," says William Likoff, MD. Unlike other texts on angiography, this book evaluates patients with coronary heart disease, not as a homogeneous group, but as subsets characterized by their clinical presentations, laboratory findings, ECG and stress tests, as well as the underlying anatomy and physiology. The authors have masterfully and concisely correlated clinical and angiographic findings to make prognostic and therapeutic decisions, including the indications for surgical procedures, particularly bypass surgery.

253 pp./131 angiographs (1978) $25.00 (CIP)



CORONARY BYPASS SURGERY. CARDIOVASCULAR CLINICS SERIES. Volume 8, Number 2

Guest Editor, **Shahbudin H. Rahimtoola, MD, FRCP,** Professor of Medicine, Division of Cardiology, University of Oregon Health Sciences Center, Portland, Oregon

In less than a decade, aortocoronary bypass surgery has become the procedure most often recommended by cardiologists — exerting a dominance never acquired by any other surgical technique in cardiology practice. In this new addition to the Cardiovascular Clinics Series, Dr. Rahimtoola and his contributors have meticulously and thoroughly placed coronary bypass surgery in clinical perspective — not simply as a contrasting competitor to medical therapy, but as a valued adjunct to the overall management of coronary heart disease.

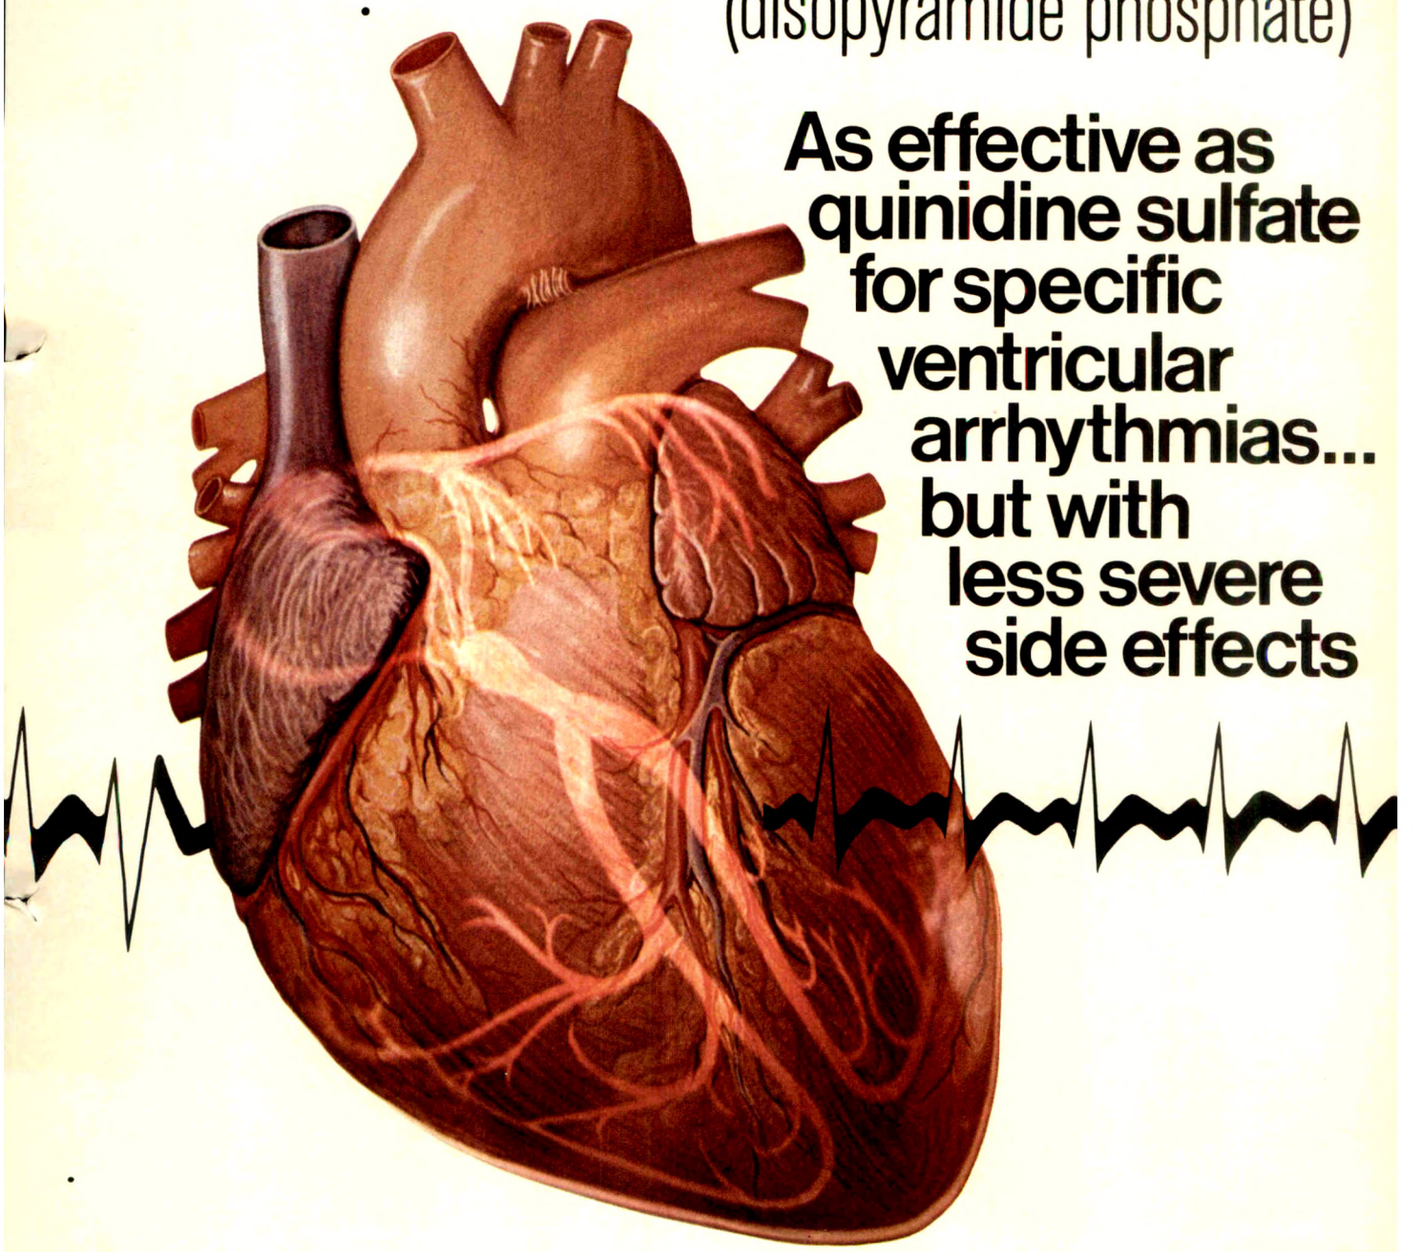
From Searle

Norpace®

(disopyramide phosphate)



As effective as quinidine sulfate for specific ventricular arrhythmias... but with less severe side effects

Efficacy thoroughly proved and documented—no other antiarrhythmic agent subjected to such rigidly controlled study prior to introduction

Effective in specific ventricular arrhythmias—indicated in premature ventricular contractions (PVCs): unifocal, multifocal or paired PVCs or episodes of ventricular tachycardia (VT)

Excellent patient tolerance—less severe side effects than quinidine . . . and significantly better tolerated

Dose-related plasma levels—plasma levels correlate closely with dosage

Minimal effect on hemodynamics—rarely alters blood pressure significantly at recommended oral doses, and may reduce cardiac output by about 10%

Please see last page for a brief summary of prescribing information.

In specific ventricular arrhythmias...proved

Norpace®

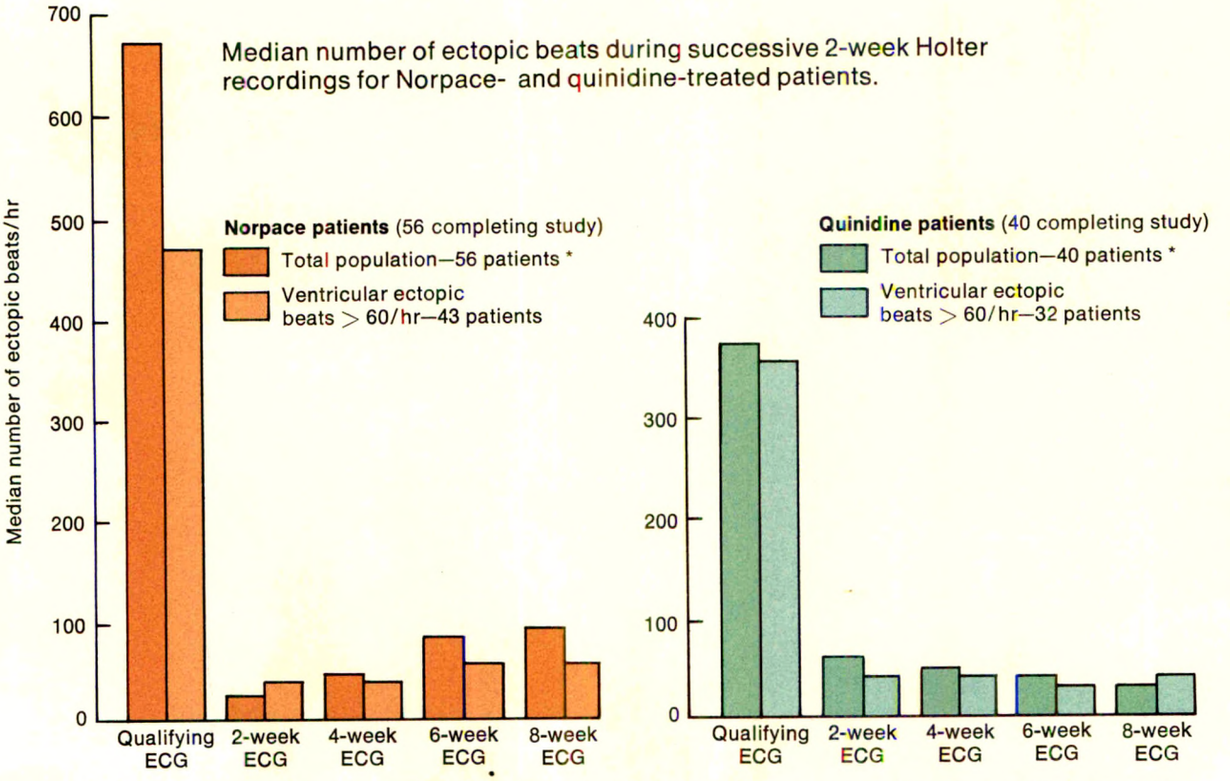
(disopyramide phosphate)

as effective as quinidine sulfate...

Results of double-blind controlled studies

A double-blind multicenter clinical study involving five investigators was conducted to compare the relative effectiveness and tolerance of Norpace and quinidine sulfate. Prior to qualifying for the study, each patient had antiarrhythmic medication discontinued for at least one week. Nine-hour Holter recordings were then used to establish an admission criterion of at least 60 ectopic beats per hour (PVCs, PACs or combination of the two). All other arrhythmias were excluded except paroxysmal ventricular or atrial tachycardias occurring in conjunction with the above. It was apparent that both drugs were capable of reducing ectopic activity and maintaining suppression throughout the course of therapy.

Median number of ectopic beats during successive 2-week Holter recordings for Norpace- and quinidine-treated patients.



* Includes patients with more than 60 total (atrial and ventricular) ectopic beats per hour but who had fewer than 60 ventricular ectopic beats per hour.

There was no statistically significant difference in reduction of ectopy between the two drugs.

Copyright © 1977, G. D. Searle & Co.

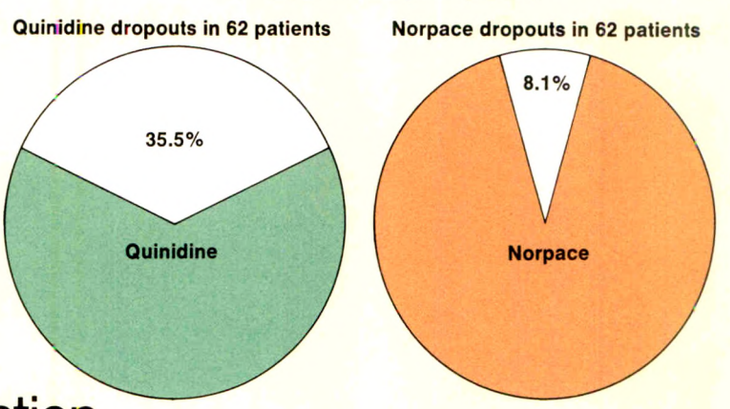
effective by extensive Holter monitoring

with less severe side effects

Significantly fewer dropouts with Norpace

(disopyramide phosphate)

The entire study population was analyzed for side effects. The side effects experienced by Norpace patients were usually mild and mainly anticholinergic, including: dry mouth, urinary hesitancy, constipation, blurred vision. The anticholinergic side effects were generally transient. Adverse reactions with quinidine were more serious and affected a greater number of patients. The most common symptoms were: severe diarrhea; gastrointestinal symptoms including cramps, nausea and vomiting; dizziness; fever; and rash.



Dosage and administration

Supplied as 100-mg and 150-mg capsules. Dosage should be individualized based on response and tolerance. Usual adult dosage is 400 to 800 mg per day given in divided doses four times daily, following an initial loading dose.

Recommended dosage regimen

Patient type	Loading dose	Maintenance dose
Adult	300 mg	150 mg q 6 h
Adults of smaller stature; or with moderate renal insufficiency, hepatic insufficiency, cardiomyopathy, or possible cardiac decompensation	200 mg	100 mg q 6 h
Adults with severe renal insufficiency C_{cr} less than 40 ml/min	200 mg	100 mg given approximately every half-life (see Note below)

Note: Since Norpace is excreted in the urine, renal insufficiency appreciably extends the half-life of the drug. The chart below provides guidelines to the appropriate Norpace dosage in such patients.

Norpace dosage interval adjustment for patients with renal insufficiency

Creatinine clearance (ml/min)	40-15	15-5	5-1
Approximate maintenance-dosing interval	q 10 h	q 20 h	q 30 h

Norpace plasma half-life may also be prolonged in patients with significant liver disease.

Please see next page for a brief summary of prescribing information.

SEARLE

Norpace®
(disopyramide phosphate)

as effective as quinidine sulfate for specific ventricular arrhythmias...with less severe side effects

Before prescribing Norpace, please consult complete prescribing information, a summary of which follows:

Indications: Norpace is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).

Norpace is equally effective in treating the above arrhythmias in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia, atrial arrhythmias or arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.

Contraindications: Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.

Warnings: Severe hypotension has been observed on rare occasions, primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. If hypotension develops Norpace should be discontinued promptly unless it is due to the arrhythmia.

Norpace should not be used in the presence of poorly compensated or uncompensated congestive heart failure unless it is exacerbated by or caused by an arrhythmia and proper treatment including optimal digitalization has been accomplished. In some patients with marginally compensated heart failure, Norpace may cause cardiac decompensation. In these patients, progressing congestive heart failure should generally be treated with cardiac glycosides and diuretics and the course of treatment closely followed. Norpace dosage should be reduced or discontinued if adequate control of congestive failure is not attained.

If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of the benefit versus the risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker.

Because of its anticholinergic properties, Norpace should not be used in patients with glaucoma or urinary retention, unless adequate overriding measures are taken.

Precautions: If significant widening (greater than 25%) of the QRS complex occurs, Norpace should be discontinued. If Q-T prolongation greater than 25% occurs and if ectopy continues, monitor closely and consider discontinuing Norpace.

Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits.

The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block.

Norpace should be administered cautiously to patients who are receiving or who have recently received other antiarrhythmic drugs. Excessive widening of the QRS complex may occur in such instances.

Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage.

Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy.

Use in Pregnancy and Lactation: Safe use in pregnancy has not been established. The use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus.

It is not known whether disopyramide is excreted in human milk. However, studies in rats have shown that the concentration of disopyramide and its metabolites is up to three times greater in milk than in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted.

Labor and Delivery: The effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown.

Pediatrics: The safety and effectiveness of Norpace in children have not been established.

Adverse Reactions: *Anticholinergic:* dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention. *Genitourinary:* urinary frequency and urgency, dysuria. *Gastrointestinal:* nausea, pain/bloating/gas, anorexia, diarrhea, vomiting. *Central Nervous System:* nervousness, depression, insomnia, impotence, dizziness, general fatigue/muscle weakness, headache, malaise, and rarely, reversible acute psychosis. *Cardiovascular:* edema/weight gain, cardiac conduction disturbances, shortness of breath, syncope, chest pain, hypotension. *Dermatologic:* generalized rash/dermatoses.

Dosage and Administration: Dosage must be individualized for each patient on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily, following an initial loading dose. The recommended initial dosage schedule for adults is a single loading dose of 300 mg, followed by 150 mg every six hours.

For patients of small stature, or for those with moderate renal insufficiency, hepatic insufficiency, cardiomyopathy, or possible cardiac decompensation, a loading dose of 200 mg is recommended, followed by 100 mg every six hours.

For patients with severe renal insufficiency lower doses are recommended. See complete prescribing information for details.

Overdosage: No specific antidote for Norpace has been identified; treatment of overdosage should be supportive. Overdosage might be expected to produce excessive widening of the QRS complex, worsening of congestive heart failure, hypotension, varying kinds and degrees of conduction disturbance, bradycardia and finally asystole. Obvious anticholinergic effects might also be observed. The electrocardiogram should be monitored and supportive therapy with vasopressors, sympathomimetics, cardiac glycosides and diuretics should be given as required. In vitro studies have demonstrated good dialyzability for disopyramide.

How Supplied: Capsules containing 100 mg or 150 mg of disopyramide base. Available in bottles of 100 capsules.

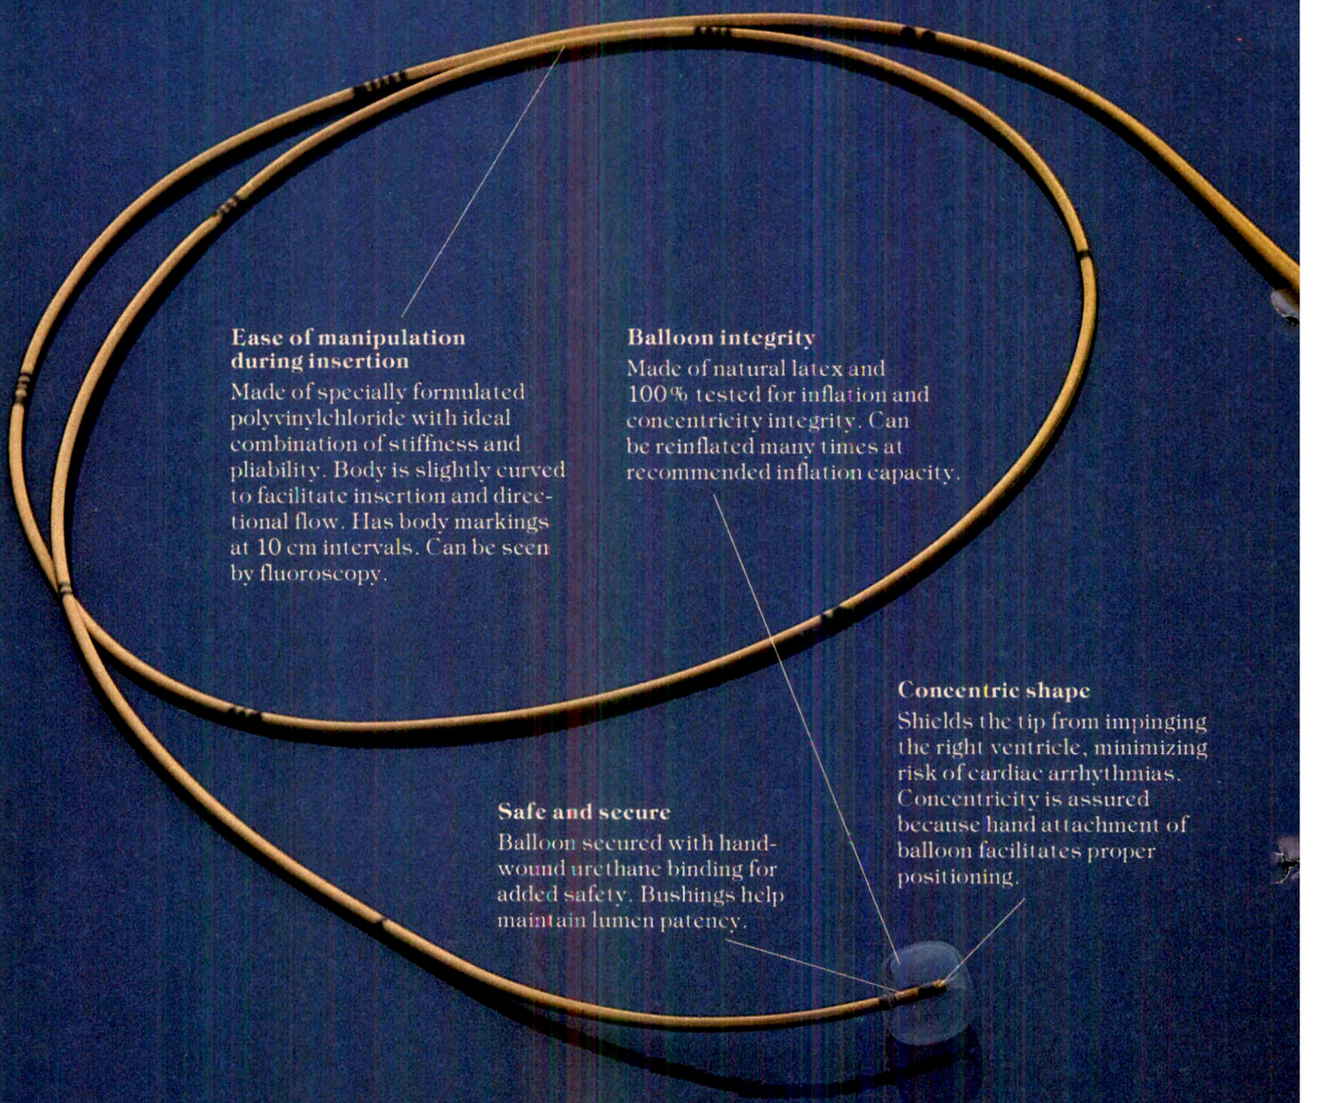
2722 SOUTH FAIRVIEW STREET ☐ SANTA ANA ☐ CALIFORNIA 92704 ☐ (714) 556-7608

What to look for in the



Ease of manipulation during insertion
Made of specially formulated polyvinylchloride with ideal combination of stiffness and pliability. Body is slightly curved to facilitate insertion and directional flow. Has body markings at 10 cm intervals. Can be seen by fluoroscopy.

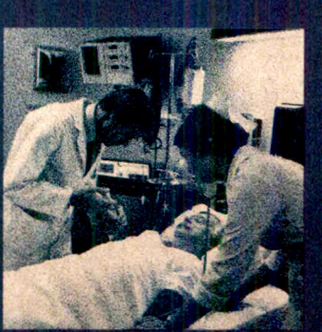
Balloon integrity
Made of natural latex and 100% tested for inflation and concentricity integrity. Can be reinflated many times at recommended inflation capacity.

Concentric shape
Shields the tip from impinging the right ventricle, minimizing risk of cardiac arrhythmias. Concentricity is assured because hand attachment of balloon facilitates proper positioning.

Safe and secure
Balloon secured with hand-wound urethane binding for added safety. Bushings help maintain lumen patency.

These are the features that have helped make the Edwards' SWAN-GANZ Catheter from Edwards Laboratories the most widely used in the world. In fact, of all open heart medical teaching centers in the United States, 85% of them routinely use the SWAN-GANZ Catheter for hemodynamic monitoring.

The reasons? More clinical experience (over one-half million inserted), hundreds of published papers in the medical literature, unsurpassed manufacturing quality (15 separate quality control checks), meticulous hand-



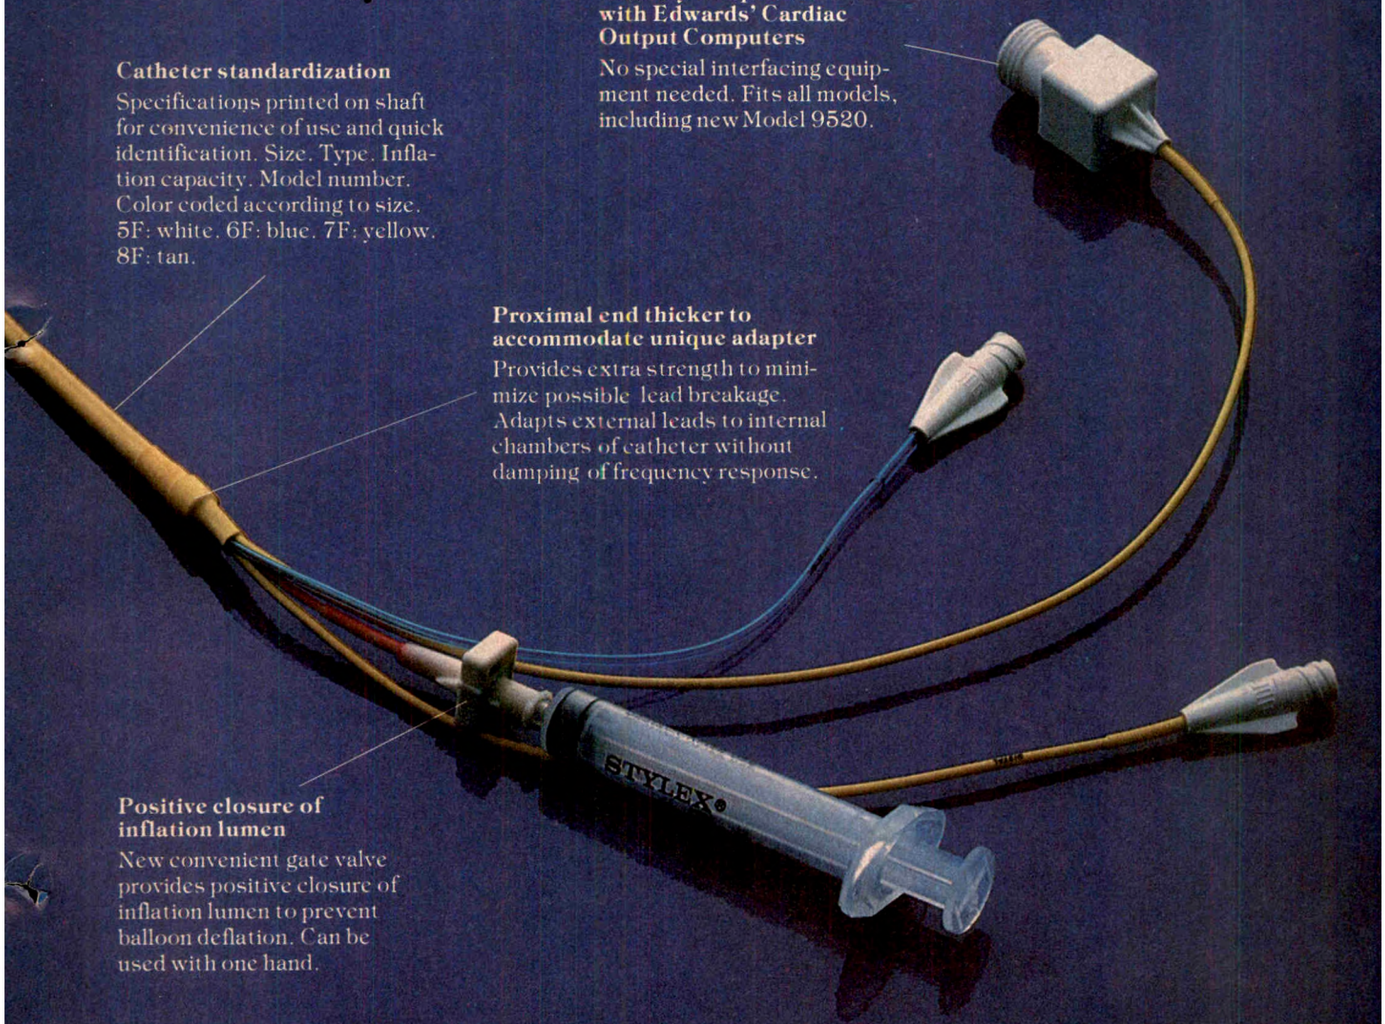
SWAN-GANZ is a registered trademark, Edwards Laboratories.

SWAN-GANZ® Catheter.

Directly compatible with Edwards' Cardiac Output Computers
No special interfacing equipment needed. Fits all models, including new Model 9520.

Catheter standardization
Specifications printed on shaft for convenience of use and quick identification. Size. Type. Inflation capacity. Model number. Color coded according to size. 5F: white. 6F: blue. 7F: yellow. 8F: tan.

Proximal end thicker to accommodate unique adapter
Provides extra strength to minimize possible lead breakage. Adapts external leads to internal chambers of catheter without damping of frequency response.



Positive closure of inflation lumen
New convenient gate valve provides positive closure of inflation lumen to prevent balloon deflation. Can be used with one hand.

wound construction, 100% testing, wide selection of catheter types/sizes, and support by a company dedicated to excellence in cardiovascular devices.

A complete description of SWAN-GANZ Catheters, details on insertion, placement and complications are described in journal reprints and technical data available from Edwards.

InterLith™-RP.

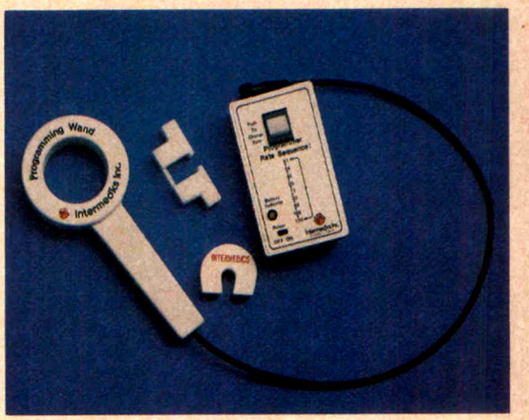
The pacemaker with a fail-safe rate programming design.

It took Intermedics to combine the most straightforward, uncomplicated rate programming system in the industry with the proven reliability of c-mos circuitry. Utilizing the superior longevity of a lithium power cell, Intermedics now offers you one of the smallest, lightest, most comfortable programmable pacemakers available...the InterLith-RP.

This pacemaker, unlike others on the market, utilizes circuitry that has been uniquely designed to avoid accidental reprogramming. This fail-safe feature requires the occurrence of two simultaneous electrical events; first, the magnetic reed switch must be closed and secondly, the programmer must be activated in immediate proximity to the pacemaker. The nine programmable rates are 51, 55, 60, 65, 72, 80, 90, 103 and 120 BPM. The rate is incremented from one value to the next by simply depressing the programming button.

A triumph of design, the InterLith-RP is hermetically sealed in tissue-compatible interference-resistant 316L stainless steel and measures only 6.0 cm × 4.6 cm × 1.5 cm (bipolar unit measures 6.3 cm in height), enabling a smaller incision resulting in a more cosmetic pocket. All edges are smoothly rounded for greatest patient comfort.

A lithium cell, plus low current drain under load, give the InterLith-RP a potential longevity in excess of 12 years*; like all other Intermedics pacemakers, the InterLith-RP is backed by a replacement credit agreement. Its universal connector readily accepts Intermedics' leads as well as most manufacturers' leads without adapters, making it an excellent choice when a replacement pulse generator is needed. InterLith-RP. The better programmable pacemaker.



For the location of your nearest Intermedics representative, or for additional information about our products, call toll-free 1-800-231-2330. In Texas, call collect 1-713-233-8611.

Intermedics Inc.

*Based on 72 BPM, 500 OHM load and 100% pacing.

InterLith is a trademark of Intermedics, Inc.

Note: The InterLith RP is currently being clinically evaluated.

See the InterLith RP at the American College of Cardiology Convention, March 6-9, Anaheim, California. Intermedics' Island booth #28.

Intermedics Pulse Generators

INDICATIONS FOR USE Pacemakers may be used in any application where asynchronous or demand ventricular pacing is indicated. These include congenital or acquired complete heart block which may be continuous or intermittent in nature, various types of sinus node dysfunction, WPW syndrome, carotid sinus hypersensitivity, drug induced bradycardia, and various ventricular arrhythmias.

The above list is not intended to be complete. The indications for pacing are increasing as the devices become more sophisticated and as methods for patient management become more widely understood.

PRECAUTIONS Implanted cardiac pacemakers have a finite service life and a relatively wide variability in service life. Factors affecting service life include the initial capacity of the battery and the shelf storage time of the manufactured pulse generator. Once implanted the anticipated service life of the generator is modified by variations in electrode system resistances, stimulation rate, and the percentage of time during which the pacemaker is inhibited. The current drain on the battery when inhibited is less than one-third of that when pacing with a typical lead installation. Other factors contributing to wide variability in service life are random electronic component failures.

All sensing pulse generators are inherently susceptible to magnetic electrical and electromagnetic fields. While design features are incorporated to minimize this susceptibility, an extraneous signal of sufficient strength and with characteristics which mimic normal cardiac activity can influence their operation. Additionally, certain environmental sources can couple sufficient energy into a cardiac pacemaker system to damage the pulse generator. Specifically, the implanting physician and the patient should be warned about the following:

(1) Electrocautery–Surgical use of electrocautery may cause temporary inhibition of the pulse generator. Additionally, pulse generator damage is possible if sufficient energy is coupled into it. Use of electrocautery within 4-5 centimeters of the implanted pacemaker can cause a direct coupling of RF energy through the lead and electrode to the cardiac muscle, producing burns or possible ventricular fibrillation.

Continuous monitoring of blood pressure and pulse should be instituted in all procedures where the use of electrocautery is contemplated. The ground plate of the electrocautery system should be placed in a manner to minimize current flow through the pacing system. A specific example is a TUR; during this procedure, the ground plate should be placed low on the buttocks or strapped to the thigh.

(2) Diathermy–A pacemaker patient should not receive this form of therapy. Very intense fields of microwave energy are involved and reactions of all sensing pulse generators are unpredictable. Total or virtually complete inhibition of the pacing circuitry is possible; however, no damage will result to the circuitry during the exposure.

(3) Microwave Ovens–Ovens, both in the home and in commercial use, in good condition and used as intended, will not affect the InterLith. Any microwave appliance which does not exceed federal guidelines of 0.5 milliwatts/cm² leakage at a point 2.5 cm. from the appliance will not affect the InterLith. However, appliances have been discovered which emit radiation in excess of 200 times these guidelines. The possibility of interference from such defective appliances does exist. The pulse generator will not be damaged by such exposure.

(4) Defibrillation–All implanted unipolar pulse generators regardless of manufacturer, can be damaged by cardiac defibrillation. Additionally, the presence of an implanted pacemaker system can increase the amount of cardiac muscle damage which results from defibrillation.

(5) Home Electrical and Gasoline Powered Appliances–Certain electrical and gasoline powered appliances can cause inhibition of an implanted cardiac pacemaker system. Pacemaker patients should be warned about the possibilities of pulse generator inhibition from some electric razors, most notably the rotary types, hand-held electric drills, power saws, and other appliances containing brush motors.

CONTRAINDICATIONS AND SIDE EFFECTS There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. The patient diagnosis and prognosis may indicate the type of pacemaker therapy used by the physician.

Body rejection phenomenon have been reported from the use of implanted cardiac pacemakers. These include local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism and cardiac tamponade.

Intermedics Inc.
P.O. Box 617 Freeport, Texas 77541

Peritrate® SA
Sustained Action
(pentaerythritol tetranitrate) **80 mg**

Peritrate®
(pentaerythritol tetranitrate) **40 mg**

Peritrate®
(pentaerythritol tetranitrate) **20 mg**

Peritrate®
(pentaerythritol tetranitrate) **10 mg**

CAUTION: Federal law prohibits dispensing without prescription.
Description: Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Each tablet of Peritrate 40 mg contains pentaerythritol tetranitrate 40 mg. Each tablet of Peritrate 20 mg contains pentaerythritol tetranitrate 20 mg. Each tablet of Peritrate 10 mg contains pentaerythritol tetranitrate 10 mg. Peritrate (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg and Peritrate (pentaerythritol tetranitrate) are contraindicated in patients who have a history of sensitivity to the drug.
Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.
Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe, persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate (pentaerythritol tetranitrate) may be administered in individualized doses up to 160 mg a day. Dosage can be initiated at one 10 mg or 20 mg tablet q.i.d. and titrated upward to 40 mg (two 20 mg tablets or one 40 mg tablet) q.i.d. one-half hour before or one hour after meals and at bedtime. Alternatively, Peritrate Sustained Action 80 mg can be administered on a convenient b.i.d. dosage schedule.
Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg—double-layer, biconvex, dark green/light green tablets in bottles of 100 (N 0047-0004-51) and 1000 (N 0047-0004-60). Also unit dose, package of 10 x 10 strips (N 0047-0004-11).

Peritrate (pentaerythritol tetranitrate) 40 mg—pink scored tablets in bottles of 100 (N 0047-0008-51).

Peritrate (pentaerythritol tetranitrate) 20 mg—light green, scored tablets in bottles of 100 (N 0047-0001-51) and 1000 (N 0047-0001-60). Also unit dose, package of 10 x 10 strips (N 0047-0001-11).

Peritrate (pentaerythritol tetranitrate) 10 mg—light green, unscored tablets in bottles of 100 (N 0047-0007-51) and 1000 (N 0047-0007-60).
STORE BETWEEN 59° and 86° F (15° and 30° C).
Animal Pharmacology: In a series of carefully designed studies in pigs, Peritrate (pentaerythritol tetranitrate) was administered for 48 hours before an artifically induced occlusion of a major coronary artery and for seven days thereafter. The pigs were sacrificed at various intervals for periods up to six weeks. The result showed a significantly larger number of survivors in the drug-treated group. Damage to myocardial tissue in the drug-treated survivors was less extensive than in the untreated group. Studies in dogs subjected to oligemic shock through progressive bleeding have demonstrated that Peritrate (pentaerythritol tetranitrate) is vasoactive at the postarteriolar level, producing increased blood flow and better tissue perfusion. These animal experiments cannot be translated to the drug's actions in humans.
Full information is available on request.

Prescribe

Maximum Peritrate Dosage Simply and Conveniently

Peritrate® 40mg (pentaerythritol tetranitrate) Tablets q.i.d.

In many angina* patients, response to Peritrate is optimum when dosage is titrated to its maximum

The simple aim of Peritrate prophylaxis* is to maintain adequate nitrate levels in the body so that fewer "breakthrough" angina attacks occur. To achieve this goal, many patients require maximum dosage. Peritrate 40 mg tablets q.i.d. or Peritrate® SA Sustained Action 80 mg b.i.d. Whichever form of Peritrate you choose, be sure you use it optimally. You can expect side effects to be few.

*This drug has been evaluated as possibly effective for this indication.
See brief summary.

WHAT TO LOOK FOR IN A CATHETER INTRODUCER SET

This is the UMI Sterile Percutaneous Catheter Introducer, available in sizes 4F to 9F. Using it, you can introduce balloon "floating" catheters, closed-end catheters, or electrode probes with great ease, thereby minimizing trauma to the patient. It is carefully thought out in design and engineering, and manufactured to our high quality standards.

Here are its main features:

1. CLOSE FIT. Each component is matched with precision to its neighbor. They move freely but firmly in contact with each other.

2. THE SHEATH IS TAPERED. For greater ease of introduction, the distal tip is tapered for a closer fit with the dilator. This is an exclusive UMI feature.

3. THE SHEATH IS THIN YET STRONG. Its wall is only .007" thick. Yet there is less chance it will "accordion" passing through tissue. Both it and the dilator are made of special Teflon.®

4. THE DILATOR'S DISTAL TAPER is uniform and gradual, meeting the guide wire closely for ease of introduction.

5. THE DILATOR'S FLARE is pronounced — so that it will not enter the sheath.

6. THE GUIDE WIRE is stainless steel, manufactured to close tolerances to assure uniformity.

Although we are a small, young company, UMI already produces catheters and catheter accessories in a great number of sizes and configurations. We will also custom-make to your specifications and needs. To learn more about what we can do for you, please send for a recent reprint from *Anesthesiology Review* and our current catalog — and see us at your up-coming meeting.

See us at our booth at the American College of Cardiology Convention in Anaheim. Please stop by and get acquainted.

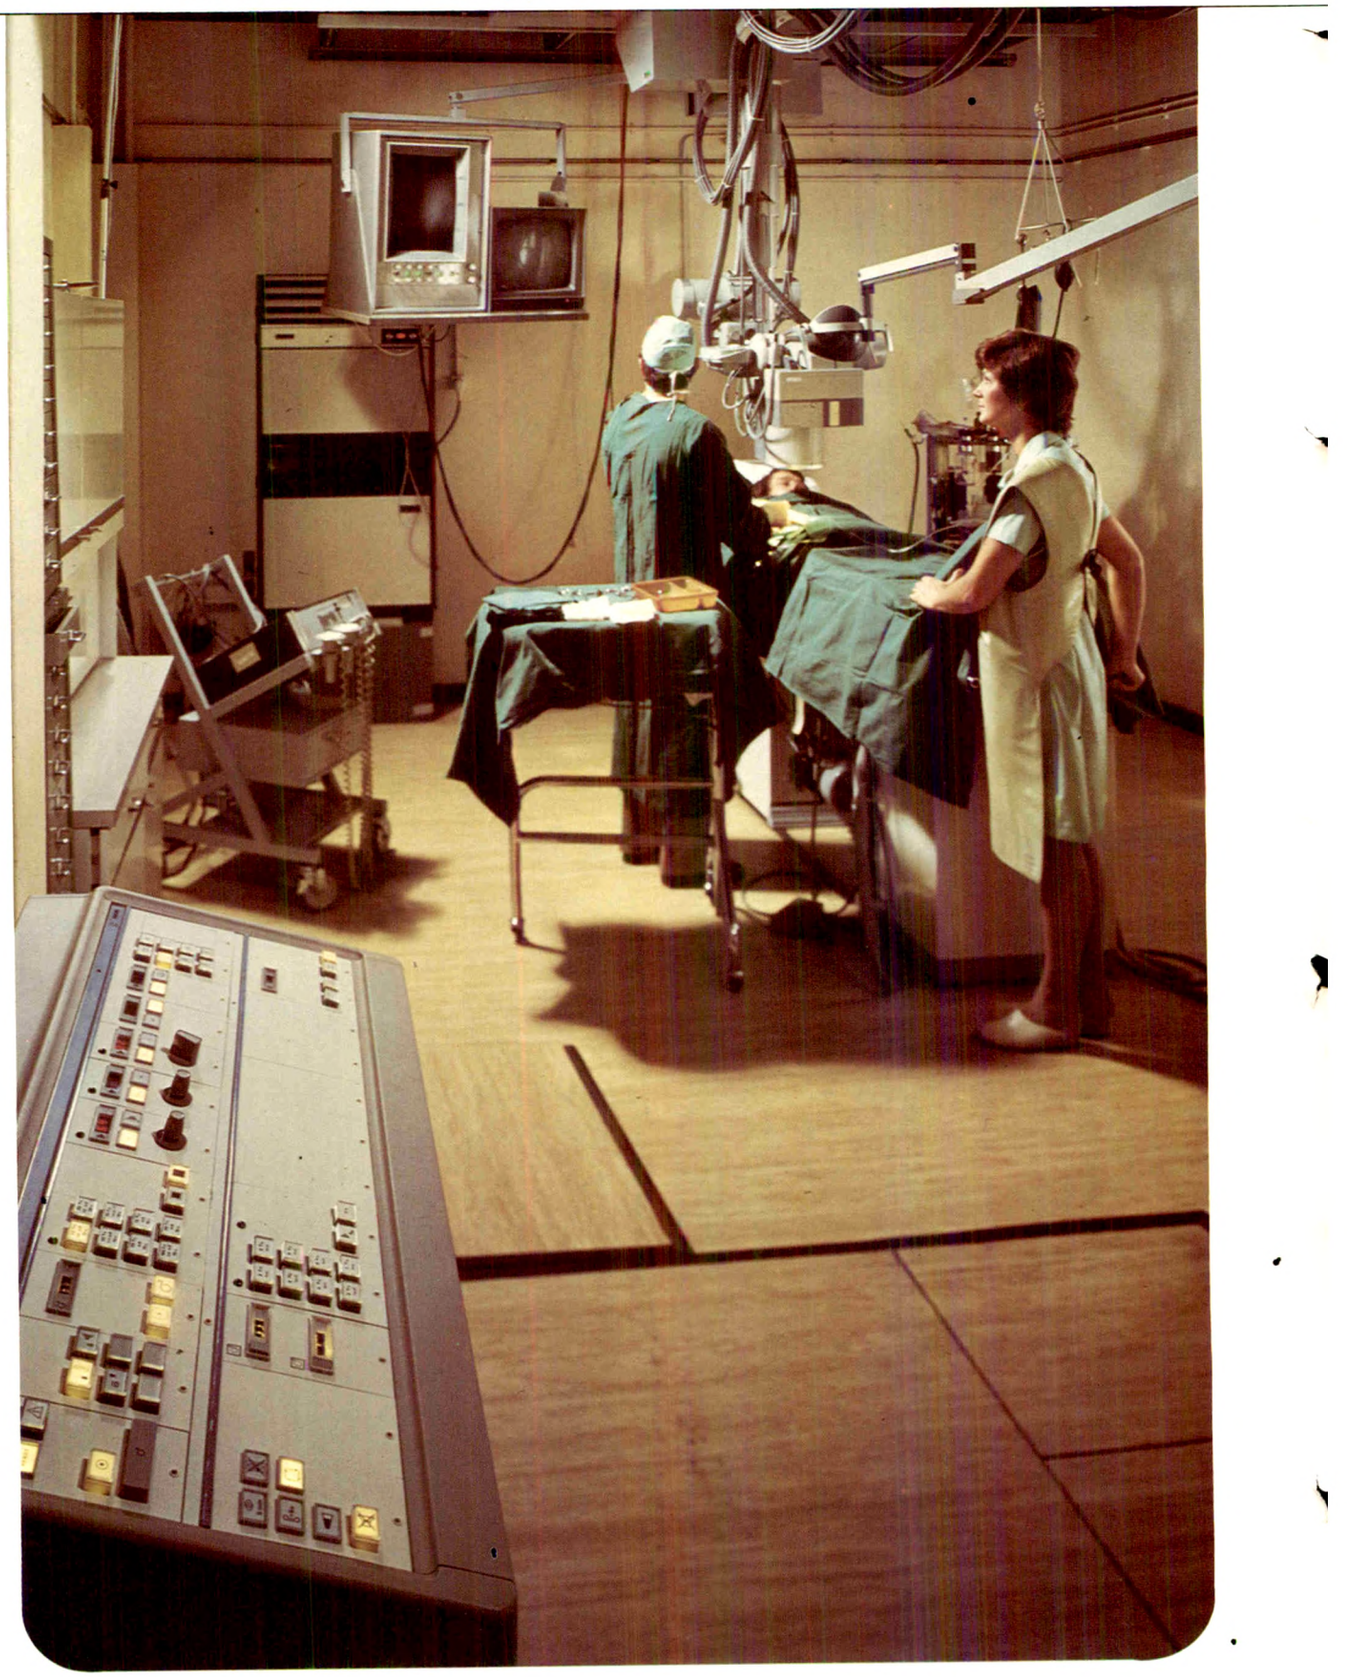
Philips Computerized X-ray Generator Guarantees Optimum Technique for Every Exposure!

PHILIPS **Optimus** M200:

the ultimate clinical application of computer technology



PHILIPS

PHILIPS®

® TM N.V. Philips of Holland

The Computer: Medical Language, Medical Results
Consider computer technology completely dedicated to cardiovascular diagnostics...micro-circuitry that thinks and operates in your language according to your parameters and your procedure needs. Consider technology advanced to a degree that guarantees the perfect exposure for every run on every patient, regardless of age, size or weight. *This* is the OPTIMUS.

Full automation makes such accuracy simple for you. A range of programs covering every examination technique is built into the generator at installation. You select the medical parameters for each program. For examination, simply turn on the generator and press one button for the program you want. The OPTIMUS does the rest.

Patient Measuring Shots: Your Instant Preview
Automatically (in 5 milliseconds), the OPTIMUS measures the absorption characteristics of the patient and then the computer selects the exact factors for an ideal exposure. Factors are selected in discrete mA/kV steps. Your technique is always the highest mA and the lowest kV.

In a fraction of a second, all other technical parameters are calculated and set by the generator. You're insured perfect results before the cine run starts. The measuring shots can be engaged at any time to determine optimum technique for any projection.

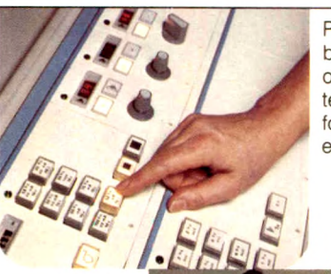
Measuring shots drastically reduce the radiation dose required by less automated systems to determine technique factors. In the time equivalent to one cine frame, you know exactly what the results will be.

Procedure interruptions due to factor adjustment or "trial and error test shots" are eliminated. You and the technician devote minimum attention to technique selection and maximum attention to your patient.

A New Standard of Image Quality
The OPTIMUS' high output permits short exposures with low tube tensions. As a result, images are rich in contrast and detail. Low kV lets you visualize extremely small vessels with unprecedented ease. And not only are geometric unsharpness and motion unsharpness both minimized, but the OPTIMUS automatically weighs one against the other in selecting the technique which optimizes image quality.

From Maximum to Minimum Instantly
The OPTIMUS' secondary tetrode system switches exposures on and off *and also regulates the kVp level.* Now it's possible to change technique from maximum to minimum instantly. This is the same basic concept Philips' cine pulse has used successfully for the past twenty years!

Full Generator Use
More than any other system on the market, the OPTIMUS gives you the *full* capability of a generator. Over 100 hospitals throughout the world are enjoying that OPTIMUS capability right now! It's the product of all Philips' experience in both generators and computer technology...the logical result of progress from Philips' cine pulse to automated Modular Generators to Anatomically Programmed Radiography. The OPTIMUS: it's the most logical choice for you, too.



Press one button for optimum technique for every exposure.

A built-in memory lets you change technique and return to the initial program with no operator changes – for every patient!

Secondary tetrodes – another first from Philips . . . 20 years ago!

The OPTIMUS: computerized because it does a job only a computer can do!

Four Steps Toward The Successful Management of Chest Disorders.

CHERNIACK: Pulmonary Function Testing

This handy guide presents the background you need to better understand both normal pulmonary function and the disturbances which occur in disease. Beginning with a valuable listing of the many terms, symbols and abbreviations used in pulmonary physiology and function testing, the book reviews basic considerations such as pulmonary mechanics, ventilation, blood flow and gas exchange. General principles of methodology in testing and calculation procedures used to determine the parameters of function are also discussed.

By Reuben M. Cherniack, MD, Prof. and Chairman, Dept. of Medicine, Univ. of Manitoba, Faculty of Medicine, Winnipeg, Canada. 291 pp. Illustd. Soft cover. $8.50. August 1977.
Order #2528-2

FRASER AND PARÉ: Diagnosis of Diseases of the Chest: An Integrated Study Based on the Abnormal Roentgenogram, Volumes 1 and 2—2nd Edition

The vastly expanded new edition of this monumental clinical study now encompasses four volumes. Coverage in the first volume ranges from the pulmonary vascular system, nervous system, pluera and diaphragm to the various aspects of chest roentgenology. The second volume deals with such areas as: infectious diseases of the lungs, embolic and thrombotic diseases, pulmonary hypertension, pulmonary diseases of cardiac origin, and much more. (Volumes 3 and 4 will be available in 1978.)

By Robert G. Fraser, MD, FRCP(C), Prof. of Radiology, Univ. of Alabama; and J.A. Peter Paré, MD, FACP, Prof. of Medicine, McGill Univ.; Joint Cardiorespiratory Service, Royal Victoria Hospital.
Vol. 1: 656 pp., 414 ill. $26.00. July 1977. **Order #3852-X**
Vol. 2: About 640 pp., 261 ill. About $26.00. Just ready.
Order #3853-8

PERLOFF: The Clinical Recognition of Congenital Heart Disease—2nd Edition

This new edition presents an uninterrupted perspective of clinical congenital heart disease from infancy to adulthood. New material includes: morphogenesis, proper classification of new or poorly understood anomalies, electro-physiology, and M mode echocardiography with special emphasis on the anatomical and physiologic manifestations of every major type of congenital cardiac disorder.

By Joseph K. Perloff, MD, Prof. of Cardiology and Pediatrics, School of Medicine, Univ. of California, Los Angeles. About 655 pp., 730 ill. About $32.50. Ready April 1978.
Order #7191-8

SALCEDO: Atlas of Echocardiography

A superb learning tool, this new atlas gives you a practical, and easily accessible source of echocardiographic information. The numerous diagrams and illustrations are carefully labeled, and helpful legends describe pertinent echocardiographic findings. It covers the normal echocardiographic anatomy, examination and evaluation of valvular, myocardial and congenital anomalies, and more.

By Ernesto Salcedo, MD, Head Cardiac Function Laboratory, and Staff Cardiologist, Cleveland Clinic Foundation. About 240 pp., 330 ill. About $16.00. Just ready.
Order #7901-3

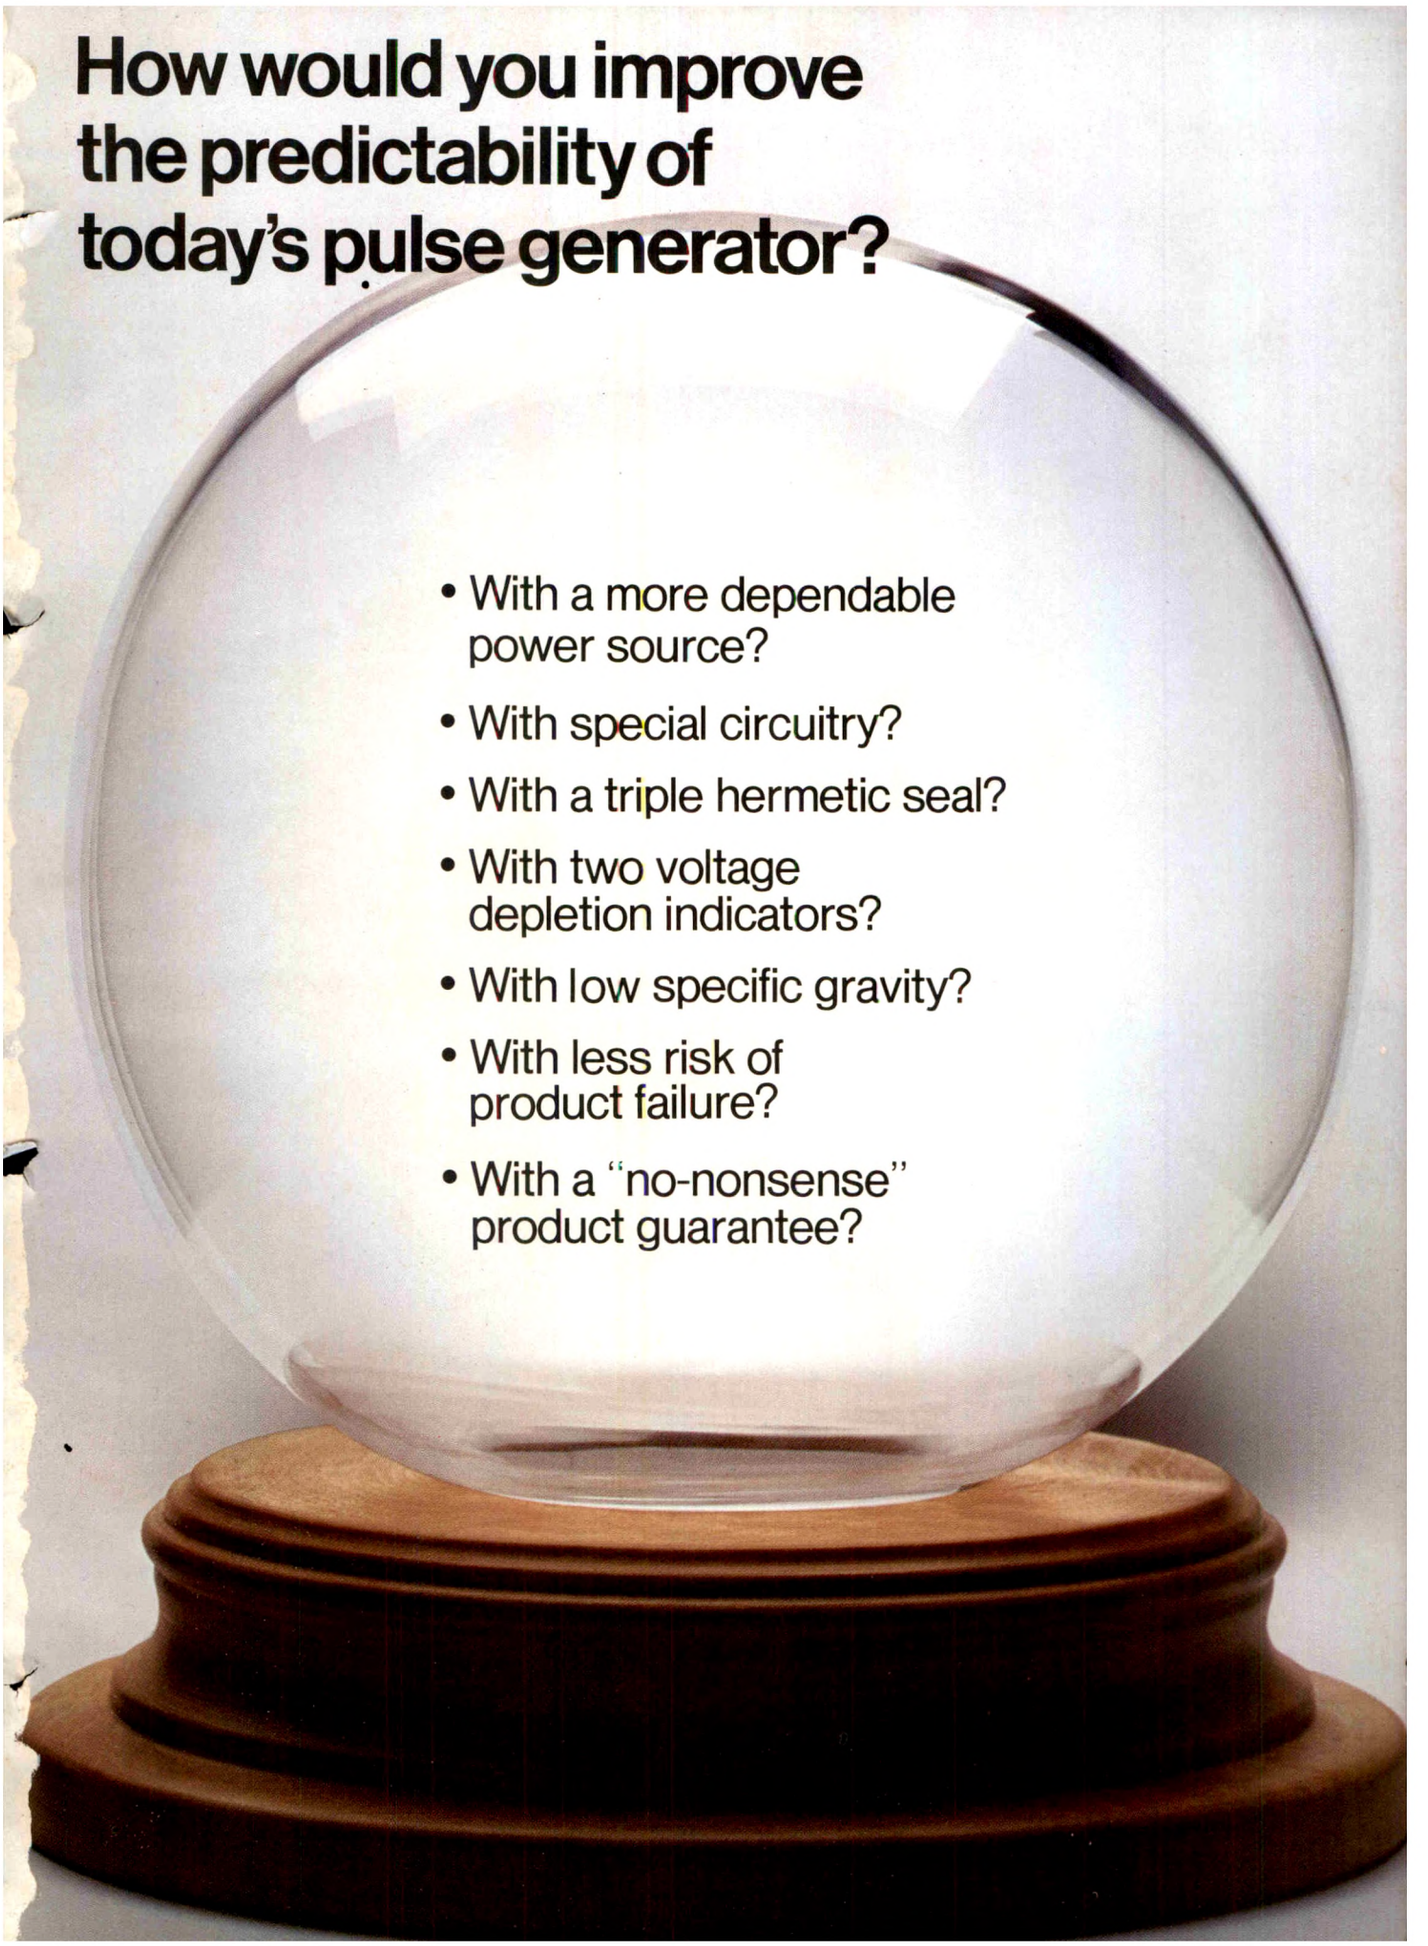
POSITION & AFFILIATION (IF APPLICABLE)

ADDRESS

CITY STATE ZIP

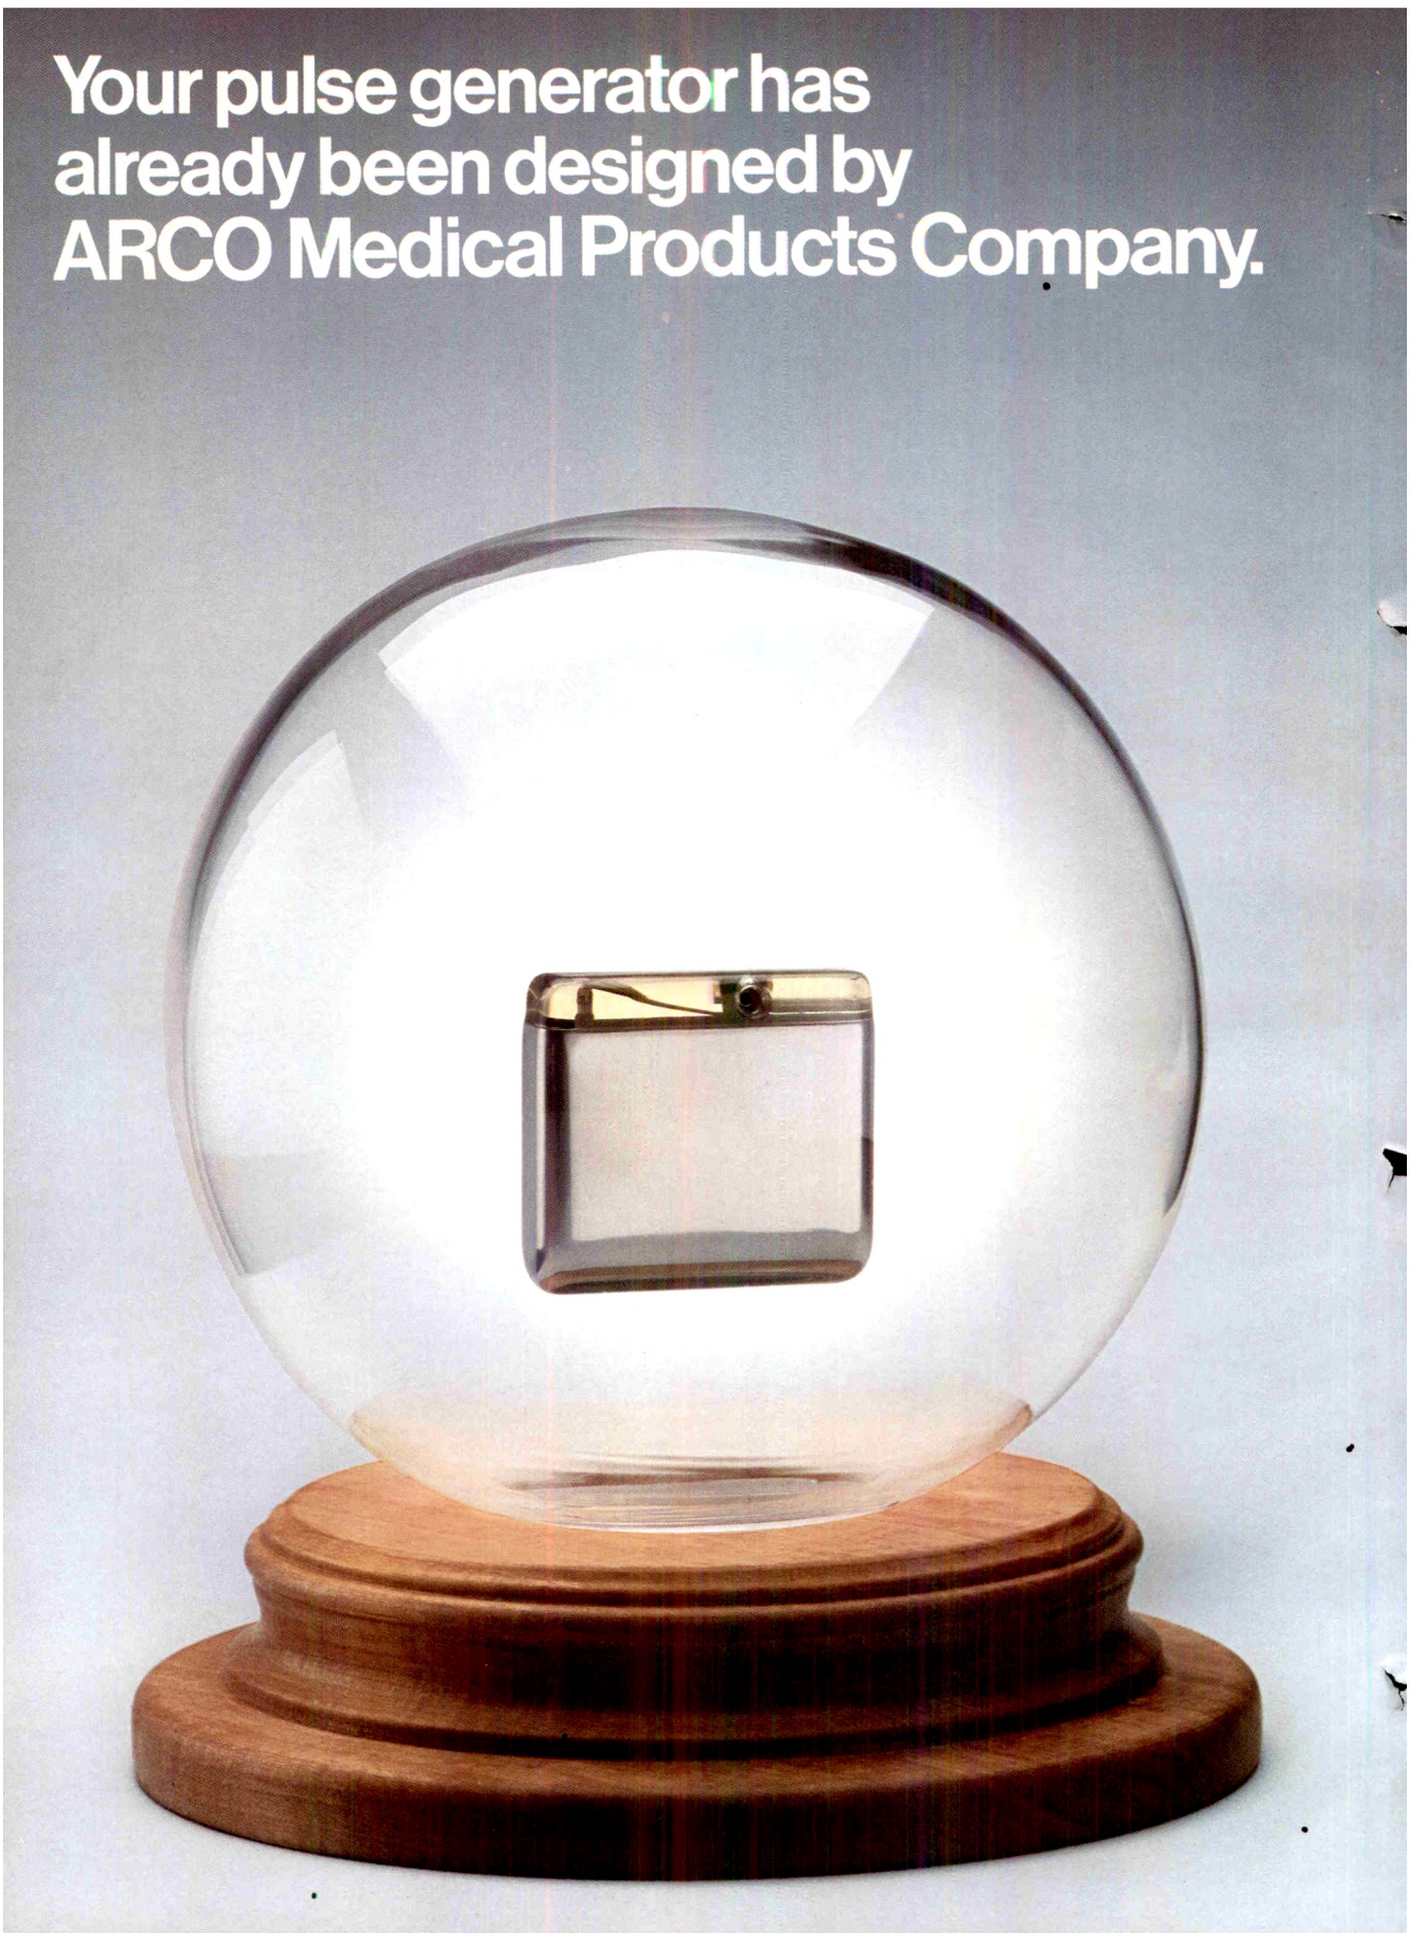
W.B. Saunders Company West Washington Sq. Philadelphia, PA 19105

How would you improve the predictability of today's pulse generator?



- With a more dependable power source?
- With special circuitry?
- With a triple hermetic seal?
- With two voltage depletion indicators?
- With low specific gravity?
- With less risk of product failure?
- With a "no-nonsense" product guarantee?

Your pulse generator has already been designed by ARCO Medical Products Company.



Improved predictability with the only lithium thionyl chloride power source.

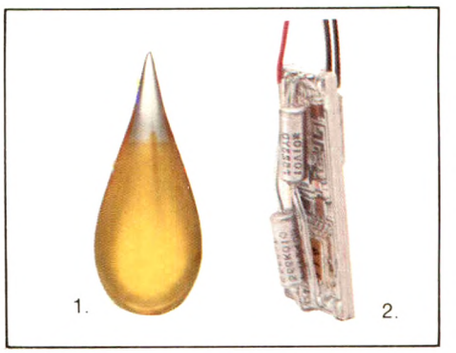
Lithium thionyl chloride, with one of the highest energy densities presently known, permits a small, lightweight battery that is longer-lasting than other cells of comparable size in any given application. Individual cell hermetic sealing and no generation of internal pressure contribute to the fact that there has not been a report of a single power source failure in clinical use (1).

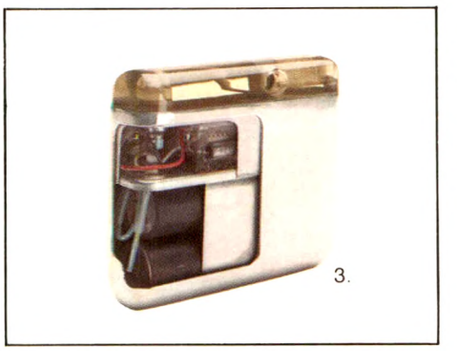
Improved predictability with specially designed circuitry.

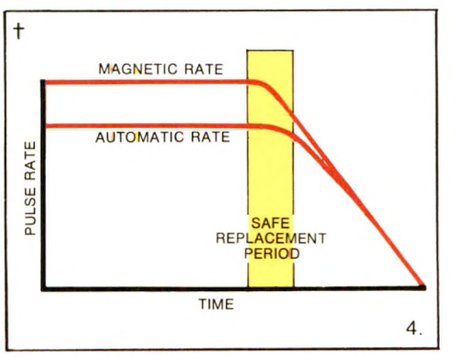
Developed specifically for use with our exclusive power cells, this circuitry offers long life and reliability. In fact, our power cells are electrically connected in a truly redundant fashion, which assures uninterrupted operation even if one cell should fail (2).

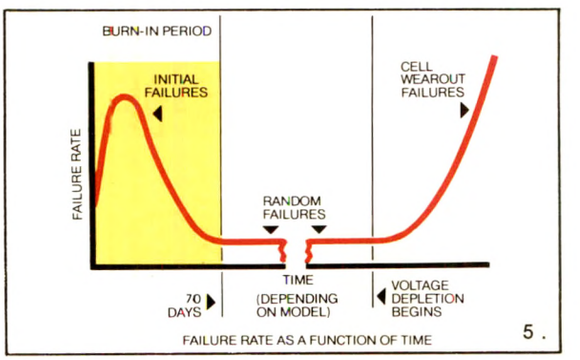
Improved predictability with a triple hermetic sealing process.

The power cells, the electronics, and the outer case of corrosion-resistant titanium are all individually hermetically sealed to provide dual protection and virtually isolate components from the invasion and migration of body fluids (3).









Improved predictability with two voltage depletion indicators.

Both an automatic and magnetic pulse rate provide advance warning of cell voltage depletion. The magnetic rate begins to decrease a number of months prior to the automatic rate to provide ample replacement time (4).

Improved predictability with a more natural specific gravity than most pulse generators.

The specific gravity of ARCOlith™ pulse generators is just slightly greater than that of the body's tissues; thus, migration is minimized for added patient comfort.

Improved predictability with an extended "burn-in" test.

Prior to market release every unit must undergo 70 days of operation. This virtually eliminates initial implant failure and assures you and your patients of effective performance and long life (5).

The predictability of ARCOlith™ pulse generators has been so improved they carry a "no-nonsense" product guarantee.

In essence:

1. Should an ARCOlith pulse generator become defective for any reason up to and including 60 days following implant, we will replace it and pay *all* reasonable surgical and hospital costs.*

2. Should an ARCOlith pulse generator become defective for any reason after 60 days up to the end of the warranty period,* we will replace it and pay up to $200 in surgical and hospital costs.*

*See warranty for specific details. Warranty applies in U.S.A. only.

†Idealized graph based on extrapolated data.

ARCOlith™ 12, 6, and 4 are now the trade names for pulse generator models LI-2, LI-4 and LI-3.

Every ARCOlith™ pulse generator offers you these predictable features:

- Titanium and epoxy casings proven corrosion resistant to body fluids and compatible with human tissue over long periods of time
- EMI shielding, high-reliability filtering components, and special circuits help to protect against electromagnetic interference
- Higher interference rate than the basic pacing rate provides additional protection against PVCs and competition, which may occur at lower levels
- High-input impedance enhances R-wave sensing
- Output stage contains voltage pulse doubler, which allows truly redundant power cells
- Visible temperature indicator informs whether unit has been subjected to excessive temperature prior to implant
- Readily adaptable to most leads
- Captive set screw-in lead connector
- 24-hour telephone diagnostic monitoring of pulse generators available at no extra cost

Disclosure Statement
ARCOlith™ Implantable Pulse Generators

Intended uses: Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to symptomatic bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses).

Contraindications: There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing systems and implantation procedure used by the physician.

Warnings: Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator.

Precautions: The physician should be aware that all pulse generators will ultimately cease to function, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, and elevated thresholds, and that proper operation may be affected by electrical interference from equipment using electrical energy, or medical complications.

Side effects: Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Noninvasive Assessment of Coronary Stenoses By Myocardial Perfusion Imaging During Pharmacologic Coronary Vasodilatation

I. Physiologic Basis and Experimental Validation

K. LANCE GOULD, MD, FACC

Seattle, Washington

This study was undertaken to establish the basic hemodynamic conditions necessary to cause abnormalities in external myocardial perfusion images of thallium-201 and technetium-99M–labeled particles as a result of defined coronary stenoses ranging from mild to severe narrowing. Twenty dogs underwent long-term instrumentation with a flow transducer and adjustable constrictor on the left circumflex coronary artery. Catheters were implanted in the aortic root and distal left circumflex coronary artery to measure pressure loss across the stenosis and in the pulmonary artery and left atrium for the injection of drugs or radionuclides, or both. All data were obtained in intact unsedated trained animals. The results from 145 images obtained at rest, during exercise or after coronary vasodilators in dogs with mild to severe coronary stenoses demonstrate the following: (1) The ratio of maximal flow in a normal to stenotic coronary artery must be at least 2:1 before defects appear in the myocardial perfusion image of thallium-201. (2) A diagnostic technique that utilizes a maximal stimulus for increasing coronary flow and an imaging agent that is distributed to the myocardium in linear proportion to coronary flow at flow rates up to 4 or 5 times resting levels will be the most sensitive method for detecting mild coronary stenoses; a diagnostic technique utilizing a submaximal stimulus for coronary flow or an imaging agent whose distribution is not proportional to flow at high flow rates will be least sensitive. (3) Myocardial perfusion imaging during coronary vasodilatation induced with intravenously administered dipyridamole is a better method for identifying moderate coronary stenoses than perfusion imaging during exercise stress in experimental animals. (4) The effect of intravenously administered dipyridamole on the coronary circulation can be closely regulated by adjusting the dose rate of infusion and can be instantaneously reversed with intravenous administration of aminophylline, a dipyridamole antagonist; dipyridamole infusion does not increase myocardial oxygen demands as much as exercise and does not invoke myocardial ischemia as a diagnostic end point. This stimulus may therefore be more readily controlled than exercise stress and is not subject to the effects on treadmill testing of motivation, chronic lung disease, peripheral vascular disease or musculoskeletal impairment.

From the Veterans Administration Hospital and The Department of Medicine, University of Washington, Seattle, Washington. This work was supported by Veterans Administration MRIS Project 3217, Seattle, Washington Washington Heart Association grant 63-2749, Seattle, Washington and by from the National Institutes of Health, Grant HL 18492-01 Bethesda Maryland. Manuscript received May 11, 1977; revised August 22, 1977, accepted September 1, 1977.

Address for reprints: K. Lance Gould, MD, Veterans Administration Hospital, 4435 Beacon Avenue, South, Seattle, Washington 98108.

Myocardial imaging of thallium-201 injected at rest and during exercise stress is an important technique in the evaluation of coronary disease. However, the number of falsely negative results in patients with significant coronary disease documented with coronary arteriography ranges from 19 to 39 percent in several large clinical studies.[1–8] Although myocardial thallium imaging is quite useful when results are positive, it is not currently adequate for use as a diagnostic screening test in lieu of coronary arteriography because of the high number of false negative results.

There are several complex reasons for false negative thallium studies, including limitations of imaging hardware and geometry,[1,9] the time at which images are obtained after thallium injection as related to redistribution of this agent with disappearance of defects,[10] the presence of balanced coronary lesions which reduce perfusion equally and therefore produce no relative perfusion defect,[11] the effects of drugs, such as digitalis, propranolol and diuretic agents on thallium uptake,[12] the technique of exercise stress[3] and the problem of overlying myocardial structures or lung.[1] The problem is further complicated by variability in interpretation of coronary arteriograms and the difficulty of relating arteriographic appearance of stenoses to their hemodynamic effects. Although these factors have been recognized as procedurally important in current medical reports, there is no published description of the more basic physiologic principles or conditions that determine whether a specific coronary stenosis will cause a defect in thallium perfusion images at rest or at high coronary flow rates during stress.

The purpose of this report is (1) to describe the hemodynamic conditions necessary to produce abnormal myocardial perfusion images caused by experimental coronary stenoses of defined hydraulic severity in chronically instrumented intact awake active animals using thallium-201 and technetium-99M–labeled macroaggregated albumin particles, and (2) to validate experimentally a new noninvasive method for assessing the hemodynamic severity of coronary stenoses based on these physiologic principles and utilizing pharmacologic coronary vasodilatation as a potentially more effective and controlled stress than exercise.

Methods

Surgical Preparation

Anesthesia in 20 male dogs weighing 22 to 28 kg was induced with intravenously administered sodium thiopental, and anesthesia was maintained with methoxyflurane anaesthetic gas delivered through a Heidbrink vaporizing bottle with supplemental oxygen delivered into the intake of a Harvard volume respirator. Through a sterile left thoracotomy the left circumflex coronary artery was dissected free and a snugly fitting electromagnetic (Zapeda, Seattle, Washington) or Doppler flow transducer was placed around the proximal circumflex coronary artery; 2 to 3 mm distally a saline-filled inflatable constrictor was tied into place. In the distal main circumflex artery prior to major branches a small tapered Tigon catheter was inserted into the lumen and sutured into place with 6-0 silk passed through a cuff on the catheter. Similar catheters were implanted into the root of the aorta, the left atrium and the pulmonary artery. All catheters and wires were tunneled under the skin and exited individually 2 cm apart through 2 mm stab wounds in the skin over the back. The chest was closed in four layers with evacuation of the pneumothorax through a chest tube that was then removed. Dogs were treated with dipyridamole (Persantine®), 75 mg, and aspirin, 900 mg, for 2 days preoperatively and for 10 days postoperatively to prevent formation of platelet clots on the catheters in the postoperative period. After 10 days these drugs were discontinued without ill effects or malfunction of the catheters. Catheters were flushed daily, filled with heparin and stoppered with obturators made from 19 gauge needles cut off at the tip and filled with Silastic.®

Implanted Instruments

Doppler flow velocity transducers were made from 3.5 × 4.5 mm LTZ-2 lead titanate-zirconate piezo ceramic soldered to stainless steel coaxial cable (AS633-ISS, 38 AWG, Cooner Sales Company, California) and mounted in cast epoxy with air backing and coated with Parylene C by vapor phase deposition (Nova Tran Corporation, California) to insulate the transducer against body fluids. The coated wire was pulled through Silastic tubing which was then filled with self-leveling RTV 734 Silastic as a protective coating against mechanical abrasion. A continuous wave-directional Doppler flowmeter (L and M Electronics, Daly City, California) was used to measure instantaneous mean cross-sectional flow velocity at 8 to 9 megahertz after being tuned to maximal signal to noise ratio. Each transducer was calibrated on shrink tubing (3.54 mm outer diameter × 3.0 mm inner diameter) through which dog blood flowed; volume flow, F, was measured with a graduated cylinder and stopwatch. Mean cross-sectional velocity, V, was calculated from the equation $V = F/A$, where A was the cross-sectional area of the lumen of the shrink tubing. The voltage output of the Doppler flowmeter was measured with a digital voltmeter over a range of flow from zero to 156 cm/sec and the calibration factor calculated as cm/sec per volt output. The L and M Doppler flowmeter with these transducers was linear from zero velocity up to the maximum measured of 156 cm/sec (600 cc/min through a tube with an inner diameter of 3 mm). The calibration factor determined in vitro before implantation was also the same as that obtained by postmortem perfusion of the left circumflex artery with blood after experiments were completed and was the same on large as on small tubes. Electromagnetic flow transducers were calibrated in vitro by perfusion with blood using a graduated cylinder and stop watch. In those experiments in which electromagnetic transducers were used, zero baseline was determined by occluding the coronary artery with the coronary constrictor at the beginning and each of each experiment.

Catheters for implantation were made from Tigon micro bore tubing (0.025 inch inner diameter × 0.04 inch outer diameter [0.064 × 0.102 cm], Norton Plastics Company, Los Angeles, California). Tubing was dipped in oil heated to 140°C, drawn to a taper, cooled on dry ice and cut to fit snugly over a 25 gauge needle. A 2 to 3 cm long section of this small tapered tubing was welded with cyclohexanone to a 2.5 inch (6.35 cm) section of larger tubing, 0.04 inch inner diameter × 0.15 inch outer diameter (0.102 × 0.381 cm). A 4 inch (10.2 cm) 25 gauge needle was inserted through the tubings such that the tip projected 1 mm beyond the tip of the tapered small catheter. A slanted 1 mm long Tigon cuff was welded onto the small tubing near the tip. At operation the needle and catheter were thrust through the arterial wall with a twisting motion up to the cuff and secured to the adventitia of the artery with a 6-0 silk suture previously passed through the Tigon cuff. The needle was then withdrawn, the tubing flushed with saline solution, clamped with a rubber shod hemostat, wiped dry with a gauze sponge and welded with cyclohexanone to a 60 cm section of the larger tubing for exiting from the chest. After 1 minute's drying time, this joint was strong enough to withstand aortic pressure. Blood was then aspirated to remove any residual cyclohexanone and the catheter was flushed and filled with heparin. There was no bleeding site with this technique because there was no arteriotomy or exit hole in the artery.

Coronary constrictors were made by wrapping a 2.5 cm long section of Silastic tubing (0.058 × 0.077 inch [0.148 × 0.196 cm]) around a 4 mm diameter steel rod and bonding a stiff

radiolucent backing (strips of X-ray film) over it with self leveling Silastic RTV 734. One end of the tubing was sealed with RTV and the other end glued to a 50 cm long thick-walled silastic actuator tubing (0.030 × 0.095 inch [0.076 × 0.241 cm]) for exiting from the chest. The constrictor was evacuated under high vacuum and filled with saline solution before each experiment.

Experimental Procedure

Dogs were trained to lie quietly on a table and experiments were begun 2 weeks postoperatively when resting heart rates had decreased to 60 to 80 beats/min and resting mean aortic pressure was 65 to 85 mm Hg. Aortic and coronary pressures distal to the constrictor were measured with Bio-Tec BT-70 pressure transducers or differential pressures across the stenosis using a differential pressure gauge (National Semiconductor Coporation, Santa Clara, California, part no. Lx1701D), or both. Needle obturators, stopcocks and plastic parts were all filled by immersion under sterile saline solution in a vacuum chamber that was then evacuated under high vacuum in order to remove micro air bubbles and maximize frequency response. Sterile saline solution debubbled in the vacuum chamber was also used for flushing connections between catheters and pressure gauges. For each experiment pressure calibrations were recorded with 100 mm Hg pressure applied to the aortic, coronary and differential transducers at the beginning, middle and end of each study.

Protocol: Recordings were made on an Electronics for Medicine DR-12 with a direct writer. After a 10 minute rest period in a darkened room with no one moving about the laboratory, flow and pressure calibrations and baseline control recordings were made of the electrocardiogram, coronary flow velocity and aortic, coronary and differential pressures. The coronary constrictor was then expanded with saline solution under pressures up to 2,000 mm Hg (40 psi) depending on the severity of stenosis desired. The expansion pressure was held constant at the chosen level by a water-sealed ball valve in line with an automatic pressure regulator attached to an air pressure source. During the first 30 minutes after inflation of the constrictor, the stenosis tended to drift and become less severe despite constant inflation pressure. This early drift in stenosis was most likely due to squeezing fluid out of the tissues that grew between the arterial wall and the constrictor. After 30 minutes of adjustment the stenosis remained stable at whatever level of severity was selected. A dose of 0.5 cc of papaverine in a concentration of 2.0 mg/cc in debubbled saline solution was then injected through the coronary catheter to produce transient hyperemia while mean pressures and flow were recorded. Three minutes later when flow had returned to control levels dipyridamole was injected intravenously to produce more sustained maximal coronary flow. At peak response to dipyridamole, which occurred 4 minutes after the intravenous injection, thallium-201 was injected intravenously or technetium-99m–labeled macroaggregated albumin (MAA) or albumin microspheres were injected into the left atrium. In exercise experiments dogs ran on an enclosed treadmill instead of receiving dipyridamole to increase coronary flow. A radionuclide imaging agent was then injected as the dog ran at the 9th minute of a 10 minute run at 12.8 km/hour on a 10° incline.

Dogs were then externally imaged with an Ohio Nuclear Series 100 gamma camera in left lateral, 45° left anterior oblique and the same left anterior oblique view but with the gamma camera tilted 10° so that the camera faced cephalad, slightly "looking" up the long axis of the left ventricle. Thallium-201 was imaged at 80 keV with a full width half maximal window, and technetium-99m was imaged at 140 keV, also with a full width half maximal window. In each ease 300,000 count images were obtained with a low sensitivity high resolution collimator. Myocardial images were obtained 1 week apart to allow residual activity from the experiment of the previous week to decay to levels undetectable with external imaging. Thallium-201 cannot be imaged satisfactorily in the presence of technetium-99m because the 140 keV gamma emission of technetium causes a secondary lead (of the collimator) gamma emission of 80 keV, the same energy as that of the thallium-201 gamma emission. Technetium-99m images were therefore also obtained on this once weekly imaging schedule.

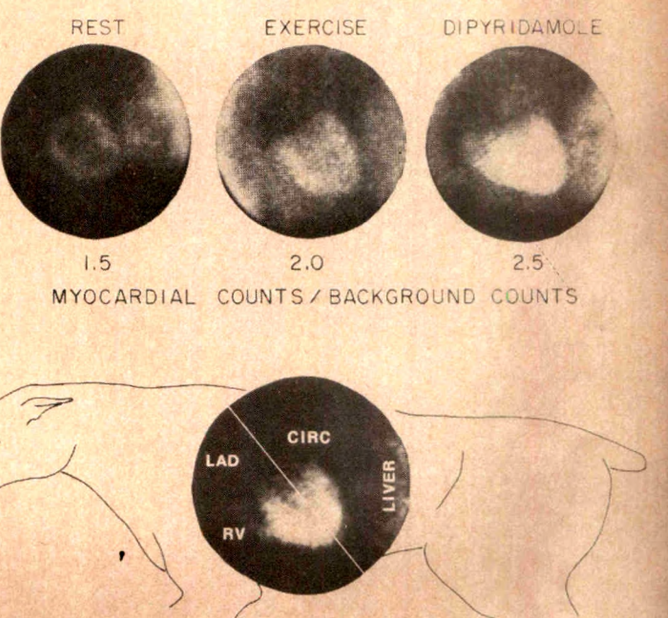

FIGURE 1. Myocardial perfusion images of a dog after intravenous injection of thallium-201 at rest, during treadmill exercise and during coronary vasodilatation induced with intravenously administered dipyridamole. All images were processed identically with 5 percent background subtraction. The orientation of myocardial images in relation to canine anatomy is shown with the distribution of the left anterior descending (LAD) and left circumflex (CIRC) coronary arteries. Relative myocardial uptake of thallium-201 and the quality of the images, expressed as myocardial:background activity ratios (before background subtraction), were greatest after dipyridamole infusion. RV = right ventricle.

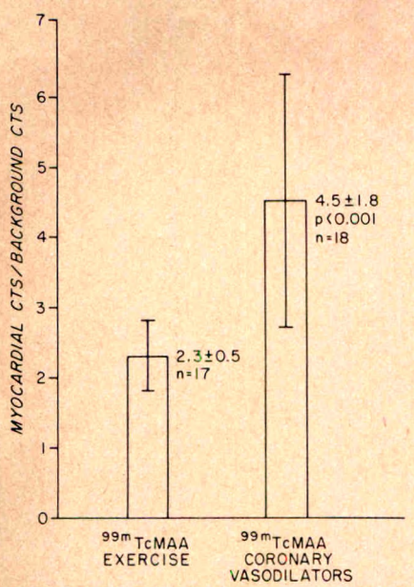

FIGURE 2. Relative myocardial activity (CTS) expressed as myocardial: background ratios of perfusion images obtained after left atrial injection of technetium-99m-labeled macroaggregated albumin (^{99m}TcMAA) during treadmill exercise and during coronary vasodilatation induced with dipyridamole. n = number of images; p = probability. Values expressed as mean ± 1 standard deviation.

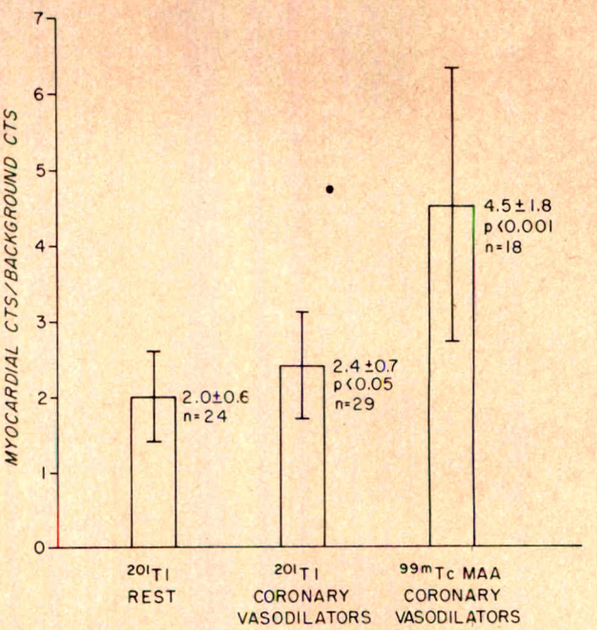

FIGURE 3. Relative myocardial activity (CTS) expressed as myocardial: background ratios of perfusion images obtained after intravenous injection of thallium-201 (^{201}Tl) and left atrial injection of technetium-99m–labeled macroaggregated albumin (^{99m}TcMAA) during comparable coronary vasodilatation with intravenously administered dipyridamole. Values indicate mean ± 1 standard deviation.

Data Analysis

Recordings of differential pressure and flow were manually traced on a Grafpen GP-2 ultrasonic digitizing tablet and processed in a PDP-8 computer. The coronary flow velocity and pressure difference between the aorta and the distal main circumflex artery (pressure gradient) due to a stenosis were digitized into 100 pressure points and a corresponding 100 velocity points for each cardiac cycle and were digitally filtered using the method of central differences. The digital filter was equivalent to a low pass filter flat to 15 hertz and having linear rolloff from 15 to 30 hertz (−40 decibels down at 30 hertz) and introduced no phase shift. During each cardiac cycle the pressure gradient and flow velocity were correlated by a quadratic equation having the general form $\Delta P = FV + SV^2$, where ΔP is the pressure loss in mm Hg, V is the coronary flow velocity in cm/sec, F is the coefficient of pressure loss due to viscous friction and S is the coefficient of pressure loss due to flow separation or localized turbulence downstream from the stenosis (and Gould KL, unpublished data).[13] For single heart cycles the constants F and S were determined that best fit this general equation to the experimental data by computer utilizing a general purpose curve-fitting algorithm previously described.[14] Three to six heart cycles for flow ranging from resting control to peak flow during coronary vasodilation were analyzed for each stenosis. Computer printouts of experimental data for each cardiac cycle were obtained with pressure gradient plotted on the vertical axis and flow velocity on the horizontal axis.

All radionuclide imaging data were collected and stored in dedicated computer systems consisting of Nova II and 1220 with 24K and 32K core memory, (Medical Data Systems, Ann Arbor, Michigan), 128 × 128 matrix display, dual magnetic disc drives and tape storage systems. Original scintiphotographs of in vivo perfusion images were used for interpretation. Computer-reproduced images with 5 percent background subtraction were used for illustrations and all images shown for comparison purposes in this article were processed identically with identical 5 percent background subtractions so that artifactual or apparent abnormalities were not created by computer reproduction. Localized profiles of each image were located on memory oscilloscopic display to determine the ratio of myocardial to background activity. Each dog had control images taken at rest and after coronary vasodilators or exercise, or both, without stenoses of the coronary arteries as well as with stenoses. The average number of images per dog was 7.5.

Results

Figure 1: This figure shows examples of identically processed myocardial perfusion images of a normal dog after intravenous injection of thallium-201 at rest, during treadmill exercise and after intravenous injection of dipyridamole. The uptake of thallium-201 by the myocardium relative to lung, that is, the myocardial to background ratio, determined from original measurements of activity without background subtraction, reflects the quality of the image and relative myocardial uptake. In this example dipyridamole produced a greater increase in coronary flow and thallium-201 uptake than treadmill exercise. Subsequent figures show mean myocardial to background ratios of images obtained under various conditions using intravenously administered thallium-201 and technetium-99m–labeled macroaggregated albumin.

Figure 2: This figure shows the relative degree of uptake of technetium-99m macroaggregated albumin, an entirely flow-distributed agent, during exercise and during pharmacologic coronary vasodilatation. The mean myocardial to background activity ratio during treadmill exercise was 2.3 ± 0.5 (mean ± standard deviation), which is considerably lower than the 4.5 ± 1.8 ($P < 0.001$) found during pharmacologic coronary vasodilatation. This observation indicates that

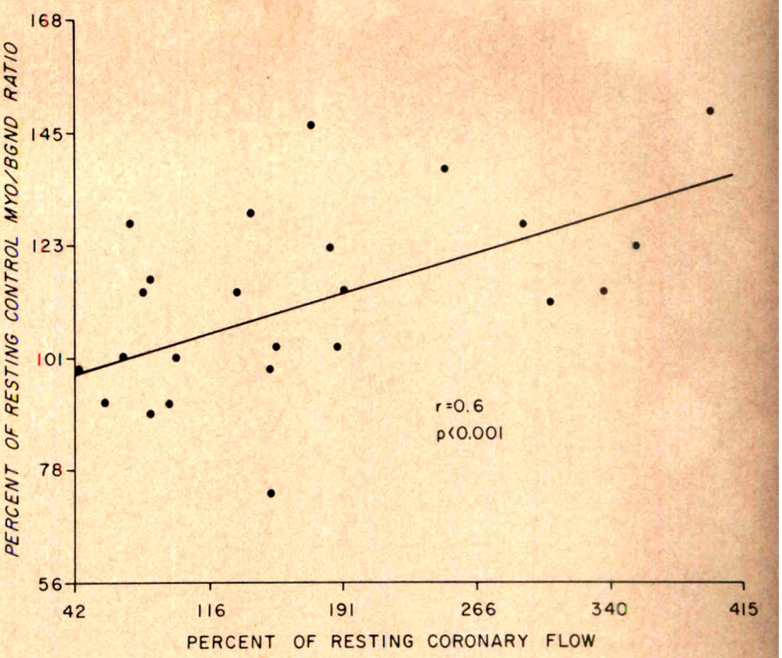

FIGURE 4. Relation between percent change in coronary flow from resting control values and percent change in relative myocardial activity expressed as myocardial: background (MYO/BGND) ratios of thallium-201 perfusion images. The relative myocardial uptake of thallium-201 failed to increase in proportion to increases in flow. Coronary flow was varied by using various intravenous doses of dipyridamole up to 0.6 mg/kg.

in experimental animals coronary vasodilators are a more effective stimulus for coronary flow than treadmill exercise.

Figure 3: This figure shows the effects of using an imaging agent, technetium-99m macroaggregated albumin, whose distribution is proportional to flow in contrast to thallium-201, whose uptake is not proportional to flow at high flow rates. For comparable flow stimuli using coronary vasodilators, the myocardial to background ratios of 4.5 ± 1.8 for technetium-99m macroaggregated albumin images were higher than the 2.7 ± 0.7 observed with thallium-201. This finding suggests that an imaging agent that is distributed in the myocardium in proportion to flow will result in better myocardial images than an imaging agent that is not taken up by the myocardium in proportion to flow at high flow levels of up to 4 or 5 times baseline levels.

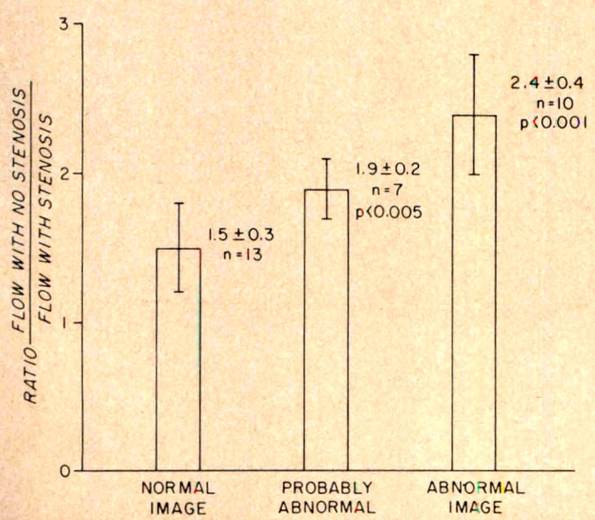

FIGURE 5. Ratio of maximal flow in the normal coronary artery to maximal flow in the stenotic coronary artery during coronary vasodilation in relation to myocardial images of thallium-201 injected after intravenous administration of dipyridamole. Values expressed as mean ± 1 standard deviation.

Figure 4: This figure shows that the percent change in myocardial to background ratios of thallium-201 did not increase proportionately with percent increase in coronary flow measured with a flowmeter. There was a poor correlation between thallium-201 uptake measured with external imaging and increase in coronary flow for flow levels up to 4 times resting levels ($r = 0.6$) with sufficient scatter to prevent estimation of changes in coronary flow from thallium uptake.

Figure 5: This figures shows the ratios of peak coronary flow after administration of a vasodilator in a normal coronary artery to the peak flow with a stenosis on the artery in relation to perfusion defects in thallium-201 images taken after infusion of dipyridamole. A 2:1 flow ratio indicates that during coronary vasodilation flow in the normal artery was twice as great as in the stenotic artery; a 1:1 flow ratio indicates no impairment of maximal flow. A flow differential between the normal and stenotic coronary artery of 2.4 ± 0.4 times was required to cause a definite defect in the thallium image.

Table I: This table shows pressure losses across stenoses and coronary pressures distal to the stenoses in relation to

TABLE I

Pressures with Thallium-201 Myocardial Images

Myocardial Image	ΔP (mm Hg)	Distal Coronary Pressure (mm Hg)
Normal (no. = 12)	25 ± 7	57 ± 15
Probably abnormal (no. = 7)	37 ± 9 $P < 0.025$	49 ± 16 NS
Abnormal (no. = 9)	45 ± 15 $P < 0.005$	37 ± 9 $P < 0.005$

ΔP = pressure losses across stenoses; NS = not significant; P = probability.

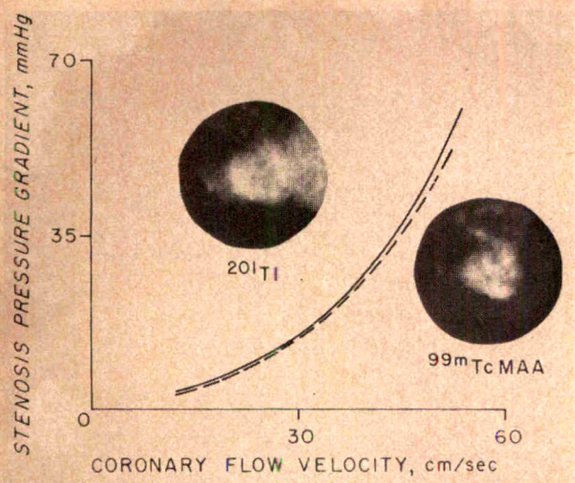

FIGURE 6. Graphic plot of the pressure gradient-flow velocity relation characterizing the hemodynamic severity of stenoses of the left circumflex coronary artery of a dog. A stenosis of defined hemodynamic severity was applied and a thallium ^{201}Tl perfusion image obtained during dipyridamole induced coronary vasodilatation. After completion of the study the stenosis was released. One week later, after all residual thallium activity had disappeared, a second stenosis of identical severity was applied and a perfusion image was obtained of technetium-99m macroaggregated albumin (^{99m}TcMAA) injected into the left atrium during comparable coronary vasodilatation. In this manner the relative sensitivity of different imaging procedures for detecting identical stenoses were tested. In this example with a moderate circumflex stenosis a perfusion image of thallium-201 injected during dipyridamole-induced coronary vasodilatation failed to demonstrate a defect **(upper left image and solid line).** However, with a hemodynamically identical stenosis a perfusion image of technetium-99m–labeled macroaggregated albumin injected into the left atrium during comparable coronary vasodilatation showed a mild but definite decrease in activity in the circumflex distribution **(right border of the lower right image and dashed line).** Left lateral views are shown.

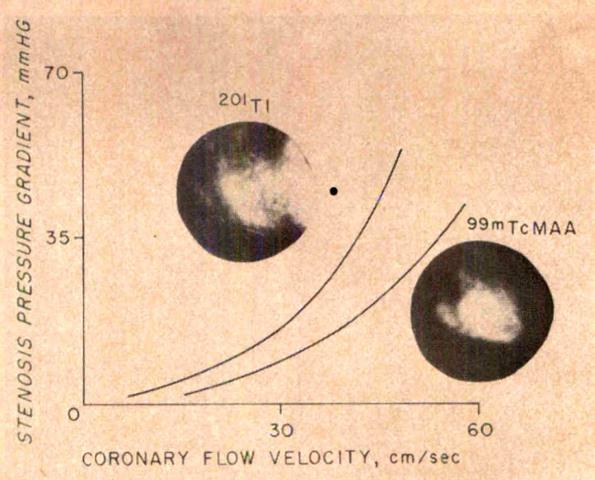

FIGURE 7. Hemodynamic characteristics of coronary stenoses producing comparable defects on thallium and technetium MAA perfusion images. There is a mild but definite decrease of activity in the circumflex distribution **(right border)** of the thallium (^{201}Tl) image **(upper left photograph** and **upper curve)** as well as the technetium-99m macroaggregated albumin (^{99m}TcMAA) image **(lower right photograph** and **lower curve).** The pressure gradient-flow velocity relation characterizing the hemodynamic severity of the stenosis causing the thallium defect is steeper than for the stenosis causing the defect on the technetium image. Thus, a more severe stenosis was required to produce a thallium than a technetium defect.

perfusion defects in thallium-201 myocardial images. Abnormal images were associated with stenosis gradients of 45 ± 15 mm Hg and distal coronary pressures of 37 ± 9 mm Hg at peak coronary vasodilatation when thallium-201 was injected. *P* values shown are in comparison with the normal images in which the stenoses were too mild for detection by myocardial imaging.

Figure 6: From an experimental point of view, the severity of a stenosis is best defined in terms of its pressure-flow characteristics, that is, the plotted or mathematical relation between the pressure gradient caused by a coronary stenosis and the flow velocity through the coronary artery[13,15,16] (and Gould KL, unpublished data). The pressure gradient due to a stenosis was related to coronary flow velocity according to a curved line (shown as an example in Fig. 6). For a fixed coronary stenosis, the pressure gradient increased as flow velocity increased in response to any stimulus, such as exercise or coronary vasodilators. With more severe stenosis the pressure gradient-flow velocity relation became steeper and more curved, moving upward and leftward on the graph. With less severe stenosis the relation moved downward and rightward. This method of defining the severity of the stenosis in hydraulic terms did not require knowledge or comparison of the geometry of the stenosis or size of the coronary artery because the effects of percent narrowing, absolute stenosis

TABLE II

Hemodynamic Changes with Abnormal Images

	Thallium-201	*P* Value	Technetium-99m Macroaggregated Albumin
Flow ratio*	2.4 ± 0.4 (no. = 10)	<0.025	1.9 ± 0.4 (no. = 13)
Pressure gradient (mm Hg)	45 ± 15 (no. = 9	NS	38 ± 6 (no. = 13)
Distal coronary pressure (mm Hg)	37 ± 9 (no. = 9)	<0.05	45 ± 8 (no. = 13)

* Ratio of flow with no stenosis to flow with stenosis.
NS = not significant; *P* = probability.

diameter, length and degree of streamlining all had a final common influence on pressure loss or flow velocity. Figure 6 illustrates two hemodynamically identical coronary stenoses imaged during dipyridamole-induced coronary vasodilatation using thallium-201 and subsequently using technetium-99m macroaggregated albumin. For a stenosis of this relatively moderate hydraulic severity, thallium-201 imaging failed to demonstrate a defect whereas technetium-99m macroaggregated albumin clearly showed decreased perfusion in the circumflex distribution (right border) of this left lateral view.

Figure 7: This figure shows that a stenosis that yielded a mild but definite circumflex defect with thallium-201 imaging during coronary vasodilatation was more severe hydraulically (upper curve) than a stenosis that yielded a comparable defect in a technetium-99m macroaggregated albumin image during comparable vasodilatation (lower curve).

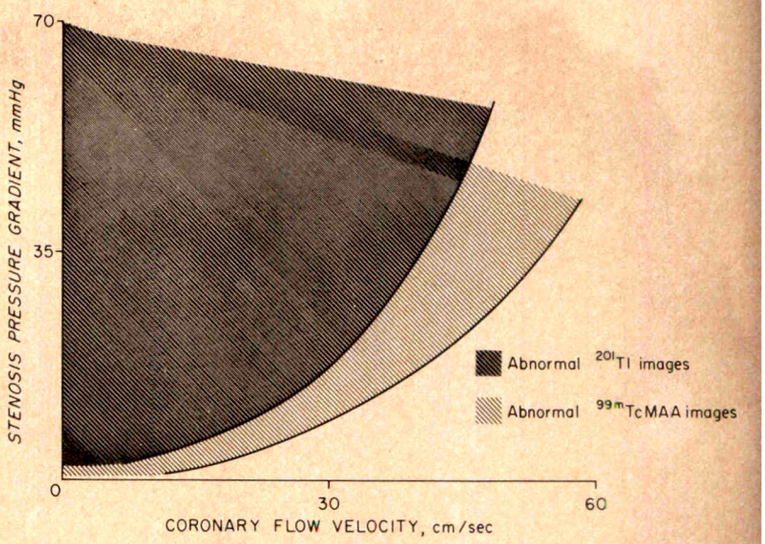

FIGURE 8. Composite pressure gradient-flow velocity curves of 24 coronary stenoses in relation to abnormal myocardial images using thallium-201 (^{201}Tl) and technetium-99m macroaggregrated albumin (^{99m}TcMAA). Less severe coronary stenoses were consistently detected with ^{99m}Tc technetium than with thallium images.

Figure 8: This figure shows the composite results of 24 coronary stenoses defined by similar pressure-flow curves in relation to abnormal myocardial images. In term of hydraulic curves, myocardial images using technetium-99m macroaggregated albumin identified milder stenoses than thallium-201.

Table II: This table compares the hemodynamic changes associated with abnormal thallium and technetium images. The ratio of maximal flow in an artery with no stenosis to maximal flow in an artery with a stenosis indicated the severity of flow impairment and relative flow maldistribution. Abnormal technetium-99m images were associated with significantly less severe flow abnormalities than abnormal thallium-201 images. Pressure losses or gradients across the stenoses and coronary pressures distal to the stenosis were also less severely affected, indicating that milder coronary stenoses were detected with technetium than with thallium. Thus, a method utilizing an imaging agent that was distributed in proportion to flow was more sensitive than an imaging agent that was not taken up in proportion to flow at high flow rates.

Figure 9: This figure illustrates one of three experiments in which there was an inadequate coronary vasodilatory stimulus for imaging the effects of coronary stenoses. In this example the two coronary stenoses were hemodynamically identical and were both imaged with thallium-201. For the image on the left associated with the solid curve, an inadequate dose of dipyridamole was used and no defect is apparent in the image. For the image on the right associated with the dashed curve an adequate dose of dipyridamole was used and a mild but definite abnormality developed in the distribution of the stenosed circumflex coronary artery.

Figure 10: This figure further illustrates this point using exercise as the "inadequate" stimulus. The stenoses in this example were hydraulically identical and both were imaged with thallium-201. In the left image the stimulus for increasing coronary flow was exercise stress and no perfusion defect developed. In the right image the stimulus was intravenously administered dipyridamole which clearly resulted in an abnormality in the distribution of the stenosed left circumflex artery. These findings indicate that a potent stimulus for coronary vasodilatation increased the sensitivity of an imaging method for assessing coronary stenoses over that of a less potent stimulus.

Figure 11: This shows the minimal dose of intravenously administered dipyridamole necessary to produce maximal or near maximal coronary vasodilatation in dogs. Maximal vasodilation was arbitrarily defined as the flow response after 10 seconds of occlusion in the absence of stenosis. Both the rate at which dipyridamole was infused and the absolute dose given were important determinants of the coronary flow response. Various intravenous dose infusion rates were tested to determine which dose rate would produce maximal or near

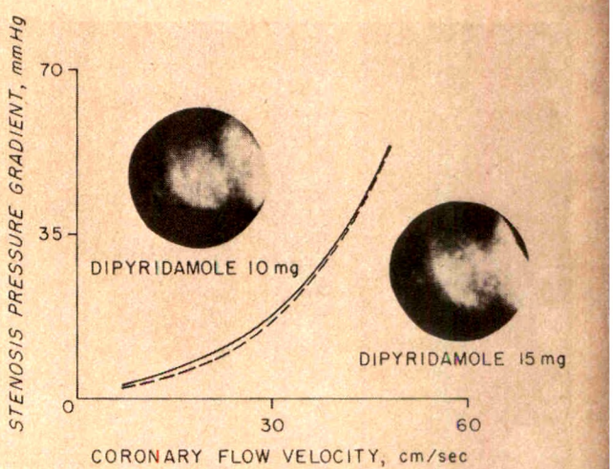

FIGURE 9. Effect of an inadequate stimulus for coronary vasodilatation on the sensitivity of thallium imaging for detecting coronary stenoses. The thallium image at **upper left** associated with the **solid line** failed to demonstrate a defect during submaximal coronary vasodilation. With a hemodynamically identical coronary stenosis **(dashed line)**, adequate coronary vasodilatation caused a mild but definite decrease of activity in the circumflex distribution **(right border)** of the thallium image at **lower right.**

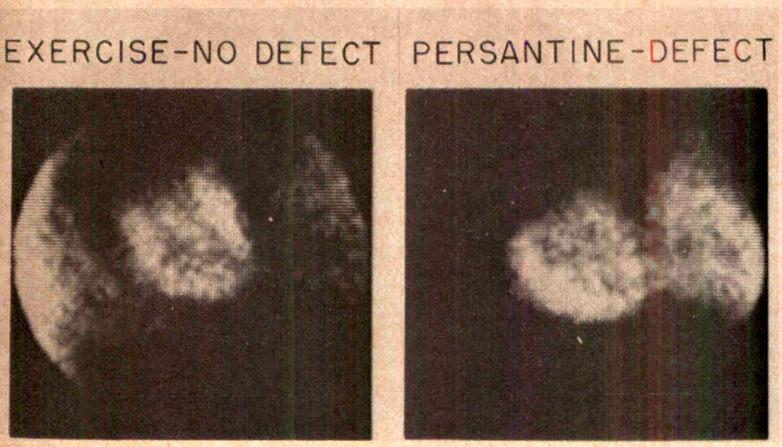

FIGURE 10. Myocardial perfusion images of thallium-201 injected during treadmill exercise **(left)** and during dipyridamole (Persantine)-induced coronary vasodilatation **(right)**. The circumflex arterial stenosis for the left image was hemodynamically identical to that for the right image with the same pressure gradient-flow velocity relation. No defect was present in the exercise thallium image **(left panel)**, whereas a definite decrease of activity occurred in the circumflex distribution **(right border)** of the dipyridamole thallium image **(right panel)**.

maximal coronary flow for 3 to 5 minutes, the time required for most thallium-201 to be taken up by the myocardium. At a dose rate of 0.142 mg/kg per min for 4 minutes coronary flow reached 95 percent of the peak flow response after 10 seconds of occlusion. The peak coronary response to dipyridamole occurred 5 minutes after the end of the 4 minute infusion and persisted for 3 to 5 minutes thereafter with this regimen. The response to a 10 mg bolus dose (average 0.4 mg/kg) and a 15 mg bolus injection (0.68 mg/kg) are also shown.

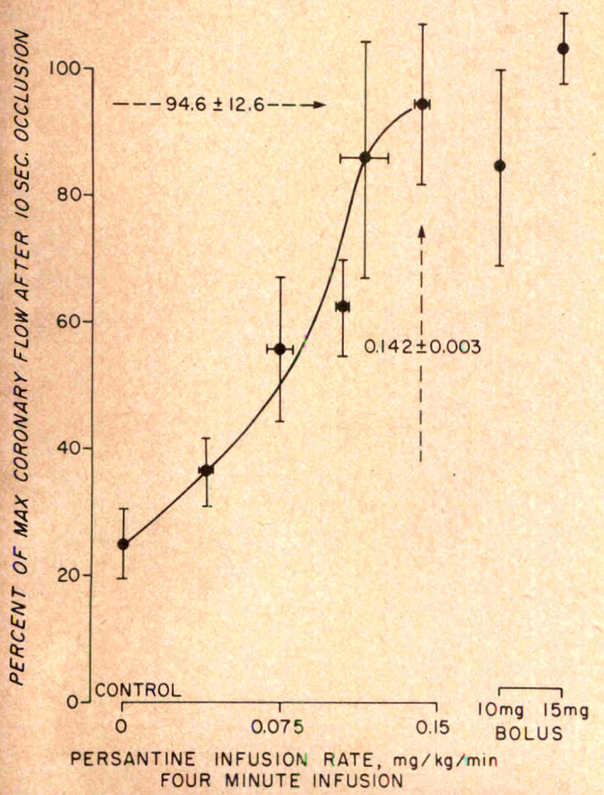

FIGURE 11. Response of coronary flow to various dose-rate intravenous infusions of intravenous dipyridamole (Persantine) in intact unsedated animals. The optimal dose rate for imaging purposes was 0.142 mg/kg per min for 4 minutes. Values indicate mean ± 1 standard deviation. MAX = maximal.

Discussion

External imaging of regional myocardial perfusion during pharmacologic coronary vasodilatation for the detection of coronary stenoses was initially reported by Gould et al. in experimental animals[17] and in man[11] and subsequently in a clinical series by Ritchie et al.[18] These studies demonstrated a physiologic basis for assessing the severity of coronary stenoses in terms of restricted coronary flow reserve and sharply separated normal subjects from patients with hemodynamically significant coronary disease. However, the method required coronary arteriography with intracoronary injection of contrast medium as the stimulus for coronary vasodilatation and intracoronary injection of technetium-99m macroaggregated albumin for imaging regional myocardial perfusion. The need for an invasive procedure limited the clinical applicability of the approach.

Horwitz et al.[19] described a pharmacologic stress test using the xenon-133 technique to measure coronary blood flow during infusion of isoproterenol. This method statistically separated a group of normal subjects from a group of patients with coronary disease. However, the patients with coronary disease had severe coronary lesions, and the sensitivity of the technique for more moderate lesions was not evaluated. In addition, the regional localization of abnormalities in myocardial perfusion could not be identified because, instead of a gamma camera, precordial counting probes were used to record total myocardial clearance curves. Yamazaki et al.[20] confirmed the use of contrast medium as well as intravenously administered dipyridamole to assess coronary flow reserve in stenotic coronary arteries of experimental animals. Cole et al.[21] recorded increased coronary flow velocity in patients with a catheter-tip Doppler velocity detector after the intracoronary injection of contrast medium. Bassan et al.[22] measured coronary sinus blood flow with a thermodilution catheter during coronary vasodilatation induced with intracoronary injection of contrast medium. This technique also statistically separated normal subjects from patients with coronary disease but there was sufficient overlap between the groups to render the results of limited diagnostic benefit in any individual patient:

Holman et al.[23] imaged xenon-133 clearance during coronary vasodilatation caused by intracoronary injection of contrast medium. Again, a normal group could be statistically separated from a group with coronary disease but the results were not specific enough for reliable diagnosis in individual cases.

More recently, noninvasive methods of myocardial imaging have become available, particularly those utilizing thallium-201. Strauss et al.[24] evaluated myocardial imaging of thallium-201 and potassium-43 injected during coronary vasodilatation induced with adenosine-5-carboxylate in order to identify subcritical coronary stenoses. The studies reported here, undertaken independently over the past 3 years, establish the physiologic requirements and validity of utilizing thallium-201 imaging during coronary vasodilatation induced with dipyridamole in order to identify coronary stenoses of hydraulically defined severity.

Treadmill exercise stress as a stimulus for coronary flow: Our results demonstrate two principal physiologic requirements of any method for assessing coronary flow reserve. The first is a potent stimulus for increasing coronary flow in order to maximize regional perfusion abnormalities that can then be imaged externally. Although exercise increases coronary flow, the relation between the level of exercise and the degree to which coronary flow increases is unclear. In our study dogs running on a treadmill at 12.8 km/hour for 10 minutes on a 10° incline increase coronary flow by 100 to 150 percent, a finding in agreement with previous reports.[25–28] This level of exercise is approximately equivalent to stage 6 or 7 of the Bruce protocol for maximal treadmill stress in man.[29] By analogy, such treadmill stress in man would therefore not be a satisfactory stimulus for coronary flow, which reportedly can increase 4 to 5 times resting levels after pharmacologic stimuli, which are more potent than treadmill stress.[30]

However, higher coronary flow levels have been reported during treadmill testing in dogs under certain conditions. Particularly well trained dogs[31] or dogs making the transition from rest to exercise[32] or pulling a loaded sled in a cross-country run may increase coronary flow by 4 or 5 times.[33] Thus, the point of maximal treadmill exercise in animals is not clearly defined and the relation of treadmill stress in dogs to treadmill stress in man is even more obscure. Dipyridamole injected intravenously during strenuous exercise stress causes considerable further coronary vasodilation and increase in coronary flow in dogs.[32] During treadmill stress in man coronary flow reportedly increases only modestly. Messer et al.[34] reported that during exercise stress the average increase in coronary flow ranged from 33 to 44 percent (average increase 39 percent), depending on the clinical diagnosis. This average was 139 percent of control resting values for all patients. Parker et al.[35] showed that coronary flow increased 77 percent over resting levels in eight normal subjects and 49 percent in seven patients with coronary disease. These figures are 177 percent and 149 percent, respectively, of control resting coronary flow values. Knoebel et al.[36] described increases of up to 100 percent in coronary flow during exercise with an average increase of 20 percent, or 129 percent of control levels in 12 patients. Holmberg et al.[37] described exercise coronary flow values averaging 252 percent of resting coronary flow or an increase of 152 percent in 10 patients. Methodologic limitations on the methods for measuring coronary flow subject all of these results to some question. Using the argon technique, which is reportedly accurate at high rates of coronary flow, Heiss et al.[38] reported coronary flow increases of 103 percent in trained and 213 percent (203 percent and 313 percent, respectively, of control resting values) in untrained subjects during exercise.

The effectiveness of exercise stress as a stimulus for coronary flow may also be limited by motivation of the subject, pulmonary or peripheral vascular disease and the effects on exercise performance of cardiac drugs such as propranolol and prior physical training. Conditioned athletes demonstrate significantly less increase in coronary flow for a given level of exercise than deconditioned subjects.[38] In the presence of coronary disease the development of myocardial ischemia during exercise may cause angina pectoris, which limits exercise to a sufficiently low level that the normal areas of myocardium are not stressed adequately and coronary flow does not increase enough to produce regional perfusion defects by external imaging.

Dipyridamole as stimulator of coronary flow: The specific type of coronary vasodilator does not appear to be of critical importance so long as it is selective for the coronary arteries, has insignificant systemic effects and has an effect for at least 3 minutes until thallium-201 is removed from the systemic circulation. Experimentally, contrast media, papaverine, adenosine triphosphate or nitroglycerin given by intracoronary injection in adequate doses or 10 seconds of occlusion provide a satisfactory stimulus for coronary vasodilatation. Coronary vasodilatation in the presence of a coronary stenosis results in an increased pressure gradient and a decrease in distal coronary pressure as coronary flow increases.[15,16,39–41] This increased pressure loss associated with increasing coronary flow through a stenosis is a basic fluid dynamic characteristic of an arterial narrowing[13,15,16,39,40] as shown by the pressure-flow relation in Figures 6 to 9. Thus, any potent coronary vasodilator has the potential of producing subendocardial hypoperfusion[27,41–48] by causing a reduction in distal coronary perfusion pressure despite an increase in epicardial coronary artery flow.

Intravenously administered dipyridamole was used in this study for several reasons: (1) It is a potent coronary vasodilator with few systemic effects; (2) it is the only selective coronary vasodilator that has been extensively used in man (in Europe) and for which the Food and Drug Administration has granted an Investigational New Drug permit in the United States for clinical studies; and (3) its pharmacologic effects on the coronary circulation can be completely blocked within a few seconds by the intravenous administration of aminophylline.[41,49–53] thereby permitting complete control of any testing procedure. In our studies at the

doses described in intact awake dogs, intravenously administered dipyridamole caused no reduction in systemic arterial pressure in contrast to the reported decrease in arterial pressure after intravenous administration of dipyridamole in anesthetized open chest animals.[41,47,54–56] In anesthetized animals we have also found that arterial pressure decreased after intravenous administration of dipyridamole.

Myocardial uptake of imaging agent proportional to coronary flow: The second basic physiologic requirement of any method for assessing coronary flow reserve is that the myocardial uptake of the imaging agent be proportional to flow at high coronary flow rates of at least 4 times resting levels. An agent whose uptake is not related to flow will be insensitive for detecting mild stenoses and an agent whose myocardial uptake is linearly related to flow will be the most sensitive. The myocardial uptake of thallium-201 is linearly proportional to flow at resting control levels down to zero,[1,9,10,24,57] but at higher flow levels necessary to assess coronary flow reserve thallium uptake is not proportional to flow. Strauss et al.[57] reported that the percent change in myocardial uptake of thallium-201 by tissue counting was 40 to 50 percent of the increase in coronary flow over resting control values measured with microspheres. We also found that the maximal thallium uptake by tissue counting during peak coronary vasodilatation after dipyridamole was only 50 to 60 percent higher than control levels. Weich et al.[58] reported that myocardial uptake of thallium-201 is proportional to flow (or extraction is constant) if the increase in coronary flow is induced by elevating myocardial oxygen demands as opposed to pharmacologic coronary vasodilatation, which does not increase myocardial oxygen requirements. In that study thallium-201 extraction was measured at coronary flow levels 4 times normal induced with coronary vasodilators. However, that value of extraction was then compared with the myocardial extraction of thallium-201 during electrical pacing, which is known to increase coronary flow by only 150 percent or less, even at rates up to 300 beats/min.[59–61] Thus, the extraction during pacing was not measured at flow rates comparable with those during coronary vasodilatation. The conclusions of that study are therefore open to question. More recently Weich et al.[62] reported that extraction of thallium-201 by the myocardium decreased logarithmically with increasing coronary flow produced with vasodilators. The predominant current evidence suggests that thallium uptake in the myocardium is increased as coronary flow increases regardless of the stimulus but is not linearly related to flow at flow rates higher than resting control values. At these high flow rates thallium-201 uptake increases by approximately one half of the increase in coronary flow statistically. However, there is sufficient variability in this proportion to prevent using uptake of thallium-201 as a quantitative index of flow changes.

Mechanisms affecting thallium imaging defects: Perfusion defects in thallium-201 myocardial images are produced predominantly by regional abnormalities of flow distribution. However, to the extent that thallium behaves like potassium, an additional mechanism may play a role. In areas of myocardial ischemia or injury, the uptake of potassium and the uptake of thallium are proportionately reduced on a metabolic basis.[62] For example, perfusion of a coronary artery at normal flow rates with unoxygenated blood produces regional myocardial ischemia with a normal volume of coronary flow. Thallium images demonstrate defects in the distribution of the coronary artery perfused with deoxygenated blood.[63] The relative importance of this metabolic mechanism in producing image defects over and above defects produced by regional flow abnormalities depends on the severity of the stenosis and myocardial oxygen requirements. Despite the problems outlined in the introduction we utilized external myocardial imaging in this study rather than tissue counting for several reasons. First, we wished to evaluate the imaging technique as it is used clinically, including the recognized problems of external imaging. Second, the experimental model was developed for repetitive studies using various types and doses of coronary vasodilators, different imaging agents and stenoses of differing severity, all using each dog as his own control. This approach is not possible with an experimental design in which myocardial tissue counting requires sacrifice of the animal.

Implication: Although myocardial uptake of thallium-201 is not linearly related to blood flow at high flow rates, this agent is the best currently available for myocardial perfusion studies in man. Experimental data suggest that myocardial imaging during pharmacologic coronary vasodilatation is an excellent method for noninvasively assessing regional coronary flow reserve and the physiologic significance of moderate coronary stenoses. Whether this approach will be more sensitive or specific than exercise testing in man will require clinical evaluation.

Acknowledgment

I am grateful to Kathy Lovgren, Dennis Lee and Ann Coleman for their superb technical assistance in these studies. The intravenous form of dipyridamole was kindly supplied by Wilbur Benson, MD, Associate Director of Clinical Research, Boehringer Ingelheim Ltd., 33 West Tarrytown Road, Elmsford, New York 10523.

Noninvasive Assessment of Coronary Stenoses by Myocardial Imaging During Pharmacologic Coronary Vasodilatation

II. Clinical Methodology and Feasibility

K. LANCE GOULD, MD
R. JEFFREY WESTCOTT, MD
PETER C. ALBRO, MD
GLEN W. HAMILTON, MD

Seattle, Washington

A noninvasive method has been developed utilizing myocardial imaging of thallium-201 injected intravenously at rest and during coronary vasodilatation induced with intravenously administered dipyridamole, a potent selective coronary vasodilator. The method has been validated in experimental animals and shown to be more sensitive than exercise imaging in identifying moderate experimental coronary stenoses. This report describes the clinical feasibility and methodology of applying the technique to man. Study of a total of 162 myocardial perfusion images in 62 patients revealed the following: (1) The quality of myocardial perfusion images of thallium-201 injected during coronary vasodilatation induced with intravenously administered dipyridamole was equal to or better than that of myocardial images of thallium-201 injected during treadmill stress. (2) Myocardial uptake of thallium-201 measured with external imaging was considerably greater during dipyridamole-induced coronary vasodilatation than during treadmill stress. (3) The optimal dose rate of intravenously administered dipyridamole for this imaging technique was 0.142 mg/kg per min for 4 minutes with the thallium injected in the 3rd to 4th minute after completion of infusion while the patient was upright, walking in place. (4) With this dose rate regimen, side effects were minimal except for the occasional development of angina pectoris; the latter was eliminated by intravenous administration of aminophylline, a complete and virtually instantaneous antagonist of dipyridamole, after thallium had been taken up by the myocardium. This new method is therefore applicable to man and the initial results warrant a larger clinical study in order to define the diagnostic sensitivity and specificity of the technique.

Assessment of the hemodynamic significance of coronary stenoses by myocardial perfusion imaging during pharmacologic coronary vasodilatation has previously been described in animals and man.[1–3] However, these initial studies were carried out during coronary arteriography and, as invasive procedures, were of limited clinical applicability although they served to establish the validity of measuring coronary flow reserve for evaluating coronary disease. More recently the basic physiologic requirements of a noninvasive method have been described in experimental animals[4,5] and validated by comparison with independent measurements of the pressure-flow characteristics of stenoses being studied.[5] The new technique utilizes myocardial imaging of thallium-201 during coronary vasodilatation induced with intravenously administered dipyridamole (Persantine®). Although there has been extensive experience with the intravenous administration of this agent in Europe, its clinical use outside the United States has not been for diagnostic myocardial imaging purposes. Therefore, questions remained regarding optimal intravenous dose rate regimens, timing of the injection of thal-

lium-201 in relation to dipyridamole infusion and the effect of body position (supine, sitting or standing) on the quality of thallium perfusion images and potential side effects. Accordingly, this study of a small series of patients was undertaken to determine whether the technical procedures developed in animals were feasible and optimal for producing high quality images in man. The study was not intended to determine the diagnostic sensitivity and specificity of the dipyridamole-thallium technique, which will be described separately for a large series of patients. The current report addresses solely the problems of feasibility and methodology in man.

Methods

Patients: A total of 62 patients undergoing diagnostic coronary arteriography and exercise stress testing for suspected coronary artery disease were studied with one of several different experimental protocols. After discussion with each patient, a written consent form describing the procedure and its potential risks and benefits was signed by the patient. Patients were hospitalized for initial clinical evaluation of suspected coronary disease. History, physical examination, routine laboratory tests, chest X-ray film and resting electrocardiogram were obtained. A standard treadmill stress test using the Bruce protocol[6,7] was then performed to determine each patient's maximal duration on the treadmill. The next day diagnostic coronary arteriography was performed using the Judkins femoral approach; 35 mm cineangiograms of the coronary arteries were obtained in multiple views using a General Electric Floricon 300 X-ray system with a resolving power of 100 lines/inch (39.4/cm).

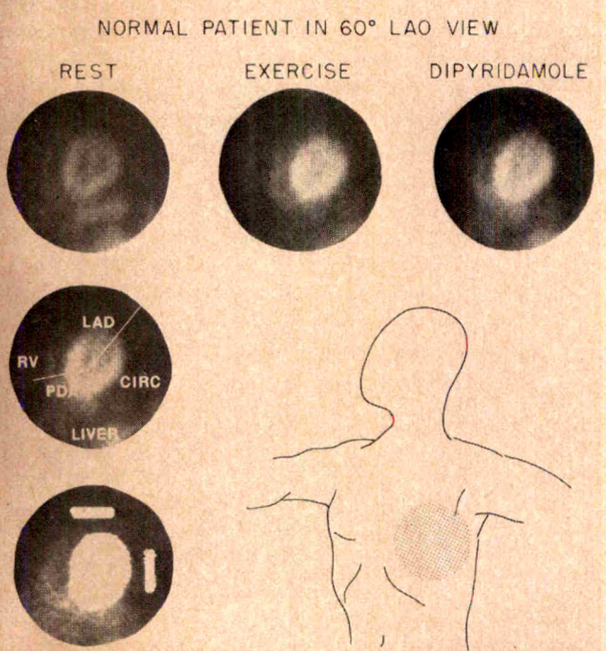

FIGURE 1. Myocardial images of a patient with normal coronary arteries in whom thallium-201 was injected at rest **(upper left),** during maximal treadmill exercise **(upper middle)** and after intravenous infusion of dipyridamole **(upper right).** All images are computer reproductions processed identically with 5 percent background subtraction for illustrative purposes. The quality of the dipyridamole image is comparable with that of the exercise image. Myocardial to background activity ratios were 2.2 at rest, 2.6 during exercise and 3.3 after dipyridamole. Orientation of images relative to human anatomy is shown with the distribution of the left anterior descending (LAD), left circumflex (CIRC) and posterior descending (PDA) coronary arteries. The **lowest panel** illustrates regions of interest for determining myocardial and background activities. RV = right ventricle.

Exercise thallium perfusion imaging: The day after coronary arteriography patients were taken to the Nuclear Medicine laboratory and 1.5 to 2.0 millicuries (mCi) of thallium-201 (New England Nuclear, Boston, Massachusetts) was injected intravenously with the patient standing. Twenty to 30 minutes later 300,000 count myocardial images were obtained with an Ohio Nuclear series 100 gamma camera in 30°, 45°, 60° left anterior oblique, left lateral and anterior posterior views. Images were recorded on Polaroid® film and also collected by a Nova II miniprocessor adapted for nuclear medicine applications (Medical Data System Corporation, Ann Arbor, Michigan) with a 128 × 128 display, dual disc drive, magnetic tape storage and software for localizing areas of interest by light pen for analysis of activity. Patients were then discharged and 1 week or more later, after residual thallium activity was no longer detectable in the heart, an exercise thallium perfusion image was obtained as follows: A second treadmill stress test was performed using the Bruce protocol. Thallium-201, 1.5 to 2.0 mCi was then injected intravenously 1 minute before the maximal duration of exercise observed in the first treadmill test. Exercise was continued for 1 minute. As soon as possible after recovery from exercise, patients underwent myocardial imaging, usually in less than 5 minutes after the treadmill was stopped; 300,000 count images of the heart were obtained in standard views as described. Fifty-seven of the 62 patients had resting and exercise images under this protocol to determine the effect of exercise on thallium uptake.

Dipyridamole thallium perfusion imaging: Thirty-eight of these 57 patients returned to the Nuclear Medicine laboratory 1 week or more after the exercise thallium image for a dipyridamole thallium test. A 19 gauge butterfly needle was placed in a large forearm or antecubital vein and taped securely in place. Injection of dipyridamole into small veins on the dorsum of the hand often resulted in a localized burning discomfort that did not occur with injection into large forearm veins. Precordial electrocardiographic leads were attached in the manner used for exercise testing. Baseline electrocardiogram and blood pressure were obtained. With the patient supine, intravenous infusion of dipyridamole (Boehringer Ingelheim, Elmsford, New York) was begun at an infusion rate of 0.142 mg/kg per min for 4 minutes using a Harvard model 551 infusion pump in which the standard single turn potentiometer for speed control had been replaced by a 10 turn potentiometer for more exact regulation of the rate of infusion. The readings of the 10 turn potentiometer had been previously calibrated in terms of cubic centimeters per minute by graduated cylinder and stopwatch for 5 kg steps ranging from 65 to 105 kg body weight. The electrocardiogram and blood pressure were recorded at 1 minute intervals during the infusion and for 15 minutes afterward or until baseline levels returned. In 10 of these previously exercised patients thallium-201, 1.5 to 2.0 mCi, was injected at the 4th minute after completion of the dipyridamole infusion while the patient remained supine. Twenty-eight previously exercised patients were brought to the standing position at the 2nd or 3rd minute after the end of the dipyridamole infusion and walked in place. Thallium was then injected at the 5th minute after completion of dipyridamole infusion while the patient continued walking in place for 3 to 5 minutes after injection of thallium. The patient then resumed the supine position. Twenty to 30 minutes after injection of thallium, standard myocardial images were again obtained as described. The time interval be-

tween thallium injection and imaging was later reduced to 5 minutes or less. In six patients three different dose rate regimens of dipyridamole were used to establish the optimal regimen for imaging purposes.

Analysis of thallium images: Original Polaroid photographs of myocardial perfusion images were interpreted independently by three observers and subsequently read again by a group of three observers together for a "consensus" interpretation. Images were analyzed quantitatively as follows: The resting control myocardial image was displayed on a persistence oscilloscope and the heart outlined with a light pen. Two separate representative background areas were also outlined. The contour of these areas of interest was stored in computer memory and then applied to all other images of a given patient so that areas of interest would be identical for that patient. Because the heart was not always located in the same position in different images of a patient, a computer program was developed to translate an image until the area of interest outline determined in the resting image was visually superimposed on the exercise or dipyridamole image. The activity in each area of interest was normalized for duration of imaging, dose of thallium injected in millicuries and number of channels in the area of interest. Units of activity were thus expressed as counts per minute per channel per millicurie injected. The quality of the images and the relative myocardial uptake of thallium were quantitatively evaluated in terms of myocardial to background activity ratios using the average of the two background areas. The results of analyzing exercise and dipyridamole images were expressed as percent of resting control values. For illustrations shown all images were processed identically with 5 percent background subtraction.

Analysis of data: The effects of maximal treadmill exercise and dipyridamole on thallium activity in myocardial areas, background areas and myocardial to background activity ratios of 162 thallium myocardial images from 62 patients were analyzed in five overlapping groups as follows: (1) 57 patients with resting and exercise thallium perfusion images studied to compare exercise and resting myocardial images with paired t testing; (2) 40 patients with resting and standard dipyridamole thallium images in the supine or standing position studied to compare dipyridamole and resting myocardial images with paired t testing; (3) 38 patients with resting, exercise and dipyridamole perfusion images studied to compare exercise and dipyridamole images with paired t testing; (4) 6 patients with thallium images after standard infusion and three different nonstandard dipyridamole dose rate regimens to determine the optimal standard dipyridamole dose rate for imaging purposes; and (5) 43 patients receiving dipyridamole under a standard or nonstandard dose regimen to evaluate potential side effects.

Results

Normal patient: Figure 1 shows an example of a myocardial perfusion image of a normal patient with thallium-201 injected at rest, during treadmill exercise and after intravenous administration of dipyridamole. The exercise image was more distinct than the resting image with a greater myocardial to background ratio. The right ventricle was also visible as a crescent of activity at the left of the image. The quality of the dipyridamole image was equal to that of the exercise image with a comparable myocardial background ratio and equal visualization of the right ventricle.

Exercise and dipyridamole images during exercise versus rest: Although the exercise and dipyridamole images were comparable in quality and visual appearance, the changes in myocardial and background activity of the exercise image as compared with the resting image were different from those for dipyridamole. Figure 2 shows the average counting activity of myocardial areas, background areas and myocardial to background ratios of each exercise image expressed as a percent of values from the resting control image of each patient. During exercise the counts per minute per channel per unit dose of thallium injected for the myocardial area decreased to 92.3 ± 15.8 (mean ± 1 standard deviation) percent of the resting control image and this decrease was statistically

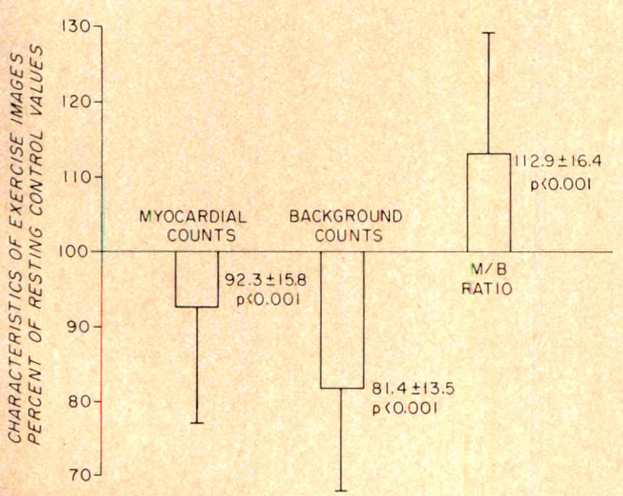

FIGURE 2. Changes in myocardial and background activity of exercise thallium images in 57 patients expressed as percent of resting control values. Activity of the myocardial area decreased significantly below control resting values. Background activity decreased to a greater and statistically significant extent. Myocardial to background (M/B) ratios increased significantly primarily because of the decrease in background activity. Significance is shown according to a paired t test comparing exercise and resting values for each patient. Bars indicate ±1 standard deviation. p = probability.

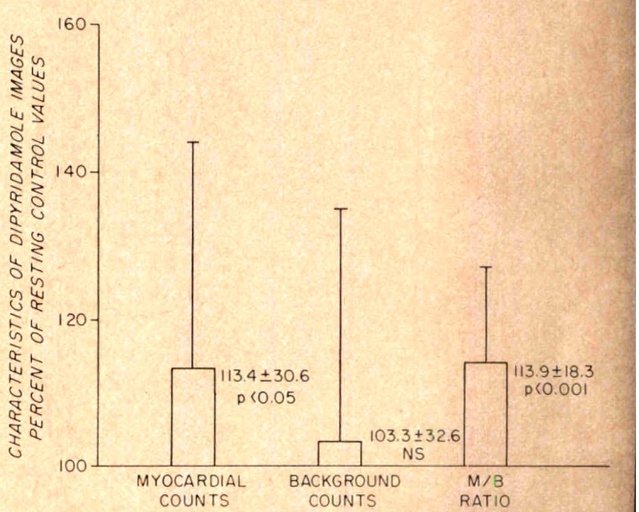

FIGURE 3. Changes in myocardial and background activity of dipyridamole thallium images in 40 patients expressed as a percent of resting control values. Activity of the myocardial area increased significantly. Background activity increased somewhat but the change was not statistically significant. Myocardial to background (M/B) ratios increased significantly primarily because of the increase in myocardial activity. Significance is shown according to paired t test comparing dipyridamole and resting values for each patient. Bars indicate ±1 standard deviation. NS = difference not significant.

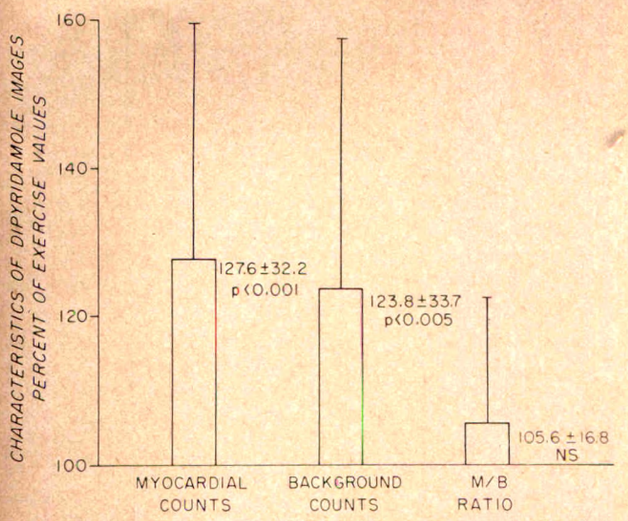

FIGURE 4. Comparison of myocardial (M) and background (B) activity of dipyridamole and exercise thallium images in 38 patients. Activity of the dipyridamole images are expressed as a percent of exercise values. Both myocardial and background activity of the dipyridamole images were significantly greater than for exercise images. Significance is shown according to paired *t* test comparing dipyridamole and exercise values for each patient. Bars indicate ±1 standard deviation.

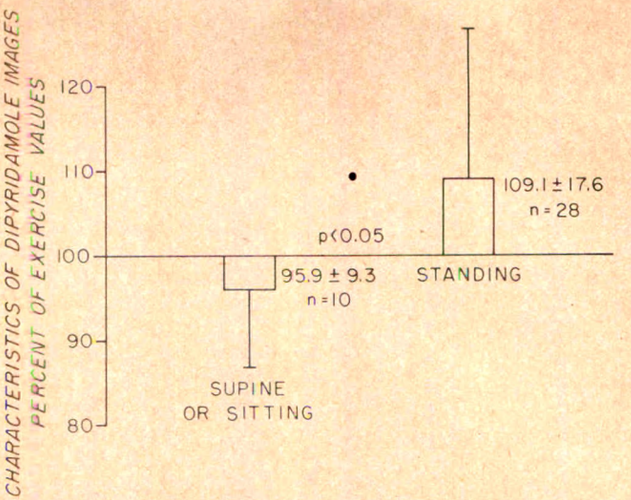

FIGURE 5. Effect of body position at the time of thallium injection on the myocardial to background activity ratios of myocardial images taken after intravenous administration of dipyridamole in 38 patients and expressed as percent of exercise values. The quality of images as reflected in myocardial to background ratios was significantly improved by injecting the thallium with the patient in the standing position. The *P* value is shown according to an unpaired *t* test comparing standing with supine or sitting patients. Bars indicate ±1 standard deviation. n = number of patients.

significant ($P < 0.001$). The counts in the background area decreased to a greater extent, to 81.4 ± 13.5 percent of resting counts, also a statistically significant difference ($P < 0.001$). The myocardial to background ratio therefore increased significantly during exercise to 112.9 ± 16.4 percent of control myocardial to background ratios thereby resulting in an improvement in the visual appearance of the image ($P < 0.001$).

Figure 3 shows data for dipyridamole images presented in comparable fashion. The counts per minute per channel per dose of thallium in myocardial areas of dipyridamole images increased to 113.4 ± 30.6 percent of activity in resting control images ($P < 0.05$). Counts in background areas also increased but to a lesser and statistically insignificant extent than in myocardial areas. The average myocardial to background ratio therefore increased to 113.9 ± 18.3 percent of resting ratios ($P < 0.001$) with a corresponding improvement in image quality as compared with the resting image.

Direct comparison of exercise and dipyridamole images (Fig. 4): Activity of myocardial areas, background areas and myocardial to background ratio of each dipyridamole image was expressed as a percent of values from the exercise image of the same patient. Counts per minute per channel per dose of thallium in the myocardial areas on the dipyridamole images were higher than on the exercise images, averaging 127.6 ± 32.2 percent of the exercise image ($P < 0.001$). Counts of the background areas of dipyridamole images were also significantly higher than on exercise images. Myocardial to background ratios of dipyridamole images were slightly higher than for exercise images, but the difference was not statistically significant. These results indicate that both exercise and dipyridamole improved the quality and myocardial to background ratios of thallium perfusion images but by different mechanisms. During exercise the improved myocardial to background ratio resulted primarily from a reduction in background activity whereas after infusion of dipyridamole the improved myocardial to background ratio resulted primarily from an increase in myocardial activity.

Effect of body position at the time of thallium injection on myocardial perfusion images after infusion of dipyridamole (Fig. 5): In patients who remained supine during dipyridamole infusion and injection of thallium, the resulting images had myocardial to background ratios that were only 95.9 ± 9.3 percent of exercise ratios. However, in patients who rose to the standing position with walking in place for 1 to 2 minutes before and 3 to 5 minutes after injection of thallium, myocardial perfusion images demonstrated higher myocardial to background ratios of 109.1 ± 17.6 percent of exercise ratios for the same patients. The difference between standing and supine or sitting myocardial to background ratios for dipyridamole images expressed as a percent of exercise ratios was statistically significant. If only standing patients are considered the myocardial to background ratio for dipyridamole images of 2.3 ± 0.5 is slightly but significantly higher than the ratio for exercise images of 2.1 ± 0.4 by paired *t* testing ($P < 0.02$).

Effects of various dose rate regimens of dipyridamole on myocardial to background ratios of images and blood pressure: Either smaller doses or slower dose rate infusions of dipyridamole failed to increase myocardial to background ratios to the same extent as the standard regimen of 0.142 mg/kg per min for 4 minutes (0.57 mg/kg total dose). In four patients this same total dose of 0.57 mg/kg was given as an intravenous bolus injection. The fourth patient had significant orthostatic hypotension with blood pressure decreasing from 120/75 to 80/40 mm Hg when standing although while supine his pressure had remained normal. After he resumed the supine position with elevation of his legs, his blood pressure immediately returned to 122/70 mm Hg without sequelae. He had no angina pectoris or electrocardiographic changes, showed no subsequent enzyme changes and had normal coronary arteriograms. No further trials of this bolus regimen were undertaken. The effects of the procedure, that is, combined dipyridamole and standing-in-place-walking, on blood pressure and heart rate were as follows: Control supine systolic

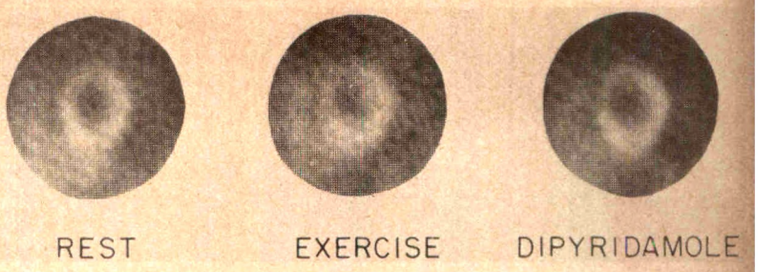

FIGURE 6. Myocardial images in 30° left anterior oblique view of a patient with isolated disease of the left anterior descending coronary artery after intravenous administration of thallium-201 at rest **(left),** during maximal treadmill exercise **(center)** and after intravenous administration of dipyridamole **(right).** At rest no perfusion defect was apparent. In the exercise image a probable defect appeared in the left anterior descending coronary arterial distribution. In the dipyridamole image this defect was quite distinct as a thinning in the activity of the left ventricular wall. The quality and sharpness of the dipyridamole image are equal to or better than those of the exercise image. All images were processed identically with 5 percent background subtraction.

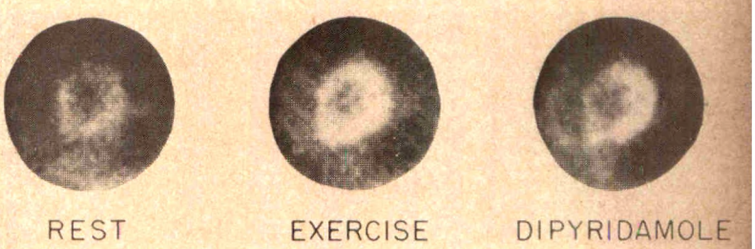

FIGURE 7. Myocardial images in 45° left anterior oblique view of a patient with isolated disease of the left anterior descending coronary artery after intravenous injection of thallium-201 at rest **(left),** during maximal treadmill exercise **(center)** and after intravenous infusion of dipyridamole **(right).** At rest no defect was apparent. The exercise image in the same view also failed to show a definite abnormality. However, the dipyridamole image showed a large distinct definite abnormality. All images were processed identically with 5 percent background subtraction.

blood pressure by cuff was 130 ± 17 mm Hg and decreased to 121 ± 18 mm Hg during standing-in-place-walking after dipyridamole (P <0.001). Corresponding changes for diastolic blood pressure were 81 ± 10 mm Hg down to 74 ± 10 mm Hg (P <0.001). Control supine heart rate was 64 ± 8 beats/min and increased to 88 ± 12 beats/min during standing after dipyridamole (P <0.001).

Patients with isolated left anterior coronary artery disease: Figure 6 illustrates thallium perfusion images of a patient at rest, during treadmill exercise and after dipyridamole infusion. At rest the image was normal with equal activity in the left anterior descending, left circumflex and right coronary arterial distributions. During exercise there was less activity in the left anterior descending distribution arterial corresponding to the location of coronary disease and this relative perfusion deficit was as distinct or more distinct in the dipyridamole image than in the exercise image. Figure 7 shows another patient who had a normal resting image as well as a probably normal exercise image in this view. However, the dipyridamole image showed a definite and severe perfusion defect in the distribution of left anterior descending coronary artery disease. This patient also had moderately severe angina pectoris 5 minutes after completion of dipyridamole infusion and 1 minute after thallium injection. The angina pectoris was also associated with S-T segment depression. Both chest pain and electrocardiographic changes disappeared within several seconds after the intravenous administration of 125 mg of aminophylline, which terminated the coronary vasodilatory effects of dipyridamole after the thallium had been taken up by the myocardium.

Side effects: Of the 43 patients given dipyridamole, the patient who received a larger than standard dose rate was the only one who had a significant unexpected side effect, that is, orthostatic hypotension treated by resumption of the supine position and leg raising. Eighteen of the 43 patients (42 percent) had mild transient headache, 23 (53 percent) experienced mild transient facial flushing, 6 (14 percent) had mild transient nausea and 12 (28 percent) had mild fleeting angina pectoris that required no therapy. Two patients (5 percent) experienced significant angina pectoris that stopped immediately with intravenously administered aminophylline after thallium had been taken up by myocardium. High quality images showing perfusion abnormalities were obtained in both patients. The onset of angina pectoris after infusion of dipyridamole was gradual, developing over 3 to 4 minutes in each case. Therefore, there was sufficient time before giving aminophylline for complete thallium uptake by the myocardium with resulting good images of perfusion abnormalities. All but one patient stated that the dipyridamole test was preferable to the treadmill exercise test. The infusion imaging procedure was more easily performed and required less technician-physician time than exercise imaging.

Heart rate and myocardial to background ratios of dipyridamole images: Patients with the largest increases in heart rate after dipyridamole also showed the greatest increases in myocardial to background ratios of dipyridamole images, as shown in Table I. For this table, patients were ranked in sequential order from greatest to least increase in supine heart rate after dipyridamole infusion. Corresponding myocardial to background ratios of dipyridamole images were then listed beside heart rate change for each patient and the data were grouped into quartiles for statistical comparison. In addition, corresponding changes in heart rate, blood pressure-heart rate product and myocardial to background ratios during exercise with degree of exercise impairment were listed for each ranked patient and averaged for each quartile for comparative purposes.

The results suggest that there is a variable dose effect of a fixed rate, milligram per kilogram per minute infusion of dipyridamole on heart rate and myocardial to background ratios of dipyridamole images. Patients with larger increases in heart rate during exercise did not have higher myocardial to background ratios in exercise images. The maximal pressure-rate product and severity of exercise impairment were not significantly different among these quartiles. Therefore, differences in heart rate response cannot be ascribed to severity of coronary disease but must be associated wih a variable response to a fixed, per kilogram dose of dipyridamole. It may therefore be possible to titrate the dose rate of dipyridamole infusion for each patient up to a fixed limit using supine heart rate response as an end point of the dose effect in order to achieve a more uniform maximal vasodilatory effect. The efficacy of

TABLE I

Relation of Increase in Heart Rate and Myocardial/Background Ratios After Dipyridamole and Exercise

Quartile	Dipyridamole % ΔHR	Dipyridamole M/B Dipyr / M/B Rest	Dipyridamole PRP	Exercise % ΔHR	Exercise M/B Exer / M/B Rest	Exercise % FAI

*Significant difference of each quartile compared with the 1st quartile with a probability (*P*) value of $P = 0.001$ or less.

Dipyr = dipyridamole; Exer = exercise; FAI = functional aerobic impairment expressed as percent impairment of values in normal age-sex matched control subjects; M/B = myocardial/background; NS = nonsignificant difference from value in first quartile; % Δ = average percent increase ±1 standard deviation; PRP = maximal exercise pressure-rate product ÷ 100.

dose tritration as compared to a fixed dose rate infusion on diagnostic sensitivity and specificity is currently being examined.

Discussion

Cardiovascular effects and optimal dose rate regimen of dipyridamole: The most important questions about the dipyridamole-thallium method for assessing the physiologic significance of coronary disease involve the effectiveness of dipyridamole as a selective coronary vasodilator and the dose-rate regimen providing optimal image quality with least side effects. Table II shows the reported range of dose-rates.[8–18] Figure 8 shows the cardiovascular effects of intravenous administration of dipyridamole in 28 patients reported on by Tauchert et al.[8,9] The changes expressed as percent of control resting values were calculated for this figure from the original data listed in tables for individual patients by Tauchert (data extracted from Tables 3 and 4 of reference 8). The wide standard deviation is due to a less than 3 times response in three patients. Coronary flow increased to an average of four times baseline control values with a minor but statistically significant increase in cardiac output and heart rate and decrease in aortic pressure. The dose-rate of dipyridamole producing these effects was 5 mg intravenously every 2 minutes for a total of 0.5 mg/kg. Hilger[10] measured the change in coronary sinus oxygen saturation of 10 resting patients during intravenous administration of 50 mg of dipyridamole over 15 minutes. Coronary sinus oxygen saturation increased by more than 200 percent (to 3 times resting values) reflecting corresponding changes in coronary flow. Smaller doses given more rapidly failed to produce comparable responses. Hilger[10] utilized a larger total dose than our standard regimen of 0.56 mg/kg (39.2 mg for a 70 kg man) but gave it at a slower rate over 10 to 15 minutes as opposed to our 4 minute infusion. Several investigators have used larger doses and reported significant side effects. Wilcken et al.[11] gave 0.6 mg/kg of dipyridamole intravenously over 5 minutes to 10 normal subjects and 3 patients with coronary disease. The three patients manifested severe angina pectoris with marked S-T depression for several hours with normal blood pressure and without subsequent enzyme changes or permanent sequelae. Mantero and Conti[12] also reported significant

Reported Dose Rates of Intravenous Dipyridamole Administered to Patients

Reference	Dose	Duration of Infusion	Patients (no.)
13	20 mg	2 min	18
14	10 mg	Bolus dose	9
8	0.5 mg/kg	2.5 mg/min	28
15	0.5 mg/kg	2.5 mg/min	32
10	50 mg	15 min	10
16	0.5 mg/kg	10 min	60
11	0.6 mg/kg	5 min	13
12	80–100 mg	40–60 mg/20 min	109
17	20 mg	Bolus dose	9
18	0.43–0.86 mg/kg	Bolus dose	7

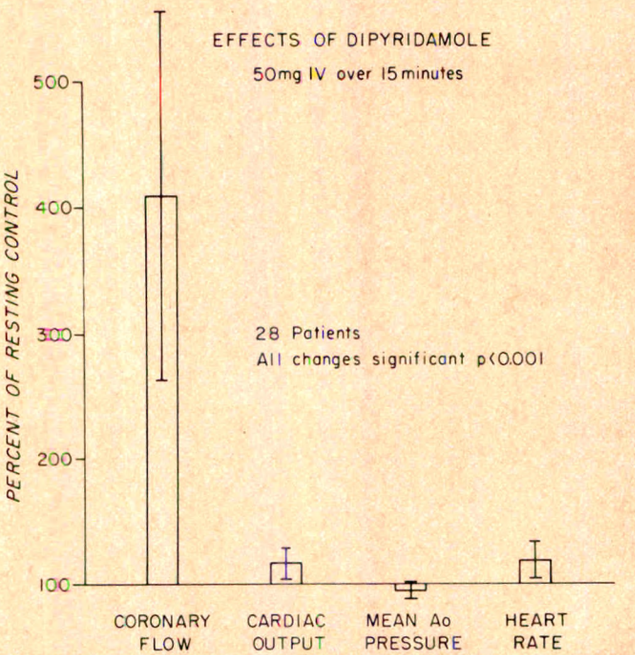

FIGURE 8. Effect of intravenously administered dipyridamole on heart rate, central aortic (Ao) mean pressure, cardiac output and coronary flow measured with the argon technique. Changes caused by dipyridamole are expressed as percent of control resting values. Results shown in this figure were calculated from data listed for individual patients as reported by Tauchert et al.[8] (data extracted from their Tables 3 and 4). The dose-rate of intravenous (IV) infusion of dipyridamole used by Tauchert et al. was 5 mg every 2 minutes for a total dose of 0.5 mg/kg. Coronary flow increased to approximately 4 times resting values with relatively minor changes in cardiac output, aortic pressure and heart rate. Bars indicate ±1 standard deviation.

chest pain in 22 of 109 patients with coronary disease in whom very large doses of 80 to 100 mg of dipyridamole were infused over a 20 minute period. However, in neither of these studies was aminophylline used to terminate the effects of dipyridamole.

Mechanisms leading to angina pectoris or myocardial ischemia: After intravenous administration of dipyridamole myocardial oxygen consumption reportedly decreases or increases slightly in anesthetized dogs[19,20] and increases 20[14,15] to 100 percent[8] in man. There are therefore two potential causes for ischemia after infusion of this drug. One is the modest increase in myocardial oxygen consumption. However, most patients in our study who demonstrated perfusion defects due to coronary disease had no angina or S-T changes. The second and most likely mechanism arises from the pressure-flow relations characterizing coronary stenoses previously described[21–24] (and Gould LK, unpublished data). As flow velocity increases through a coronary stenosis the energy or pressure losses due to viscous friction increase in linear proportion to flow velocity, and pressure losses due to flow separation (vortex shedding) increase as a function of the square of velocity. Thus, at increased coronary flow the pressure loss is greater than at resting coronary flow and distal coronary perfusion pressure is correspondingly less despite increased flow in the epicardial artery. With coronary vasodilatation, coronary flow and pressure gradient increase across the stenosis, distal coronary perfusion pressure decreases and the subendocardium may become underperfused.

Such a mechanism may explain the experimental results of previous workers[25–27] who found impaired subendocardial perfusion during coronary vasodilatation or exercise in animals with proximal coronary stenoses. Although demonstrated experimentally, decreased perfusion of the subendocardium during coronary vasodilatation in the presence of coronary stenoses cannot be definitively proved in man by the microsphere technique used in animals, which requires counting tissue samples. However, Figures 6 and 7 do demonstrate particularly suggestive abnormalities in the myocardial perfusion images during dipyridamole-induced coronary vasodilatation. These images show thinning of the myocardial activity of the left ventricular wall that, in combination with chest pain and S-T segment depression in the second patient, strongly suggests hypoperfusion of the subendocardium. Thus, we believe that angina pectoris and subendocardial ischemia, which may occur in the presence of coronary disease during dipyridamole infusion, are inherent in the fact of coronary vasodilatation and are probably not specific for the type of coronary vasodilator as such.

Nevertheless, because myocardial oxygen demands are not increased as much by dipyridamole as by exercise, an imaging method using a coronary vasodilator will permit greater coronary dilatation and greater differences in regional myocardial blood flow before ischemia develops as compared with exercise stress. These greater differences in regional coronary flow distribution obtainable by coronary vasodilators may therefore make a pharmacologic method more sensitive than exercise stress in identifying early coronary lesions. The sensitivity of the dipyridamole method or other pharmacologic techniques thus depends on the adequacy of coronary vasodilatation. The dose rate of dipyridamole infusion is therefore crucial to the effectiveness and safety of the dipyridamole method. Doses of less than 0.142 mg/kg per min for 4 minutes did not consistently produce high quality myocardial images. Titration of the dose according to heart rate response may provide a means of producing more uniform maximal drug effect. Angina pectoris may also occur but the use of intravenously administered aminophylline as a relatively instantaneous and complete antagonist of dipyridamole provides control of its effects and a large safety factor in the dipyridamole method.[10,16,28–31] Any other coronary vasodilator that was more potent than dipyridamole would further increase the sensitivity of imaging techniques for identifying coronary disease. However, the risk of subendocardial ischemia might also increase and therefore an antagonist would be required to terminate the effects of the coronary vasodilator if necessary.

Coronary or myocardial steal after dipyridamole: Intravenous administration of dipyridamole or other potent coronary vasodilators reportedly may cause "coronary or myocardial steal"[11,12,25,31–36]; although applied loosely, the term "steal" is defined as an absolute reduction in coronary flow to an area of myocardium, particularly the endocardium, during some stimulus for coronary vasodilatation. The safety of dipyridamole has therefore been questioned. The expression "coronary steal" is not specific and refers to a spectrum of pressure-flow changes that are more clearly explained in terms of the pressure gradient-flow relation described in the preceding article.[5] With coronary vasodilatation the coronary pressure distal to a stenosis decreases as total flow in the epicardial artery increases.[1,2,5,21–23,31]

Under these hemodynamic conditions there are two circumstances in which the term "steal" has been applied. In the first case, for single vessel disease the coronary pressure distal to a stenosis might decrease enough so that pressure is inadequate to perfuse the endocardium despite an increase in total flow in the epicardial artery. In this case the underperfusion of the endocardium could be only relative with normal or increased absolute flow but reduced endocardial to epicardial flow ratios[31,35,36] that should *not* be called "steal." However, if the vasodilatory stimulus were great and the fall in coronary pressure distal to the stenosis were profound, as with severe stenoses or with combined coronary vasodilators and pacing, the absolute endocardial flow in cc/min per g of endocardium would decrease despite an adequate or even increased epicardial artery flow[25–27,31,35,36]; then epicardial "steal" might be an appropriate term. However, the terminology in this circumstance is debatable.[26,31] In the second case, for two (or more) vessel disease with collateral channels between the distal beds, a greater decrease in distal coronary pressure in one bed might shunt blood away from the other better perfused bed through the collateral channels with a decrease in absolute endocardial

flow[31,34–36]; "steal" would then be an appropriate term.

For any of these hemodynamic changes the final common result would be an imbalance between blood supply and demand regardless of whether exercise, pharmacologic coronary vasodilatation or progressively severe stenosis caused the abnormal hemodynamic conditions. Thus, if "coronary steal" with ischemia does occur after dipyridamole, it is of no greater consequence than ischemia induced by exercise. In either instance the stimulus producing ischemia should be removed by stopping exercise or by giving aminophylline in order to terminate the effects of dipyridamole. For imaging purposes the major point is that coronary vasodilators provide greater differences in regional perfusion before ischemia develops as compared with exercise, in which myocardial oxygen demands are increased greatly. Thus, perfusion defects in dipyridamole images are seldom associated with significant angina pectoris whereas defects in exercise images are commonly associated with significant angina.

Effect of body position at the time of injecting thallium: Body position has an important effect on myocardial to background ratios of perfusion images after dipyridamole. The quality of images and myocardial to background ratios are considerably improved by having the patient walk in place for 1 to 2 minutes before, during, and 3 to 5 minutes after the injection of thallium. We do not have a satisfactory explanation for this observation but one possibility is that pulmonary blood volume, transit time and capillary surface area are greater in the supine position than in the upright position.[37] Consequently, lung uptake of thallium is probably greater and therefore background activity greater in the supine than in the upright position. The upright position[37] or exercise,[38] or both, decreases pulmonary blood volume and transit time and would be expected to result in reduced lung uptake of thallium and improved myocardial to background ratios.

Effect of exercise on myocardial uptake of thallium on external images and the problem of background activity: The lack of increased counting activity in myocardial areas of exercise images was somewhat unexpected. For this reason 57 patients were studied to verify these results. Either no change or a reduction in activity of the myocardial area, as well as a greater reduction in background activity, was usually observed. These observations are compatible with two explanations: (1) Pulmonary transit time is reduced during exercise and there is less time than during rest for thallium uptake by the lungs; (2) in man coronary blood flow reportedly increases with exercise to a lesser extent than to the 4 times baseline levels (300 percent) increase occurring after administration of coronary vasodilators. Average increases in coronary flow during exercise previously reported range from 33 to 44 percent,[39] 49 to 77 percent,[40] 7 to 58 percent,[41] 222 to 272 percent[42] and 103 to 213 percent.[43] An increase of 331 percent was reported in one study[44] in which coronary flow was measured only during exercise with no resting control values; the reported increase was based on an estimated, not measured, resting coronary flow value and is therefore open to question. These relatively modest changes in coronary flow during exercise compared with the ranges after coronary vasodilators may not be sufficient to produce regional differences in thallium uptake that are measurable with external imaging, particularly if one considers that thallium is not taken up in proportion to increases in flow at high coronary flow levels.[45,46]

In addition, the interpretation of counting activity in areas of myocardium in thallium images is complicated by the activity of lung overlying the heart. In experimental animals we have studied this problem by imaging the thorax before and after removing the heart and replacing it with an equal-sized balloon filled with saline solution.[47] The true background activity in the region immediately in front of and behind the heart was much less than activity of adjacent image areas on either side of the heart. We therefore believe that counting activity in the area of the myocardium measured with external imaging is of limited validity as an indicator of qualitative directional changes in myocardial thallium uptake and coronary flow. Certainly, the activity in areas of myocardium in thallium images cannot be used as a quantitative measure of coronary flow because thallium uptake is not proportional to flow at high coronary flow rates and because true background activity behind the heart cannot be reliably predicted from activity in areas adjacent to the heart, thereby precluding background correction.

One possible solution to the problem of overlying background activity is the use of tomography to obtain cross-sectional images of the myocardium. Tomographic images would potentially reduce the effect of background activity, improve visualization of the posterior myocardium by eliminating overlapping myocardial structures and provide an indication of epicardial to endocardial flow distribution. However, the technology for high resolution tomographic imaging of the heart is in developmental stages and these advantages are potential, not proved.

Implications: Myocardial perfusion imaging with thallium-201 during coronary vasodilatation with intravenously administered dipyridamole is feasible as a routine diagnostic procedure in patients. However, it is necessary to pay careful attention to dose rates of infusion, timing of thallium injection, body position and proper monitoring of the patient's blood pressure, electrocardiogram and clinical symptoms. We also believe that patients with angina pectoris at rest should not be studied with dipyridamole because diagnostic image defects would be expected without introduction of a stress.

Acknowledgment

We are deeply indebted to Kathy Lovgren, Dennis Lee and Ann Coleman for the superb laboratory work that made these studies possible. Dr. Wilbur M. Bensen, MD, of Boehringer Ingelheim, Ltd., Elmsford, New York, kindly provided the intravenous form of dipyridamole for clinical application under Investigational New Drug permit number 12560 issued to K. L. Gould, MD, by the Food and Drug Administration on July 1, 1976.

New Serial Contrast Technique for Assessment of Left to Right Shunting Patent Ductus Arteriosus in the Neonate

HUGH D. ALLEN, MD, FACC
DAVID J. SAHN, MD, FACC
STANLEY J. GOLDBERG, MD, FACC

Tucson, Arizona

A new serial echocardiographic contrast technique for detection of patent ductus arteriosus has been developed and validated by clinical course (33 infants), surgical observations (13 infants) and autopsy observations (4 infants). A left to right shunting patent ductus arteriosus was demonstrated in 30 of 33 prospectively studied premature infants (mean weight 1,371 g) using this new contrast method. The demonstration of left to right ductal shunting was accomplished by hand injection of a nonviscous material (saline solution, 5 percent dextrose in water or the patient's own blood) through an umbilical arterial catheter placed with its tip located above the diaphragm during recording of a suprasternal notch echocardiogram. In positive studies, both the transverse aortic arch and right pulmonary artery were opacified. If no left to right shunt existed, only the transverse aortic arch was opacified.

This serial study helped elucidate the natural history of patent ductus arteriosus. Twenty-four of the 30 patients with a positive study initially had a left to right shunting patent ductus arteriosus without an audible murmur. Three of these patients with silent patent ductus arteriosus later had congestive heart failure and two required operative ligation of the patent ductus. The high rate of detection of silent patent ductus arteriosus and its bedside confirmation when suspected are important in the serial management of critically ill newborns with this condition. The test is safe and sensitive and it is useful for early demonstration of silent patent ductus arteriosus, for clarifying the origin of murmurs and for confirming spontaneous, operative or pharmacologic closure of a patent ductus arteriosus.

Clinical management of the premature infant with the respiratory distress syndrome is subject to many complications, one of which is patent ductus arteriosus.[1–4] The latter is usually suspected when a murmur is audible, peripheral pulses are increased, the heart is enlarged and increased pulmonary vascularity is evident in the thoracic roentgenogram. Echocardiography has been used in several recently reported studies[5–8] to assess left atrial and left ventricular dimensions, which can reflect increased pulmonary blood flow associated with the patent ductus arteriosus or with the effects of associated congestive heart failure, or both. Standard echocardiographic evaluation of infants with this condition has been performed in the anteroposterior (precordial) plane. A recent extension of echocardiography has been the imaging and measurement of the transverse aortic arch, right pulmonary artery and left atrium (Y′ left atrial dimension) in a superoinferior plane from the suprasternal notch.[9] The combination of precordial and suprasternal techniques has allowed a bidimensional evaluation of left atrial size, often detecting enlargement or shape distortion of the left atrium that may have been missed in the precordial examination.

Concern has been expressed recently regarding the large patent ductus arteriosus that is "silent" and undetected using standard clinical criteria for noninvasive bedside identification. Thibeault et al.[10] confirmed the presence of a patent ductus arteriosus by taking a single thoracic roentgenogram during hand injection of angiographic contrast material through an umbilical arterial catheter placed in the thoracic aorta. Their study showed that the patent ductus arteriosus was "silent" in 22 of 27 premature infants at a mean age of 39 hours. Murmurs were never heard in 10 of these patients, and cardiomegaly was often present before the appearance of a murmur. Although this type of aortography is confirmatory, the technique involves injection of radiographic contrast material, use of ionizing radiation and performance of the single X-ray film at exactly the correct time. Gramiak et al.[11] and later Valdes-Cruz et al.[12,13] demonstrated that rapid hand injection of a sterile nonviscous material such as Cardiogreen® dye, saline solution, dextrose in water or the patient's own blood into a vessel or cardiac chamber produces a contrast echocardiogram that shows the internal limits of that structure and demonstrates the cardiac flow patterns in conditions such as intracardiac shunts or valve insufficiency.

In this investigation we developed and validated an arterial contrast echocardiographic technique that confirms the presence of a left to right shunting patent ductus arteriosus and elucidates more clearly its natural history in premature infants.

Methods

The only criterion for selection of infants for this study was the need to have a clinically indicated umbilical arterial catheter placed by the attending neonatologist. After explanation of the procedure and the risks involved, informed consent was obtained from the infant's parents under a Human Subjects approved protocol.

Technique: The tip of the umbilical arterial catheter was placed in the descending thoracic aorta between the third and sixth thoracic vertebrae. Its position was then checked with a thoracic roentgenogram. After a standard echocardiographic study, a suprasternal echocardiogram was obtained for imaging of the transverse aortic arch, right pulmonary artery and left atrium (Fig. 1). The echocardiogram was obtained

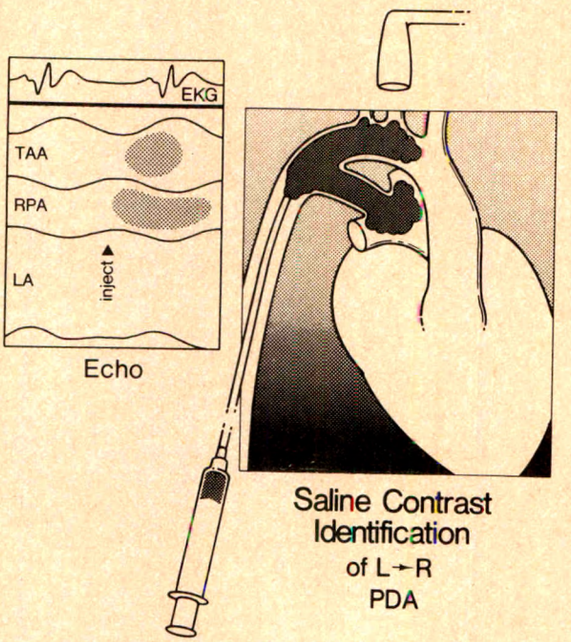

FIGURE 1 (above). Diagram **(right)** showing contrast material hand-injected through a catheter placed in the thoracic aorta during recording of a suprasternal notch echocardiogram. The transverse aortic arch fills. If a patent ductus arteriosus (PDA) is shunting left to right (L → R), the right pulmonary artery also fills. The echocardiogram (diagrammed at **left**) shows opacification in the otherwise clear transverse aortic arch (TAA) and right pulmonary artery (RPA) after injection. EKG = electrocardiogram; LA = left atrium.

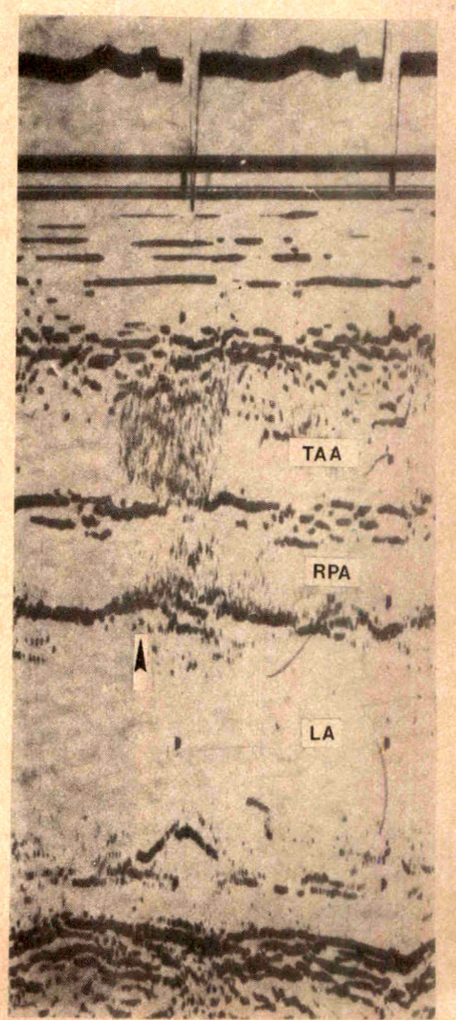

FIGURE 2 (right). Echoaortogram from a patient with a left to right shunting patent ductus arteriosus. The **arrow** shows the timing of injection. Contrast material opacifies the transverse aortic arch (TAA) and then the right pulmonary artery (RPA). Calibration markers are noted in the left atrium (LA).

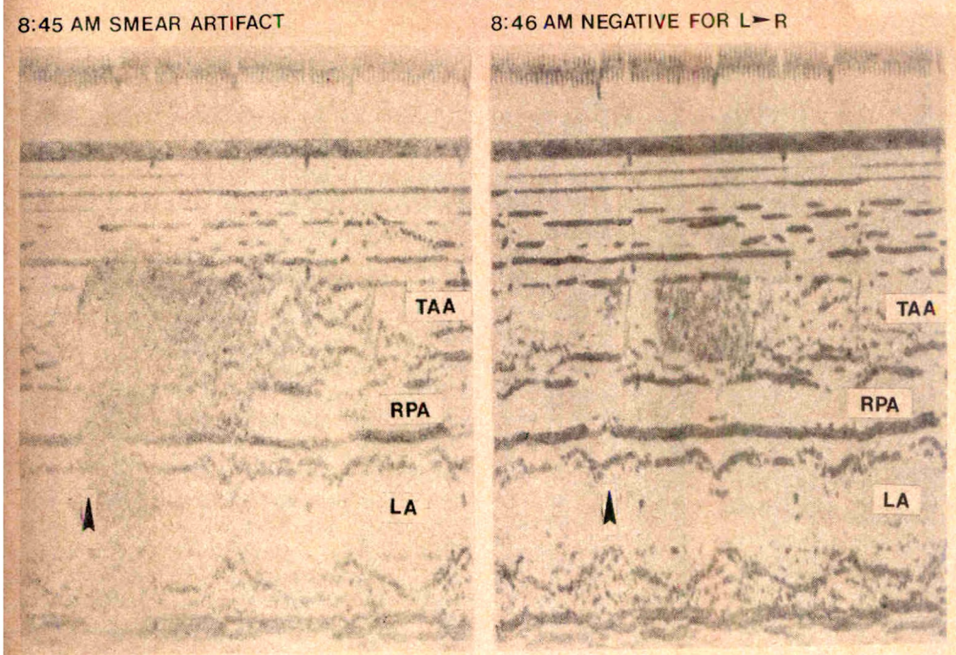

FIGURE 3. False positive "smear" artifact. **Left panel,** echo opacification traversing the entire echocardiogram. This is the result of too forceful a hand injection of contrast material. **Right panel,** an echoaortogram performed 1 minute later is negative for left to right shunting and does not show the smear artifact. **Arrows** indicate timing of injection. using a 5 megahertz suprasternal transducer[9] and a commercially available echocardiograph. Echocardiograms were recorded on a continuous ultraviolet strip chart recorder. The echocardiographic "contrast" material was then hand-injected into the thoracic aorta through the umbilical arterial catheter during the recording of the suprasternal echocardiogram. Usually 1/2 to 1 cc of saline solution, dextrose in water or the patient's own blood was used as a contrast material for the echoaortogram. The maximal total amount of either saline solution or dextrose in water used was 2 cc, particularly in the smaller neonates weighing between 500 and 1,500 g. This amount usually provided four to five individual injections for evaluation. If more injections were required, the patient's blood was drawn and reinjected.

Interpretation: A left to right shunting patent ductus arteriosus was confirmed if an echocardiographic opacity was noted, not only in the transverse aortic arch but also in the right pulmonary artery (Fig. 2). The study was considered negative if the opacification occurred only in the transverse aortic arch and not in the right pulmonary artery. The injec-

tion was considered invalid if no density occurred in the transverse aortic arch or if a "smear" artifact was noted (Fig. 3). The smear artifact was easily recognizable and probably results from imaging of off-axis echoes after too forceful an injection of the contrast material. Such artifacts could be avoided by less forceful injection or an increase in the damping and reject of the instrumentation. The low gain-high reject level required for adequate lateral resolution in these small premature infants accounts for the faintness of the echocardiograms in this report. They were deliberately overexposed with high contrast technique for adequate visualization.

Results

One hundred twenty-eight serial echocardiographic contrast studies were performed in 33 consecutive patients. The mean weight of the infants was 1,371 ± 435 g (mean ± standard deviation) and their age at first study ranged from 4 hours to 9 days. All infants with catheters were prospectively studied because no parent refused consent.

Clinical course correlated with echocardiographic studies: The serial course of our patients is shown in Figure 4. Three of the 33 infants had studies negative for patent ductus arteriosus. None of these three ever had signs of patent ductus arteriosus on physical examination or in the thoracic roentgenogram, and none manifested congestive heart failure. At the time of the first study, these infants were aged 12 hours, 2 1/2 days and 1 1/2 days, respectively.

Thirty infants had positive studies. Twenty studies performed were on the first day, and 14 of these were positive for left to right ductal shunting in the first study. Twenty-four of the 30 infants with a positive study had an initially silent ductus. The ductus remained silent in 11 of these 24, including 3 who had congestive heart failure and 3 who had spontaneous ductal closure. In five symptomatic patients the patent ductus arteriosus remained open.

Of the 30 infants with a positive study 21, including the 3 who had no murmur, manifested clinical signs of congestive heart failure. All of these infants were treated with intravenously administered Lanoxin® at an average total digitalizing dose of 30 μg/kg body weight. In four patients with congestive heart failure, the patent ductus arteriosus spontaneously closed, as confirmed in subsequent negative contrast studies. Three patients with congestive heart failure died, two with murmurs and one

with a silent patent ductus arteriosus. The cause of death was bronchopulmonary dysplasia in two of these patients and intraventricular cerebral hemorrhage in one patient. A patent ductus arteriosus was confirmed at postmortem examination in all three infants.

Patients undergoing surgical ligation of ductus: Thirteen infants did not respond to medical management and underwent surgical ligation of the patent ductus arteriosus. Two of these patients had silent patent ductus arteriosus preoperatively and throughout their course. Contrast studies performed in eight patients postoperatively revealed a negative study in seven and a positive study in one. The patient with a positive study subsequently died, and a probe patent ductus arteriosus with a slightly loose ligature around it was present at autopsy. These infants were not operated on solely on the basis of the echocardiographic data alone although the latter were combined with the thoracic roentgenographic findings and physical findings of congestive heart failure. No roentgen angiographic examinations were performed.

No complications occurred during this study as a result of the umbilical arterial catheters or the contrast technique.

Serial echoaortography: *Spontaneous closure of ductus:* Figure 5 shows serial contrast echoaortograms from a patient who had spontaneous closure of a patent ductus arteriosus. The first contrast study is positive for a left to right shunting ductus (the left panel demonstrates echocardiographic opacification of both the transverse aortic arch and right pulmonary artery). In the second study, performed 3 days later, no left to right ductal shunting is evident. The typical course for such an infant is graphically displayed in Figure 6. On the first day, when initially studied, the infant had a negative study and had no murmur or congestive heart failure. Congestive heart failure, an increased left atrial dimension and a positive contrast study were observed on the second day. A murmur was not heard until the 4th day. On the 5th day, the contrast study was negative, the murmur and congestive heart failure were gone and the left atrial dimension in the precordial echocardiogram had decreased toward normal. Four days later, before withdrawal of the umbilical arterial catheter, the left atrial dimension was still normal and the contrast study was negative.

Surgical ligation of ductus: Figure 7 shows pre- and postoperative echocardiograms from a patient who underwent ligation of a large silent patent ductus arteriosus. Before operation he had congestive heart failure (without a murmur). Serial data for a patient whose ductus was ligated are shown in Figure 8. This patient had a positive contrast study at age 8 hours and was mechanically ventilated. His contrast study remained positive throughout the rest of his course until he underwent ductal ligation. He did not have a murmur until the 5th day but had congestive heart failure requiring digitalization on the 4th day. After operative intervention the left atrial dimension returned to normal, the contrast study was negative, the murmur was gone and he had no congestive heart failure.

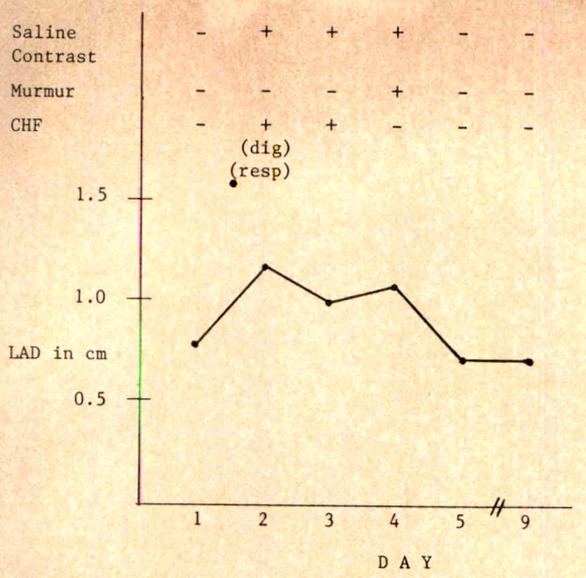
Discussion

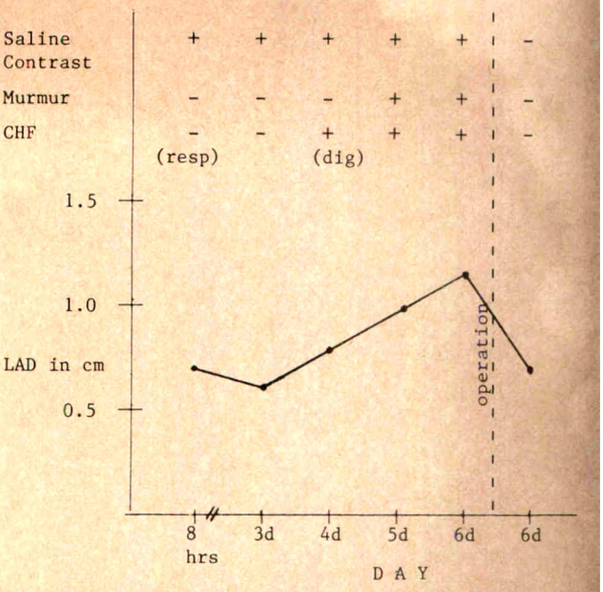
This study reports the development and validation of a reliable, safe and serially applicable bedside echocardiographic contrast technique for demonstrating a left to right shunting patent ductus arteriosus in premature infants. The technique does not require the use of angiographic contrast materials or ionizing radiation (except for initial confirmation of the location of the catheter). Nonetheless, a negative study does not mean that the duct is closed but only that a left to right shunt does not exist at the time. Echocardiography is often used in assessing the condition of infants with patent ductus arteriosus by comparing measurements of left atrial dimension, left atrial-aortic ratio or left ventricular dimension (all of which may be increased in the presence of a large left to right shunt) with standards attributing deviation from normal[14] to the effects of left to right shunts. However, standard echocardiography alone does not define the site of the left to right shunt, which might originate from a ventricular septal defect, for example. Additionally, left atrial and left ventricular enlargement can occur in premature infants as a result of fluid overload or left ventricular failure (sepsis, hypoglycemia).[8] Our contrast technique is specific for the demonstration of a left to right ductal shunt. Although the test is not quantitative, it is a sensitive qualitative detector even of small shunts.

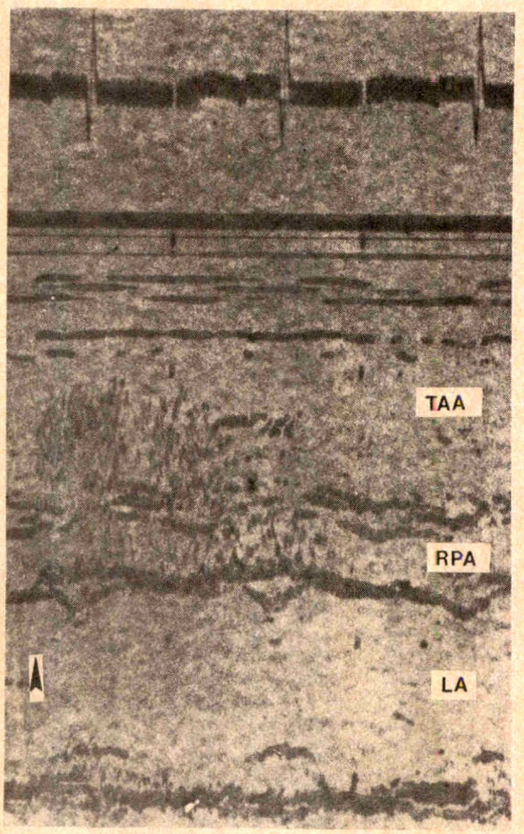
Detection of silent ductal shunt: Some large ductal shunts may be "silent" if the duct is the size of the pulmonary artery and pulmonary hypertension is present. Early detection of these shunts is important, especially when the standard echocardiogram shows unexplained left atrial enlargement. The importance of the silent patent ductus arteriosus was stressed by Thibeault et al.,[10] who reported an incidence of silent ducts similar to that of our study. The need to identify a patient with a silent ductus is evident from our finding that 3 of our 30 patients who had congestive heart failure and 2 who required operation had never had a murmur.

Advantages of serial tests: The serial application of this contrast test proved useful. The dynamics of shunting through a patent ductus arteriosus often change, and the duct can spontaneously close and reopen during the course of respiratory disease in any infant. With the catheter in place, the contrast injections can be repeated as often as necessary. This safe, simple procedure has several important uses in our neonatal intensive care nursery. It provides important differential diagnostic information for evaluating the large silent patent ductus arteriosus. Additionally, when a murmur is present but is atypical, this test confirms the presence of a patent ductus arteriosus and, in conjunction with a complete M mode echocardiographic evaluation, often helps to rule out other complicating cardiac disease. Unfortunately, no simple method yet exists for ruling out ventricular septal defect; further, this technique cannot be used to differentiate ascending aorta to pulmonary artery shunts such as truncus arteriosus or aorticopulmonary window from a patent ductus arteriosus.

Potential risks of umbilical arterial catheters: The catheter in our study was placed higher in the aorta than is the custom in many neonatal nurseries where it is usually placed below the renal arteries. Neal et al.[15] performed aortography in 19 patients with umbilical







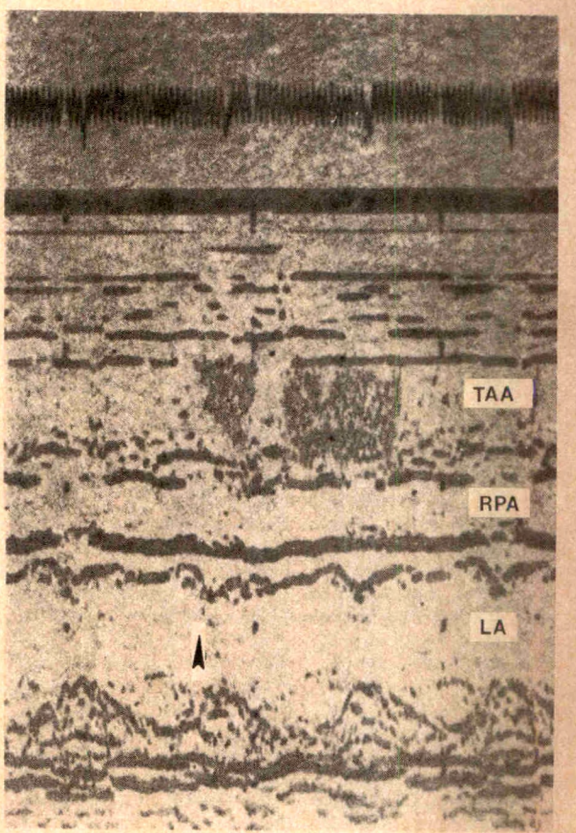


FIGURE 6 (upper left). Serial observations in a premature infant weighing 1,525 g who had spontaneous closure of a patent ductus arteriosus. Days are shown on the **abscissa.** On the **ordinate,** the **uppermost row** of plus or minus signs shows whether the saline contrast study was positive or negative. The **second row** shows whether a murmur was present or absent. The **third row** shows whether the patient had congestive heart failure (CHF). Note that the patient received digitalis (dig) and was on a respirator (resp) on the second day of life. He had no murmur. The **lowest graph** shows the Z axis left atrial dimension (LAD), in centimeters, throughout the patient's course.

FIGURE 7 (bottom). Serial echocardiograms in a patient who had a "silent" patent ductus arteriosus that required operative ligation. **Left panel,** a positive contrast study with opacification of the transverse aortic arch (TAA) and right pulmonary artery (RPA). The left atrial (LA) dimension is quantitatively enlarged. **Right panel,** taken from an echocardiogram performed 4 hours after ligation of the ductus. The contrast study is negative and the left atrial size is decreased. **Arrows** indicate timing of injection.

arterial catheters to assess the frequency of clinically silent thromboses from the catheter. Eighteen of these patients had distinct arterial thrombus formation demonstrated by hand injection of contrast material at the time of catheter removal. Further, 12 other patients from their series died, and 7 of these had arterial clots at autopsy. Only one of these patients had clinical evidence of vascular occlusion before aortography although a second infant became symptomatic after the study. Boros et al.[16] reexamined 14 of the children who had aortograms performed by Neal et al.[15] and could not find any correlation between radiographically determined femoral or tibial length differences, pulse pressure differences or the location of the thrombi noted in the 1971 Neal aortograms. While the risk of renal involvement in catheter-associated thrombosis may exist with a high catheter location, the frequency of clotting with different catheter locations has never been systematically investigated. Other complications of umbilical arterial catheters include vessel perforation, infection, fistula, renal vein thrombosis and vasospasm.[17–19] None of these potential complications occurred in our patients. One must always weigh potential risk against potential benefit for any test. In our experience the importance of ductus identification, especially of the symptomatic silent ductus, often outweighs the potential risks of high catheter placement. The high position of the umbilical arterial catheter in our study was usually necessary for only a few days.

Implications: Echoaortography is a safe and sensitive method for demonstrating left to right ductal shunts in premature infants and is useful for serial confirmation of a left to right shunting patent ductus arteriosus. The only potential hazards are related to the safety of umbilical arterial catheters. The incidence of "silent" ductus arteriosus has been underestimated in studies that have not identified the silent ductus. Serial contrast evaluations are useful in defining the natural history of ductal shunting as an aid in the serial management of critically ill premature infants. They are clinically indicated in any premature infant with the respiratory distress syndrome who has an umbilical arterial catheter in place.
